Contributing Authors

PART 1 OPERATIVE TECHNIQUES IN THORACIC AND ESOPHAGEAL SURGERY

Marco E. Allaix, MD, PhD
Postdoctoral Fellow
Department of Surgery and Center for Esophageal Diseases
Pritzker School of Medicine
University of Chicago
Chicago, Illinois

Scott A. Anderson, MD
Assistant Professor of Surgery
Department of Surgery
Division of Pediatric Surgery
University of Alabama at Birmingham School of Medicine
Pediatric Surgery
Children's Hospital of Alabama
Birmingham, Alabama

Shanda Haley Blackmon, MD, MPH
Associate Professor of Surgery
Department of Thoracic Surgery
Mayo Clinic
Rochester, Minnesota

Nathalie Boutet, MD
Resident
Centre Hospitalier de l'Université de Montréal
University of Montréal
Montreal, Québec, Canada

Brett Broussard, MD
Resident
Department of Surgery
UAB School of Medicine
Birmingham, Alabama

William R. Carroll, MD, FACS
George W. Barber Jr. Professor of Surgery
Division of Otolaryngology
Director
Section of Head and Neck Oncology
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Robert J. Cerfolio, MD, FACS, FCCP
Professor of Surgery
Chief Thoracic Surgery
James H. Estes Endowed Chair for Lung Cancer Research
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Mike K. Chen, MD
Professor
Vice Chairman
Department of Surgery
Director
Division of Pediatric Surgery
University of Alabama at Birmingham School of Medicine
Children's Hospital of Alabama
Birmingham, Alabama

Mark J. Eichler, MD
Instructor
Minimally Invasive and Bariatric Fellow
Department of Surgery
Division of General Surgery
Oregon Health & Science University
Portland, Oregon

Awad El-Ashry, MD
Resident
Department of General Surgery
University of Alabama at Birmingham
Birmingham, Alabama

Peter Ferson, MD
Professor of Thoracic Surgery
Department of Cardiothoracic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Luke M. Funk, MD, MPH
Assistant Professor of Surgery
Minimally Invasive and Bariatric Surgery
University of Wisconsin
Madison, Wisconsin

Robert E. Glasgow, MD
Associate Professor
Section Chief
Department of Surgery
Gastrointestinal and General Surgery
Division of General Surgery
Vice Chairman
Clinical Operations and Quality
University of Utah
Salt Lake City, Utah

Catherine Go, MD
Resident
Department of Surgery
Division of Vascular Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Tyler Grenda, MD
House Officer
Department of Surgery
Section of General Surgery
University of Michigan Health System
Ann Arbor, Michigan

William Grist, MD
Associate Professor of Otolaryngology
Department of Otolaryngology
Division of Head & Neck Surgery
Emory University
Atlanta, Georgia

Mary T. Hawn, MD, MPH
Professor, Chief of Gastrointestinal Surgery
Department of Surgery
Division of Gastrointestinal Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Alexander T. Hillel, MD
Assistant Professor
Department of Otolaryngology–Head and Neck Surgery
Division of Laryngology
Johns Hopkins University School of Medicine
Baltimore, Maryland

John G. Hunter, MD
Professor and Chair
Department of Surgery
Division of General Surgery
Oregon Health & Science University
Portland, Oregon

Ryan Levy, MD
Assistant Professor of Thoracic Surgery
Department of Cardiothoracic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Moishe Liberman, MD, PhD
Director
CHUM Endoscopic Tracheobronchial and Oesophageal Center
Division of Thoracic Surgery
Assistant Professor of Surgery
University of Montréal
Montréal, Quebec, Canada

Jules Lin, MD, FACS
Assistant Professor
Department of Surgery
Section of Thoracic Surgery
University of Michigan Health System
Ann Arbor, Michigan

James D. Luketich, MD
Professor of Thoracic Surgery
Department of Cardiothoracic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Ryan A. Macke, MD
Clinical Instructor
Department of Cardiothoracic Surgery
University of Pittsburg School of Medicine
Pittsburgh, Pennsylvania

John Christopher McAuliffe, MD, PhD
Resident
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

W. Scott Melvin, MD
Professor of Surgery
Chief
Division of General and Gastrointestinal Surgery
Director
Center for Minimally Invasive Surgery
Department of Surgery
The Ohio State University
Columbus, Ohio

Robert E. Merritt, MD
Associate Professor of Surgery
Division of Thoracic Surgery
The Ohio State University Wexner Medical Center
Columbus, Ohio

Douglas Minnich, MD, FACS
Assistant Professor of Surgery
Department of Surgery
Division of Cardiothoracic Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Klaus Mönkemüller, MD, PhD, FASGE
Professor
Department of Gastroenterology
Basil Hirschowitz Endoscopic Center of Endoscopic Excellence
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Ellen H. Morrow, MD
Senior Fellow
Acting Instructor
Center for Esophageal and Gastric Surgery
University of Washington Medicine
Seattle, Washington

Christopher R. Morse, MD
Department of Surgery
Division of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts

Jason Leonard Muesse, MD
Fellow
Thoracic Surgery
Emory University School of Medicine
Emory University Hospital
Atlanta, Georgia

David D. Odell, MD, MMSc
Assistant Professor
Department of Cardiothoracic Surgery
Division of Thoracic and Foregut Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Brant K. Oelschlager, MD
Director
Center for Esophageal & Gastric Surgery
Surgical Specialties Center
University of Washington Medical Center
Byers Endowed Professor in Esophageal Surgery
Department of Surgery
Division of General Surgery
University of Washington School of Medicine
Seattle, Washington

Mark Orringer, MD
Professor, Section of Thoracic Surgery
University of Michigan Hospitals
Ann Arbor, Michigan

Marco G. Patti, MD
Professor of Surgery
Department of Surgery and Center for Esophageal Diseases
Pritzker School of Medicine
University of Chicago
Chicago, Illinois

Shajan Peter, MD
Assistant Professor
Department of Gastroenterology
Basil Hirschowitz Endoscopic Center of Endoscopic Excellence
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

C. Daniel Smith, MD
Professor of Surgery
Department of Surgery
Mayo Clinic
Jacksonville, Florida

Cameron T. Stock, MD
Resident
Division of Thoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts

Elizabeth A. Warner, MD
Senior Fellow
Acting Instructor
Center for Esophageal & Gastric Surgery
Surgical Specialties Center
University of Washington Medical Center
Department of Surgery
Division of General Surgery
University of Washington Medicine
Seattle, Washington

Benjamin Wei, MD
Assistant Professor
Division of Cardiothoracic Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

C. Mel Wilcox, MD, MPH, FASGE
Professor
Department of Gastroenterology
Basil Hirschowitz Endoscopic Center of Endoscopic Excellence
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Sam T. Windham, III, MD
Associate Professor of Surgery
Co-Director
Surgical Intensive Care Unit
Section of Burns, Trauma, and Surgical Critical Care
Department of General Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

James Wiseman, MD
Resident
Houston Methodist Hospital
Houston, Texas

Kirk P. Withrow, MD
Assistant Professor of Surgery
Division of Otolaryngology
University of Alabama at Birmingham
Birmingham, Alabama

PART 2 OPERATIVE TECHNIQUES IN GASTROINTESTINAL SURGERY

Waddah B. Al-Refaie, MD, FACS
Chief
Surgical Oncology
MedStar Georgetown University Hospital
Surgeon-in-Chief
Lombardi Comprehensive Cancer Center
Washington, DC

Melissa M. Alvarez-Downing, MD
Resident
Department of Colorectal Surgery
Digestive Disease Institute
Cleveland Clinic Florida
Weston, Florida

Rebeccah B. Baucom, MD
Resident
Department of General Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Susan M. Cera, MD, FACS, FASCRS
Clinical Professor
Chief of Staff
Department of Colorectal Surgery
Physicians Regional Healthcare System
Physicians Regional Medical Group
Naples, Florida
Clinical Professor
Department of Colorectal Surgery
Digestive Disease Institute
Cleveland Clinic Florida
Weston, Florida

Eugene A. Choi, MD, FACS
Assistant Professor of Surgery
Department of Surgery
Section of Surgical Oncology
The University of Chicago Medicine
Chicago, Illinois

John D. Christein, MD
Associate Professor
Department of Surgery
Division of Gastrointestinal Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Ronald H. Clements, MD, FACS
Professor of Surgery
Director
Center for Surgical Weight Loss
Department of Surgery
Vanderbilt University
Nashville, Tennessee

Ashley Augspurger Davis, MD
Resident
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Elizabeth A. Dovec, MD
Advanced Minimally Invasive and Bariatric Surgery Fellow
Department of Surgery
Vanderbilt University
Nashville, Tennessee

Vikas Dudeja, MD
Department of Surgery
University of Minnesota
Minneapolis, Minnesota

Mary T. Hawn, MD, MPH
Professor, Chief of Gastrointestinal Surgery
Department of Surgery
Division of Gastrointestinal Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Todd Heniford, MD, FACS
Chief
Division of Gastrointestinal and Minimally Invasive Surgery
Carolinas Medical Center
Clinical Professor of Surgery
Department of General Surgery
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Martin J. Heslin, MD, MSHA
Professor
Surgical Oncology
Department of Surgery
Division of General Surgery
Chief
Section of Surgical Oncology
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Michael D. Holzman, MD, MPH, FACS
Associate Professor of Surgery
Chief
Division of General Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

John Daniel Hunter, III, MD
Minimally Invasive Fellow
Department of Surgery
Division of General Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Matthew M. Hutter, MD, MPH
Assistant Professor in Surgery
Harvard Medical School
Associate Visiting Surgeon
Department of Surgery
General and Gastrointestinal Surgery
Massachusetts General Hospital
Boston, Massachusetts

Kamal M.F. Itani, MD
Chief of Surgery
VA Boston Healthcare System
Professor of Surgery
Boston University
Boston, Massachusetts

Patrick G. Jackson, MD, FACS
Associate Professor of Surgery
Chief of Gastrointestinal Surgery
MedStar Georgetown University Hospital
Washington, DC

J. Spencer Liles, MD
Resident
Department of Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Ozanan R. Meireles, MD
General and Gastrointestinal Surgery
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Marcovalerio Melis, MD, FACS
Assistant Professor of Surgery
Department of Surgery
New York University School of Medicine
New York, New York

Filip Muysoms, MD
Senior Surgeon
Department of General Surgery
AZ Maria Middelares
Ghent, Belgium

Elliot Newman, MD, FACS
Associate Professor of Surgery
Department of Surgery
New York University Group Surgical Associates
New York University School of Medicine
New York, New York

Pavlos K. Papasavas, MD, FACS
Section of Metabolic and Bariatric Surgery
Department of Surgery
Hartford Hospital
Hartford, Connecticut

Michael D. Paul, MD, MPH
Department of General and Vascular Surgery
Dartmouth-Hitchcock
Concord, New Hampshire

John Roland Porterfield, Jr., MD, MSPH, FACS
Associate Professor
Department of Surgery
Division of General Surgery
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Benjamin K. Poulose, MD, MPH, FACS
Associate Professor
Division of General Surgery
Associate Director
Gastrointestinal Endoscopy Suite
Vanderbilt University Medical Center
Nashville, Tennessee

Sushanth Reddy, MD
Assistant Professor of Surgery
Department of Surgery
Division of General Surgery
Section of Surgical Oncology
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Michael J. Rosen, MD
Professor of Surgery
Chief, Division of GI and General Surgery
Director, Case Comprehensive Hernia Center
Case Medical Center
Cleveland, Ohio

George A. Sarosi, Jr., MD
Professor
Robert H. Hux Professor
Department of Surgery
Division of General Surgery
University of Florida College of Medicine
Vice Chairman for Education Surgery Residency Program
Director
Surgery Residency Program
North Florida/South Georgia VA Medical Center
Gainesville, Florida

Michael G. Sarr, MD
James C. Masson Professor of Surgery
Department of Surgery
Division of General and Gastroenterologic Surgery
Mayo Clinic
Rochester, Minnesota

John K. Saunders, MD, FACS
Assistant Professor of Surgery
Department of Surgery
New York University School of Medicine
New York, New York

Mark D. Sawyer, MD
Assistant Professor of Surgery
Department of Surgery
Division of General and Gastroenterologic Surgery
Mayo Clinic
Rochester, Minnesota

Eric G. Sheu, MD, DPhil
Minimally Invasive/Bariatric Surgery Fellow
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Darren S. Tishler, MD, FACS
Department of Surgery
Section of Metabolic and Bariatric Surgery
Director
Bariatric Surgery Program
Hartford Hospital
Hartford, Connecticut

Kristopher Williams, MD
Minimally Invasive Surgery Fellow
Department of Gastrointestinal and Minimally Invasive Surgery
Carolinas Medical Center
Charlotte, North Carolina

PART 3 OPERATIVE TECHNIQUES IN HEPATO-PANCREATO-BILIARY SURGERY

David B. Adams, MD, FACS
Professor and Head
Division of Gastrointestinal and Laparoscopic Surgery
Director
Digestive Diseases Center
Medical University of South Carolina
Charleston, South Carolina

Reid B. Adams, MD
Claude A. Jessup Professor of Surgery
Department of Surgery
Chief
Division of Surgical Oncology
Hepatobiliary and Pancreatic Surgery
University of Virginia Health System
Charlottesville, Virginia

Megan B. Anderson, MD
Resident
Department of Surgery
University of Colorado
Aurora, Colorado

Carlton C. Barnett, Jr., MD, FACS
Director of Surgical Oncology
Denver Health Medical Center
Professor of Surgery
University of Colorado Denver School of Medicine
Aurora, Colorado

David L. Bartlett, MD
Department of Surgery
Chief
Division of Surgical Oncology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Kevin E. Behrns, MD
Edward R. Woodward Professor and Chairman of Surgery
Department of Surgery
Division of General Surgery
University of Florida College of Medicine
Gainesville, Florida

Kfir Ben-David, MD
Assistant Professor of Surgery
Division of General Surgery
University of Florida College of Medicine
Gainesville, Florida
Michael E. Debakey VA Medical Center
Baylor College of Medicine
Houston, Texas

Neil H. Bhayani, MD, MHS
Clinical Instructor of Surgery
Penn State Milton S. Hershey Medical Center
Penn State Hershey College of Medicine
Hershey, Pennsylvania

Walter L. Biffl, MD, FACS
Professor of Surgery
Associate Director of Surgery
Assistant Director of Patient Safety and Quality
Denver Health Medical Center
University of Colorado Denver School of Medicine
Aurora, Colorado

Mark Bloomston, MD, FACS
Director
Surgical Oncology Fellowship Program
Associate Professor of Surgery
Department of Surgery
Division of Surgical Oncology
The Ohio State University Wexner Medical Center
Columbus, Ohio

Richard J. Bold, MD
Professor
Chief
Department of Surgery
Division of Surgical Oncology
UC Davis Medical Center
Sacramento, California

Brian A. Boone, MD
Resident
Department of General Surgery
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Adam S. Brinkman, MD
Department of Surgery
University of Wisconsin Health
Madison, Wisconsin

Jon S. Cardinal, MD
Assistant Professor of Surgery
Department of Surgery
Division of Surgical Oncology
West Virginia University
Morgantown, West Virginia

Jason A. Castellanos, MD
Resident
Research Fellow
Department of Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Eugene P. Ceppa, MD
Assistant Professor of Surgery
Section of Hepatopancreatobiliary Surgery
Indiana University School of Medicine
Indianapolis, Indiana

Shailendra S. Chauhan, MD
Associate Professor of Medicine
Division of Gastroenterology, Hepatology, & Nutrition
University of Florida College of Medicine
Gainesville, Florida

Disaya Chavalitdhamrong, MD
Division of Gastroenterology, Hepatology, & Nutrition
University of Florida College of Medicine
Gainesville, Florida

Charles S. Cox, Jr., MD
Children's Fund Distinguished Professor of Pediatric Surgery
Department of Pediatric Surgery
Director
Pediatric Trauma Program
Children's Memorial Hermann Hospital
University of Texas Health Science Center at Houston
Houston, Texas

Vanessa Cranford, MD, FRCSC
Trauma and Surgical Critical Care Fellow
Department of Surgery
UF Health Shands Hospital
Gainesville, Florida

Chasen A. Croft, MD
Assistant Professor of Surgery
Department of Surgery
Division of Acute Care Surgery
UF Health Shands Hospital
Gainesville, Florida

Kristopher Croome, MD
Resident
Department of Surgery
Division of Subspecialty General Surgery
Mayo Clinic
Hepatopancreatobiliary Surgery Fellowship
Mayo Medical School
Rochester, Minnesota

Dawood G. Dalaly, DO, MS
Surgical Critical Care Fellow
Department of Surgery
UF Health Shands Hospital
Gainesville, Florida

Daniel J. Delitto, MD
Department of Surgery
Division of General Surgery
University of Florida College of Medicine
Gainesville, Florida

Barish H. Edil, MD, FACS
Associate Professor of Surgery
Director
Pancreas and Biliary Surgery
Gastrointestinal Tumor and Endocrine Surgery
University of Colorado
Denver, Colorado

Laureano Fernández-Cruz, MD, FRCS Ed (Hon) FCRSI (Hon)
Department of Surgery
Hospital Clínic University of Barcelona
Hospital Clínic de Barcelona
Villarroel, Barcelona, Spain

William E. Fisher, MD
Professor
Department of Surgery
Michael E. DeBakey VA Medical Center
Director
Elkins Pancreas Center
Baylor College of Medicine
Houston, Texas

T. Clark Gamblin, MD, MS
Chief
Surgical Oncology
Stuart D. Wilson Professor of Surgery
Department of Surgery
Division of Surgical Oncology
Medical College of Wisconsin
Milwaukee, Wisconsin

Brian S. Geller, MD
Assistant Professor
Chief
Department of Radiology
Division of Vascular and Interventional Radiology
University of Florida
UF Health Shands Hospital
Gainesville, Florida

Andres Gelrud, MD, MMSc
Associate Professor of Medicine
Center for Endoscopic Research
Department of Gastroenterology
Therapeutics Section
University of Chicago Medicine
Chicago, Illinois

Ravit Geva, MD

Tel Aviv Sourasky Medical Center
Tel Aviv University
Tel Aviv, Israel

Ryan T. Groeschl, MD
Resident
Department of Surgery
Division of Surgical Oncology
Medical College of Wisconsin
Milwaukee, Wisconsin

Anand R. Gupte, MD
Assistant Professor of Medicine
Division of Gastroenterology
University of Florida
North Florida/South Georgia VA Medical Center
Gainesville, FL

Niraj J. Gusani, MD, MS, FACS
Associate Professor of Surgery
Department of Surgery
Section of Surgical Oncology
Penn State Milton S. Hershey Medical Center
Penn State College of Medicine
Hershey, Pennsylvania

Paul D. Hansen, MD, FACS
Medical Director
Division of Surgical Oncology
Providence Cancer Center
Portland, Oregon

Kathleen Hertzer, MD, PhD
Division of General Surgery
University of California, Los Angeles
Los Angeles, California

Robert Hetz, MD
Resident
Children's Memorial Hermann Hospital
University of Texas Health Science Center at Houston
Houston, Texas

O. Joe Hines, MD
Professor
Chief
Division of General Surgery
University of California, Los Angeles
Los Angeles, California

Steven J. Hughes, MD
Cracchiolo Family Professor
Chief
General Surgery
Division of General Surgery
University of Florida College of Medicine
Gainesville, Florida

Kamran Idrees, MD
Assistant Professor of Surgery
Department of Surgery
Division of Surgical Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Saleem Islam, MD, MPH
Associate Professor
Department of Surgery
Division of Pediatric Surgery
UF Health Shands Hospital
Gainesville, Florida

W. Cory Johnston, MD
Fellow
Hepatobiliary and Pancreas Surgery
Providence Cancer Center
Portland, Oregon

Janeen R. Jordan, MD
Assistant Professor
Department of Surgery and Anesthesia
UF Health Shands Hospital
Gainesville, Florida

Tara S. Kent, MD, MS
Residency Program Director
Department of Surgery
Beth Israel Deaconess Medical Center
Assistant Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Mohammad Khreiss, MD
Department of Surgery
Division of Surgical Oncology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Song Cheol Kim, MD, PhD
Department of Hepatobiliary and Pancreatic Surgery
University of Ulsan College of Medicine and Asan Medical Center
Seoul, South Korea

Eric T. Kimchi, MD
Associate Professor of Surgery
Medical University of South Carolina
Charleston, South Carolina

Shawn D. Larson, MBChB
Assistant Professor
Department of Surgery
Division of Pediatric Surgery
UF Health Shands Hospital
Gainesville, Florida

Kenneth K. W. Lee, MD, FACS
Jane and Carl Citron Professor of Surgery
Division of Surgical Oncology
Vice Chair for Graduate Education and
Program Director
Department of Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Aijun Li, MD
Associate Chief
Hepatobiliary Surgery Department III
Associate Professor
Eastern Hepatobiliary Surgery Hospital
Shanghai, China

KMarie Reid Lombardo, MD, MS, FACS
Consultant
Associate Professor of Surgery
Department of Surgery
Division of Subspecialty General Surgery
Mayo Clinic
Rochester, Minnesota

Nipun B. Merchant, MD
Professor of Surgery and Cancer Biology
Department of Surgery
Division of Surgical Oncology
Vanderbilt University Medical Center
Nashville, Tennessee

Rebecca M. Minter, MD
Associate Professor
Department of Surgery
Division of Hepatopancreatobiliary and Advanced Gastrointestinal Surgery
University of Michigan Health System
Ann Arbor, Michigan

Sean P. Montgomery, MD
Director
Surgical Intensive Care Unit
Assistant Professor of Surgery
Department of Surgery
Division of Acute Care Surgery
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Frederick A. Moore, MD
Professor
Chief
Acute Care Surgery
Department of Surgery
UF Health Shands Hospital
Gainesville, Florida

Katherine A. Morgan, MD, FACS
Associate Professor
Division of Gastrointestinal and Laparoscopic Surgery
Medical University of South Carolina
Charleston, South Carolina

Ido Nachmany, MD
Hepatobiliary, Transplant, and Laparoscopic Surgery
Tel Aviv Sourasky Medical Center
Tel Aviv, Israel

Bharath D. Nath, MD, PhD
Resident
Beth Israel Deaconess Medical Center
Clinical Fellow in Surgery
Harvard Medical School
Boston, Massachusetts

Udayakumar Navaneethan, MD
Department of Gastroenterology
Digestive Disease Institute
The Cleveland Clinic
Cleveland, Ohio

Kevin T. Nguyen, MD, PhD
Assistant Professor of Surgery
Department of Surgery
University of Michigan Health System
Ann Arbor, Michigan

Trang K. Nguyen, MD
Postdoctoral Scholar
Department of Surgery
Division of Surgical Oncology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Shawnn Nichols, MD, MS, FACS
Surgical Oncology Fellow
Department of Surgery
Division of Surgical Oncology
The Ohio State University Wexner Medical Center
Columbus, Ohio

Janak Parikh, MD
Co-Director
Hepato-Pancreato-Biliary Surgery Program
Providence Park Hospital
Novi, Michigan

Purvi Y. Parikh, MD
Assistant Professor
Albany Medical Center
Albany, New York

Timothy M. Pawlik, MD, MPH, PhD, FACS
Professor of Surgery and Oncology
Chief
Division of Surgical Oncology
John L. Cameron MD Professor of Alimentary Tract Diseases
Director
Johns Hopkins Medicine Liver Tumor Center Multidisciplinary Clinic
The Johns Hopkins Hospital
Baltimore, Maryland

Darren W. Postoak, MD
Assistant Professor
Department of Radiology
Division of Vascular and Interventional Radiology
University of Florida College of Medicine
Gainesville, Florida

Christopher D. Raeburn, MD, FACS
Associate Professor of Surgery
Gastrointestinal Tumor and Endocrine Surgery
University of Colorado
Denver, Colorado

Preston B. Rich, MD, MBA, FACS
Professor of Surgery
Chief
Department of Surgery
Division of Acute Care Surgery
University of North Carolina School of Medicine
Chapel Hill, North Carolina

Georgios Rossidis, MD
Assistant Professor
Department of Surgery
University of Florida College of Medicine
Gainesville, Florida

Shirin Sabbaghian, MD
Fellow of Surgical Oncology
Department of Surgery
Division of Surgical Oncology
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Teviah Sachs, MD, MPH
Clinical Fellow in Surgery
Division of Surgical Oncology
The Johns Hopkins Hospital
Baltimore, Maryland

C. Max Schmidt, MD, PhD, MBA
Professor of Surgery
Section of Hepatopancreatobiliary Surgery
Indiana University School of Medicine
Indianapolis, Indiana

Ki Byung Song, MD, PhD
Department of Hepatobiliary and Pancreatic Surgery
University of Ulsan College of Medicine and Asan Medical Center
Seoul, South Korea

Alice Ruth Reeves Folk Endowed Chair of Clinical Oncology
Professor
Chief
Oncologic and Endocrine Surgery
Medical Director
Hollings Cancer Center
Medical University of South Carolina
Charleston, South Carolina

Jose G. Trevino, MD
Assistant Professor
Division of General Surgery
UF Health Shands Hospital
Gainesville, Florida

Allan Tsung, MD
Roberta G. Simmons Assistant Professor of Surgery
Department of Surgery
Division of Hepatobiliary and Pancreatic Surgery
UPMC Montefiore
Pittsburgh, Pennsylvania

George VanBuren, II, MD
Assistant Professor
Department of Surgery
Division of Surgical Oncology
Michael E. DeBakey VA Medical Center
Baylor College of Medicine
Houston, Texas

Charles M. Vollmer, MD
Director
Pancreatic Surgery
Department of Surgery
Division of Gastrointestinal Surgery
Perelman School of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Mihir S. Wagh, MD
Assistant Professor of Medicine
Division of Gastroenterology, Hepatology, & Nutrition
University of Florida College of Medicine
Gainesville, Florida

Susanne G. Warner, MD
Clinical Instructor
Department of Surgery
Division of Hepatopancreatobiliary and Advanced Gastrointestinal Surgery
University of Michigan Health System
Ann Arbor, Michigan

Sharon M. Weber, MD
Professor
Department of Surgery
Section of Surgical Oncology
University of Wisconsin Health
Madison, Wisconsin

Mengchao Wu, MD
Chief Physician
Professor
Director
Eastern Hepatobiliary Surgery Hospital
Shanghai, China

Victor Zaydfudim, MD
Assistant Professor of Surgery
Department of Surgery
University of Virginia Health System
Charlottesville, Virginia

Herbert J. Zeh, MD, FACS
Chief
Division of Gastrointestinal Surgical Oncology
Co-Director
University of Pittsburg Medical Center Pancreatic Cancer Center
Associate Professor of Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Ivan R. Zendejas, MD
Clinical Assistant Professor
Department of Surgery
Division of Transplantation and Hepatobiliary Surgery
University of Florida College of Medicine
Gainesville, Florida

Amer H. Zureikat, MD, FACS
Assistant Professor of Surgery
Division of Surgical Oncology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Nicholas J. Zyromski, MD
Associate Professor
Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

PART 4 OPERATIVE TECHNIQUES IN COLON AND RECTAL SURGERY

Matthew Albert, MD
Florida Hospital
Orlando, Florida

Daniel Albo, MD, PhD
Dan L. Duncan Professor and Vice Chairman
Director, GI Oncology

Preface

Operative therapy is complex, technically demanding, and rapidly evolving. Although there are a number of standard textbooks that cover aspects of general, thoracic, vascular, or transplant surgery, *Operative Techniques in Surgery* is unique in offering a comprehensive treatment of contemporary procedures. Open operations, laparoscopic procedures, and newly described robotic approaches are all included. Where alternative or complementary approaches exist, all are provided. The scope and ambition of the project is one of a kind.

The text is organized anatomically in sections covering thoracic surgery, upper gastrointestinal surgery, hepato-pancreatico-biliary surgery, colorectal surgery, breast surgery, endocrine surgery, and topics related to surgical oncology and modern approaches to vascular surgery.

The editors are renowned surgeons with expertise in their respective fields. Each is a leader in the discipline of surgery, each recognized for superb surgical judgment and outstanding operative skill. Breast surgery, endocrine procedures, and surgical oncology topics were edited by Dr. Michael Sabel of the University of Michigan. Thoracic and upper gastrointestinal surgery topics were edited by Dr. Mary Hawn of the University of Alabama at Birmingham, with Dr. Steven Hughes of the University of Florida directing the section on hepato-pancreatico-biliary surgery. Dr. Daniel Albo of Baylor College of Medicine directed the section dedicated to colorectal surgery. Dr. Ronald Dalman of Stanford University edited topics related to vascular surgery, including both open and endovascular approaches. In turn, the editors have recruited contributors that are world-renowned; the resulting volumes have a distinctly international flavor.

Surgery is a visual discipline. *Operative Techniques in Surgery* is lavishly illustrated with a compelling combination of line art and intraoperative photography. The illustrated material was all executed by a single source, Body Scientific International, to provide a uniform style emphasizing clarity and strong, clean lines. Intraoperative photographs are taken from the perspective of the operating surgeon so that operations might be visualized as they would be performed. The result is visually striking, often beautiful. The accompanying text is intentionally spare, with a focus on crucial operative details and important aspects of postoperative management.

The text is designed for surgeons at all levels of practice, from surgical residents to advanced practice fellows to surgeons of wide experience. The incredible pace at which surgical technique evolves means that the volumes will offer new insights and novel approaches to all surgeons.

Operative Techniques in Surgery would be possible only at Wolters Kluwer Health, an organization of unique vision, organization, and talent. Brian Brown, executive editor, Keith Donnellan, acquisition editor, and Brendan Huffman, product development editor, of Wolters Kluwer Health deserve special recognition for vision and perseverance.

Chapter 1

Open Tracheostomy

Sam T. Windham, III   John Christopher McAuliffe

DEFINITION

- Tracheostomy is a procedure defined as the creation of a communication between the trachea and the skin of the neck anteriorly. In general, this technique is viewed as a definitive airway for the management of the critically ill patient needing prolonged ventilator support.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history from the patient may be limited as compared to standard history and physical exams normally performed on patients during routine evaluations for surgery; however, the history and physical exam should focus to determine (1) the indications for tracheostomy, (2) optimal timing for the performance of the tracheostomy, and (3) which approach will provide the safest tracheostomy for the patient.
- With respect to the indication for tracheostomy, the first and foremost indication should be that of the patient with a difficult airway who requires prolonged mechanical ventilator support. In these patients, loss of the airway can have devastating consequences. Pertinent history might include a difficult airway at the time of surgery; prior maxillofacial trauma; presence of severe inflammation or edema in the mandibular, pharyngeal, or base of tongue regions; prior head and neck radiation; or conditions that limit the mobility of the neck (e.g., ankylosing spondylitis, cervical trauma, or fixation). In these patients, early tracheostomy should be considered.
- With respect to timing of the tracheostomy, many studies have evaluated this question.
  - When endotracheal tubes were first created, the tubes were less flexible than modern tubes with low-volume, high-pressure cuffs that resulted in more tracheal trauma than modern tubes. However, tracheal trauma and stenosis still occur with modern endotracheal tubes, and as a result, this leads to one of the indications for timing of the tracheostomy. In order to minimize the risk of tracheal stenosis, most recommend performance of tracheostomy in patients for whom 2 weeks of mechanical ventilation is expected. Pena et al.[1] found that 86% of patients requiring laryngotracheal surgery for stenosis had a mean duration of 17 days of mechanical ventilation. So to minimize this risk, tracheostomy is usually recommended for expected duration of 14 days.
  - Other studies have looked at the timing of tracheostomies based on outcomes for the patients. Most studies evaluating performance of tracheostomies within the first 10 days of intensive care unit (ICU) course suggest statistically significant improvement in days on ventilator, days in the ICU, need for sedation, costs, and total hospital length of stay.[2–4] In busy hospitals, with increased ICU usage, early tracheostomy should be considered.
  - With respect to timing of the tracheostomy, an important aspect of the history to evaluate is the disease process that required the need for mechanical ventilator support. In patients with severe brain injury,[5] spinal cord injury associated with ineffective cough, severe multiple system organ failure, or in whom multiple-staged operations are planned, early tracheostomy should be considered.
- The final aspect to the history and physical exam that should be considered alters whether the patient should undergo percutaneous dilatational tracheostomy versus standard surgical tracheostomy. Certain conditions might warrant open technique over percutaneous tracheostomy.
  - In the setting of altered patient anatomy, the safer option would favor standard surgical tracheostomy with direct exposure of the trachea.
  - With respect to morbid obesity, Byhahn et al.[6] reported a greater complication rate with percutaneous dilatational tracheostomy over surgical tracheostomy (43% vs. 18%). If an extended length tracheostomy is anticipated to be needed, then surgical tracheostomy may be safer and easier approach.
  - The final consideration in preprocedural evaluation is the ventilator settings. In this setting, the surgeon must be comfortable either performing nonbronchoscopic percutaneous tracheostomies or choosing an open approach in order to minimize derecruitment.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to taking the patient for open tracheostomy, clotting parameters such as prothrombin time, partial thromboplastin time, and platelet count should be evaluated and optimized.
- Cervical spine status should be evaluated in the setting of trauma.
- Periprocedural antibiotics should be administered.

Positioning

- The patient is positioned supine with arms tucked to the side. Often, a pack is placed behind the shoulders to aid with neck extension (FIG 1).

FIG 1 ● Patient is positioned with a pack behind the scapulae in order to increase cervical extension.

TECHNIQUES

INCISION

- A no. 15 blade scalpel is used to make a vertical, midline incision approximately 30 to 40 mm along the lower neck. The cephalad extent of the incision begins at the level of the cricoid cartilage and extends caudally toward the sternal notch.
- The skin edges are elevated with Adson forceps and the dissection continues with Bovie electrocautery through the platysma and between the strap muscles (FIG 2).
- Once between the strap muscles, a Weitlaner retractor may be placed to retract the skin edges, the subdermal tissue, and the strap muscles laterally.

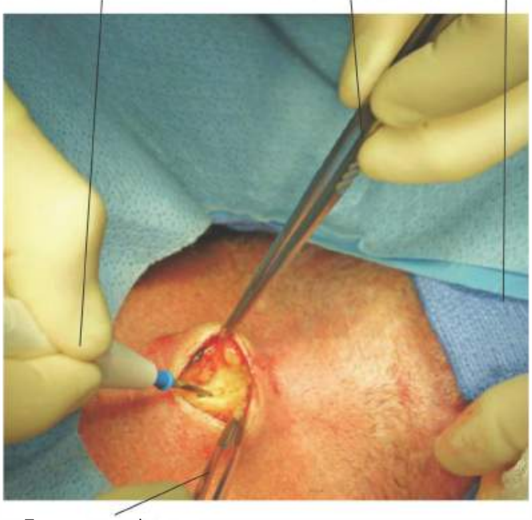

FIG 2 ● Division between the strap muscles using electrocautery.

PRETRACHEAL DISSECTION

- A gently curved, right-angle clamp is then placed in the pretracheal space at the level of the cricoid cartilage. In general, it is safest to develop the pretracheal space from cephalad to caudal direction beginning at the level of the cricoid cartilage (FIG 3A).
- Bovie electrocautery is used to divide the tissue exposed between the right-angle clamp.
- The isthmus of the thyroid is then divided using the Bovie electrocautery between the right-angle clamp (FIG 3B).
- A plane is then developed between the pretracheal tissue and the trachea laterally on each side using Bovie electrocautery (FIG 3C, 3D).

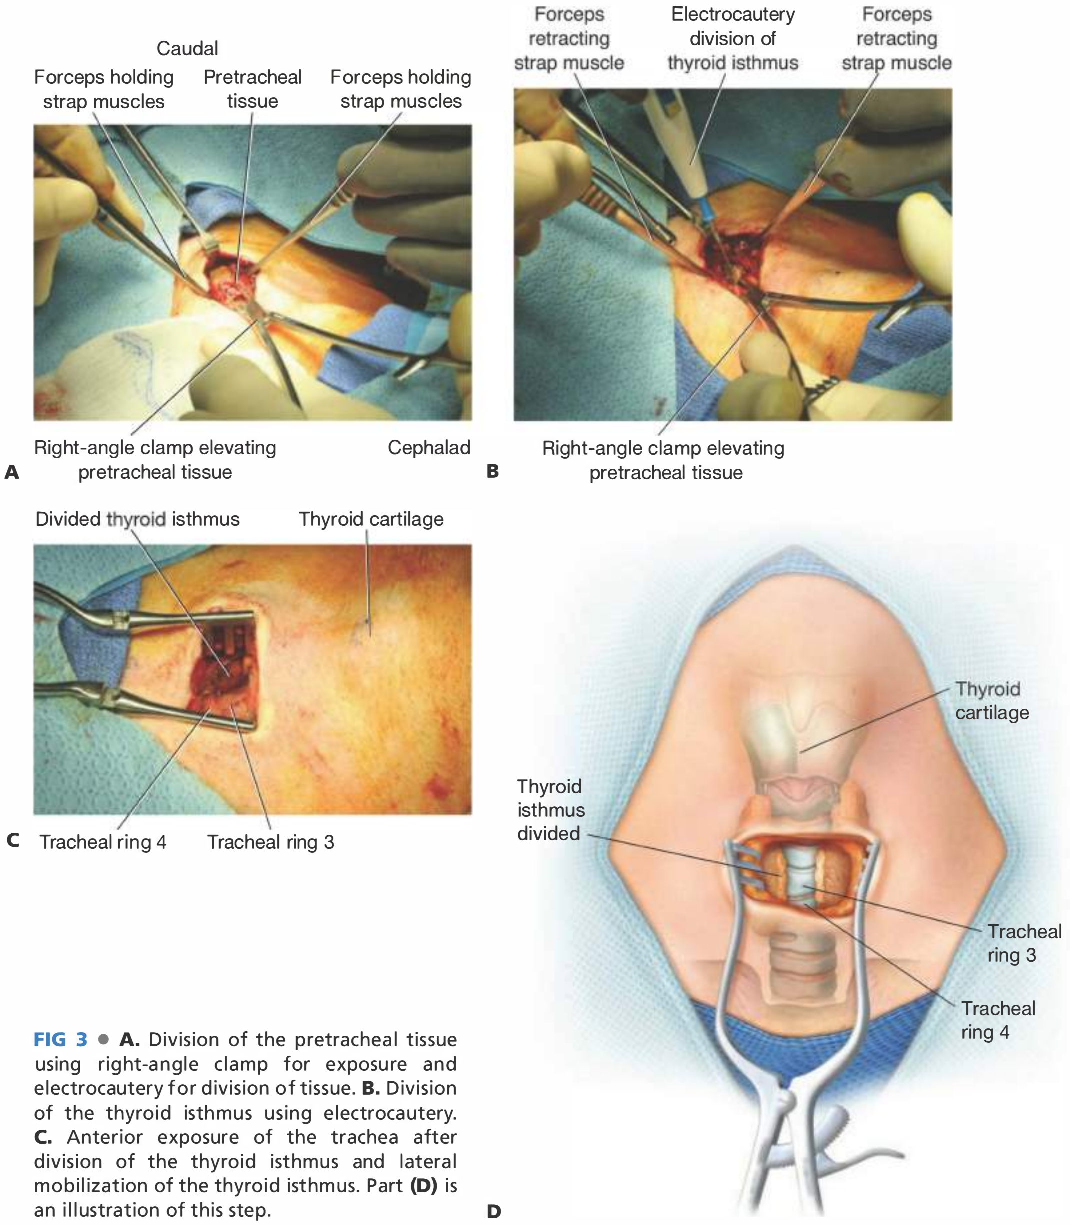

FIG 3 ● **A.** Division of the pretracheal tissue using right-angle clamp for exposure and electrocautery for division of tissue. **B.** Division of the thyroid isthmus using electrocautery. **C.** Anterior exposure of the trachea after division of the thyroid isthmus and lateral mobilization of the thyroid isthmus. Part **(D)** is an illustration of this step.

RING FIXATION

- Once the anterior and anterior lateral exposure of the trachea has been obtained, a 2-0 Prolene suture is placed through the 3rd tracheal ring laterally on each side. The endotracheal cuff should be briefly deflated as each stitch is placed so as not to incorporate the cuff with the suture (FIG 4).

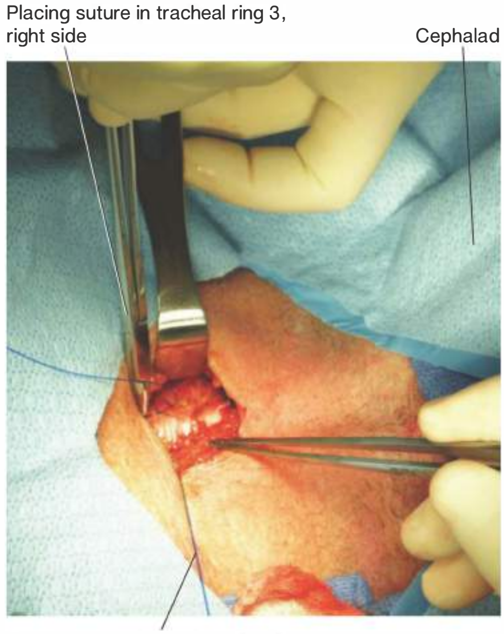

FIG 4 ● A 2-0 Prolene suture placement into the 3rd tracheal ring on each side.

TRACHEAL ENTRY

- An incision is then made with a no. 11 blade scalpel in the space between rings 2 and 3 and in the space between rings 3 and 4.
- The scalpel is then used to divide the 3rd ring, thus creating a sideways "H-shaped" opening in the trachea (FIG 5).
- A Kelly clamp or tracheal spreader is then inserted, opening the trachea.

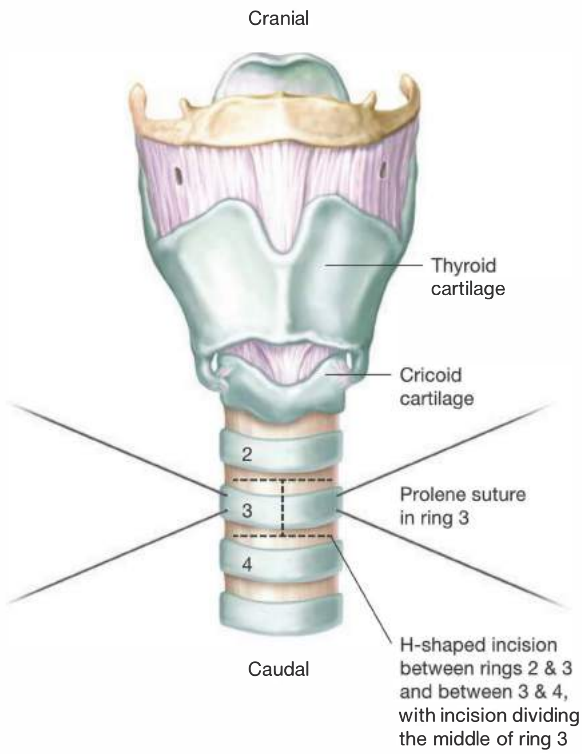

FIG 5 ● Illustration showing H-shaped incision of the trachea.

CANNULATION OF THE TRACHEA

- The endotracheal tube is then slowly withdrawn until the tip is just proximal to the tracheotomy site.
- The tracheostomy tube is then inserted into the trachea (FIG 6A,B).
- The tracheostomy tube is connected to anesthesia ventilator and end-tidal carbon dioxide (CO_2) is confirmed.

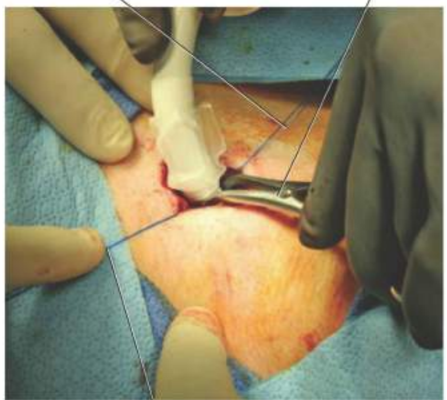

FIG 6 ● **A.** Tracheal spreader opening of the trachea. Note the endotracheal tube has been withdrawn to a location proximal to the tracheotomy. **B.** Introduction of the tracheostomy tube into the tracheotomy.

CLOSURE

- A 2-0 Prolene suture is then used to reapproximate skin edges above and below the tracheostomy tube.
- The tracheostomy tube is secured to the skin using interrupted 2-0 Prolene sutures.

PEARLS AND PITFALLS

Pretracheal dissection	■ Working from cephalad to caudad in the pretracheal plane results in less bleeding.
Ring fixation	■ Placing the sutures in the 3rd ring allows for lateral traction to open the tracheotomy for insertion of the tracheostomy tube. ■ The ring sutures also allow for reinsertion of tracheostomy tube in the case of accidental dislodgement before a tract is formed.
Tracheal entry	■ Airway fires have been described with the use of electrocautery to enter the trachea or to control bleeding of the trachea. Sharp entry with scalpel is the safest means to enter the trachea. Otherwise, fraction of inspired oxygen (FiO_2) needs to be reduced to less than 40% to minimize risk (experiments have shown flammable conditions in FiO_2 as low as 25% with use of laser).[7] ■ If division of the 3rd ring is not possible with scalpel, curved Mayo scissors can be used. ■ Insertion of the tracheostomy tube into the trachea should be at 90 degrees to the trachea. Tangential entry increases the chance of pretracheal placement of the tracheostomy tube.

POSTOPERATIVE CARE

- The 3rd ring stay sutures should stay until a tract develops between the skin and the trachea. Usually, these are removed after the first exchange of the tracheostomy tube.
- The tracheostomy tube should be exchanged between days 7 and 12 for hygiene purpose as well as to decrease the granulation tissue ingrowth into the tracheostomy tube.
- Once off the ventilator and as long as secretions are manageable, the tracheostomy tube can be downsized. Usually, the tube is downsized every other day, until the tube is size 4, at which time decannulation is performed.
- A decannulated tracheostomy stoma is covered with sterile gauze and tape and generally closes within 2 to 4 days.

COMPLICATIONS

- Rate of skin infection at surgical site: 2% to 3%
- Bleeding
- Tracheoinnominate fistula
- Tracheostomy dislodgement

Chapter 2

Cricothyroidotomy

Sam T. Windham, III

DEFINITION

- Cricothyroidotomy is an emergency procedure to establish airway access when orotracheal intubation is not possible or attempts have failed. As cricothyroidotomy has a high rate of complications compared to orotracheal intubation and tracheostomy, its role is limited to a rescue procedure for emergent airway access.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The circumstances surrounding the loss of airway are paramount to the use of cricothyroidotomy for establishment of the airway. These are broken down into patient-specific circumstances and setting-specific circumstances.
  - Patient-specific circumstances include trauma to face or upper airway, concern for cervical spine fractures, traumatic brain injury, limitations to cervical mobility, previous radiation to head and neck, and other circumstances leading to a difficult airway.
    - In certain circumstances such as potential isolated cervical spine fracture in a patient with a competent airway, attempts can be made to establish an airway by other means such as awake fiberoptic intubation or other intubation-assist devices.
    - In the setting of severe maxillofacial trauma where direct laryngoscopy is impeded by deranged anatomy, bleeding, and/or difficulty ventilating the patient, cricothyroidotomy should be considered early in the airway management algorithm.
  - Setting-specific circumstances also play a role as to the timing of emergency cricothyroidotomy in the airway algorithm. For example, considering the location where the airway is lost (such as the emergency department, operating room, or intensive care unit) will play a role in deciding what other options, equipment, and help are available.
    - If the loss of airway occurs in the operating room where full technical support is available, the full difficult airway algorithm may be used.[1]
    - The most common setting for the performance of cricothyroidotomy is for the trauma patient in an emergency room. In these patients with multiple injuries, suboptimal airway exposure due to need to maintain in-line cervical stabilization, and/or facial trauma, cricothyroidotomy should be prepared for at the first indication of a difficult airway.

SURGICAL MANAGEMENT

Preoperative Planning

- Planning for the cricothyroidotomy begins before the situation arises, such as familiarization with the steps involved in the procedure and knowledge of the equipment available to perform the procedure.
- Prepping the neck and obtaining equipment should begin with the second attempt of direct laryngoscopy in the difficult airway or at any sign of significant desaturation. Direct laryngoscopy may continue as the cricothyroidotomy is begun but should not delay the procedure.
- The pertinent anatomy and location of the cricothyroid membrane are illustrated in **FIG 1**.

Positioning

- The patient is placed in the supine position with in-line cervical spine stabilization for trauma patients.

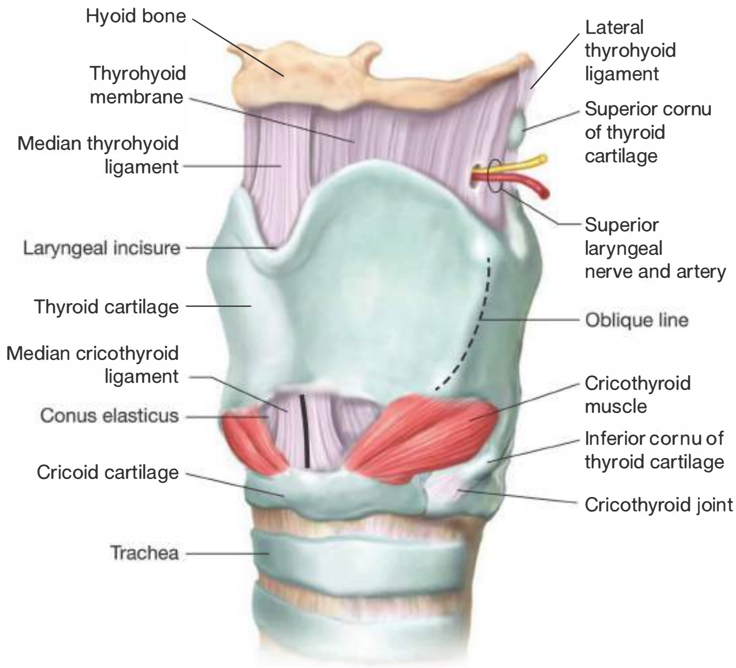

FIG 1 • Pertinent anatomy illustrating position of the cricothyroid membrane.

TECHNIQUES

PREP

- Betadine or available skin prep should be used to prep the anterior neck as quickly as possible.

INCISION

- Using a no. 10 blade or no. 15 blade scalpel, a vertical incision should be made from the prominence of the thyroid cartilage to below the level of the cricoid cartilage. This incision should be through the epidermis, dermis, and subdermal tissues (**FIGS 2** and **3**).

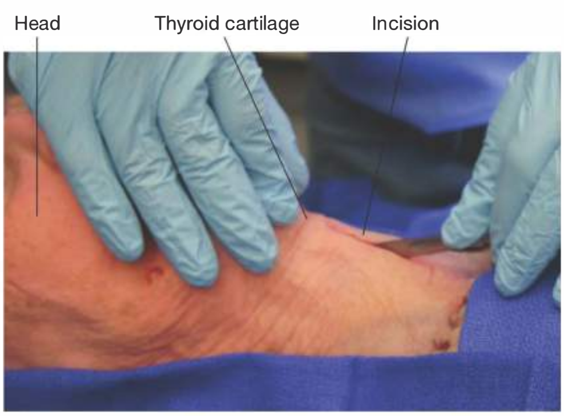

FIG 2 • Incision of the anterior neck, incising through epidermis, dermis, and subdermal tissues.

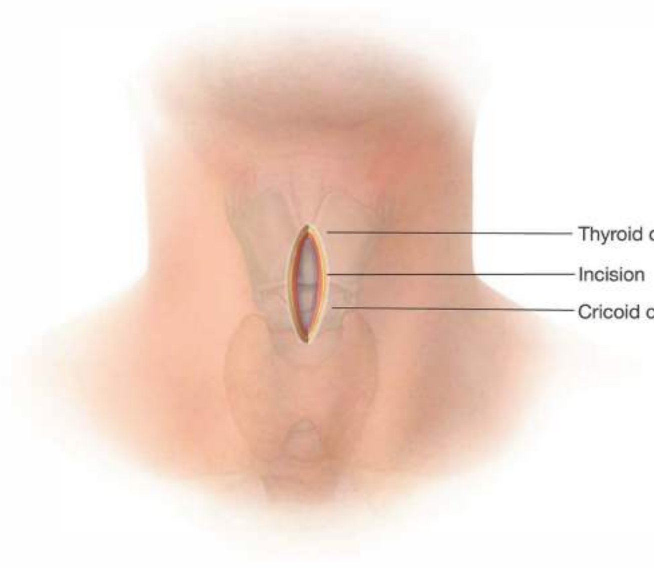

FIG 3 ● Location of the skin incision relative to anatomic landmarks.

CRICOTHYROID MEMBRANE ENTRY

- A curved hemostat is placed on the cricothyroid membrane and "popped" through the membrane. The hemostats are then opened in a vertical-oriented manner and left in place to maintain the opening in the cricothyroid membrane (**FIG 4**).
- A bougie (15 Fr) is advanced through the opening of the hemostats and into the trachea (**FIG 5**).

FIG 4 ● Curved hemostat placed onto cricothyroid membrane.

FIG 5 ● Hemostat spread to open cricothyroid membrane in able to introduce bougie into the trachea.

TECHNIQUES

INTUBATION

- A 6-0 endotracheal tube (ETT) is advanced over the bougie into the trachea and the balloon is insufflated (**FIG 6**).
- Confirmation of a tube placement should be performed with auscultation of the lung fields, end-tidal CO_2 monitor, if available, and portable chest x-ray.
- 0 Silk (or other large suture) is used to secure the ETT to the skin and prevent accidental dislodgement of the tube (**FIG 7**).

FIG 6 ● 6-0 ETT introduced into the trachea over the bougie catheter.

FIG 7 ● 2-0 Prolene used to secure the ETT in place and to close the wound.

PEARLS AND PITFALLS

Incision	■ A vertical incision is preferable, as a transverse/horizontal incision can transect the anterior jugular veins, leading to significant bleeding, and impede visualization.
Cricothyroid membrane entry	■ If a hemostat is not readily available, the blade of the scalpel can be used to incise the membrane and the handle can be used to open the membrane.
Intubation	■ A bougie does not have to be used, but once in place, it facilitates the introduction of the ETT and maintains the control of the airway. ■ Giving a twist to the ETT allows for easier introduction of the ETT through the cricothyroid membrane. ■ A tracheostomy tube can be used instead of the ETT, but often these are more difficult to find and the ETT are usually readily available.

POSTOPERATIVE CARE

- The cricothyroidotomy should be formalized to a tracheostomy within the first 48 hours to minimize risk of long-term complications of tracheal stenosis as well as to establish a safer, more definitive airway.
- In general, the cricothyroidotomy is converted to an open tracheostomy. At the same time, the wound of the cricothyroidotomy is surgically cleaned and a strap muscle can be pulled down to the site of the cricothyroidotomy to aid with wound healing.

COMPLICATIONS

- Subglottic stenosis
- Wound complications
- Occlusion of the small ETT with blood

Chapter 3

Tracheostomy: Endoscopic

Sam T. Windham, III

DEFINITION

- Tracheostomy is defined as a procedure creating a communication between the trachea and the skin of the neck anteriorly. Tracheostomy is used as a definitive manner of airway management as opposed to translaryngeal intubation for the needs of the critically ill patient. Since the mid-1980s, percutaneous dilational tracheostomy (PDT) has gained acceptance with equivalent safety as compared to standard surgical tracheostomy, with equal or fewer complications, and decreased resource usage and costs.[1,2]

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history from the patient may be limited as compared to standard history and physical exams normally performed during routine evaluations for surgery; however, the history and physical exam should focus on (1) the indications for tracheostomy, (2) optimal timing for the performance of the tracheostomy, and (3) which approach will provide the safest tracheostomy for the patient.
- With respect to the indication for tracheostomy, the first and foremost indication should be that of the patient with a difficult airway who requires prolonged mechanical ventilator support. In these patients, loss of the airway can have devastating consequences. Pertinent history might include a difficult airway at the time of surgery; prior maxillofacial trauma; presence of inflammation or edema in the mandibular, pharyngeal, or base of tongue regions; prior head and neck radiation; or conditions that limit the mobility of the neck (e.g., ankylosing spondylitis, cervical trauma, or fixation). In these patients, early tracheostomy should be considered.
- With respect to timing of the tracheostomy, many studies have aimed to evaluate this question.
  - When endotracheal tubes were first created, the tubes were less flexible than modern tubes with low-volume and high-pressure cuffs that resulted in more tracheal trauma than modern endotracheal tubes. However, tracheal trauma and stenosis still occur with modern tubes, and as a result, this leads to one of the indications for timing of the tracheostomy. In order to minimize the risk of tracheal stenosis, most recommend performance of tracheostomy in patients for whom 2 weeks of mechanical ventilation is expected. Pena et al.[3] found that 86% of patients requiring laryngotracheal surgery for stenosis had a mean duration of 17 days of mechanical ventilation. So to minimize this risk, tracheostomy is usually recommended for expected duration of 14 days.
  - Other studies have looked at the timing for when to perform tracheostomies based on outcomes for the patients. Most studies evaluating performance of tracheostomies within the first 10 days of intensive care unit (ICU) course suggest statistically significant improvement in days on ventilator, days in the ICU, need for sedation, costs, and total hospital length of stay.[4–6] In busy hospitals, with increased ICU usage, early tracheostomy should be considered.
  - With respect to timing of the tracheostomy, a final aspect to the history to evaluate is the disease process that required the need for mechanical ventilator support. In patients with severe brain injury,[7] spinal cord injury associated with ineffective cough, severe multiple system organ failure, or in whom multiple-staged operations are planned, early tracheostomy should be considered.
- Another aspect of the history and physical exam that should be considered alters whether the patient should undergo PDT versus standard surgical tracheostomy. In the past, frequently cited contraindications to PDT were altered patient anatomy, morbid obesity, coagulopathy, cervical fracture, previous tracheostomy, and high ventilator setting, all of which should be evaluated in preprocedural setting.
  - In the setting of altered anatomy, certainly, the safer option would favor standard surgical tracheostomy with direct exposure of the trachea.
  - With respect to morbid obesity, Byhahn et al.[8] reported greater complication rate with PDT over surgical tracheostomy. If an extended length tracheostomy (XLT) is anticipated due to the distance between skin and trachea, then surgical tracheostomy may be a safer approach.
  - With respect to coagulopathy, PDT can be safely performed in patients with a coagulopathy as long as the risk factors are modified prior to the procedure. If the platelet count is less than 50,000/μL, platelets should be given at the time of the procedure.[9] If the platelet count is less than 75,000/μL and the patient has other risk factors for platelet dysfunction (i.e., azotemia, antiplatelet therapy) or abnormal coagulation cascade (i.e., elevated prothrombin time or partial thromboplastin time), platelets should be given periprocedural, as well as fresh frozen plasma if the international normalized ratio (INR) is greater than 1.7.
  - With respect to cervical fixation and cervical fractures, studies have shown that PDT can be safely performed without cervical spine clearance or fixation[10] as long as cervical extension is not needed to gain adequate exposure on physical exam.
  - In patients with prior tracheostomies, PDT has been shown to be a safe approach to tracheostomy placement.[11]
  - The final consideration in preprocedural evaluation is the ventilator settings. High ventilator settings (e.g., positive end-expiratory pressure [PEEP] >14 cm H_2O, vent rate >20 breaths per minute) are a relative contraindication to PDT due to derecruitment issues during bronchoscopy. Depending on the comfort of the surgeon, a PDT can be performed with nonbronchoscopic or a standard open surgical approach.

SURGICAL MANAGEMENT

Preoperative Planning

- Probably one of the most important components for safely performing this procedure is preparation and setup.
  - Medications for the procedure usually consist of an anxiolytic (Versed), a narcotic, and a neuromuscular relaxant.

- The bed is positioned to allow access to the head of the bed so that translaryngeal reintubation can be performed.
- An intubation/airway tray should be at the bedside as well as supplies for reintubation (e.g., Yankauer suction apparatus, Ambu bag, free flowing intravenous fluid).
- The head of the bed is positioned at approximately 30 degrees.
- A respiratory therapist and a nurse are both available as part of the preoperative planning and setup portions of the procedure.
- A bronchoscopy cart is set up to be used during the procedure.
- Periprocedural antibiotics are administered.

Positioning

- For most patients, if the head of bed is elevated, a pack is not needed behind the back for neck extension, as it often does not increase the number of cartilaginous rings above the sternal notch. It is helpful, however, if the working distance between the chin and sternal notch is limited, such as in those patients with a "second chin."
- If the pack is used, usually one to two rectangular-shaped towels are positioned behind the shoulder blades.

SETUP

- The ventilator is set to deliver 100% fraction of inspired oxygen (FiO_2) in order to preoxygenate the patient. The ventilator is also adjusted to deliver a set volume, and the rate is increased in order to preventilate the patient.
- At the same time of adjusting the ventilator settings, if the patient is conscious, the anxiolytic is given. If the patient tolerates the dosing of the anxiolytic from a hemodynamic standpoint, then a narcotic is given shortly thereafter.
- Finally, the neuromuscular relaxant medication is administered.
  - The base of the neck is prepped with chlorhexidine from the chin to the nipples and from lateral aspect of the neck to the other lateral aspect of the neck.
  - Three sterile towels are used to drape the lateral aspects of the surgical field and the caudal aspect of the field. A sterile sheet is then placed to cover the entire body of the patient and is used to lay out the equipment for the procedure (**FIG 1**).

FIG 1 ● To aid with the procedure, the equipment is positioned on a sheet on the patient to minimize turning away from the operative field.

INCISION

- Lidocaine with epinephrine is infiltrated along lower midline cervical region from the externally palpated cricoid cartilage to the sternal notch.
- A 12- to 15-mm length incision is made with a no. 15 blade scalpel through the dermis along the midline. The cephalad portion of the incision should start at or just below the level of the cricoid cartilage (**FIG 2**).
- Lidocaine with epinephrine is often used to infiltrate small points of bleeding at the lower portion of the dermis and then pressure held for 10 to 20 seconds to achieve relative hemostasis before proceeding.
- Curved hemostats are then used to perform blunt dissection along the length of the incision between the strap muscles in order to better palpate the trachea to determine the point of entry.

FIG 2 ● A 12- to 15-mm incision is made along the lower midline portion of the neck. The incision is made through the epidermis, dermis, and platysma.

CANNULATION OF THE TRACHEA

- If the bronchoscope is used, it is inserted down the endotracheal tube at this point to the end of the endotracheal tube but still inside the endotracheal tube so as to protect the endoscope from trauma (**FIG 3A**).
    - The curved hemostat or the introducer needle is then used to palpate the trachea between cartilage rings 2 and 3 (**FIG 3B**).
    - The endotracheal tube and bronchoscope are withdrawn slowly until they are positioned just above the point of palpation, then the introducer needle enters the trachea under visualization of the bronchoscope (**FIG 3C**).
    - The guidewire is then passed through the introducer needle under visualization of the bronchoscope (**FIG 3D,E**).
    - If the patient has limited "reserve"/required high ventilator settings prior to the procedure, the bronchoscope can be removed prior to the dilation portion of the procedure.
- If bronchoscope is not used for the procedure, the endotracheal tube is left in position, and the introducer needle is placed on the interspace between cartilage rings 2 and 3.
    - The needle is advanced into the trachea, aspirating with a syringe as the trachea is entered. Most commonly, air or airway secretion fluid is aspirated as the trachea is entered with the introducer needle. The endotracheal tube is left down at this step to decrease the chance for a posterior tracheal wall injury with the needle.
    - The guidewire is advanced through the introducer needle.

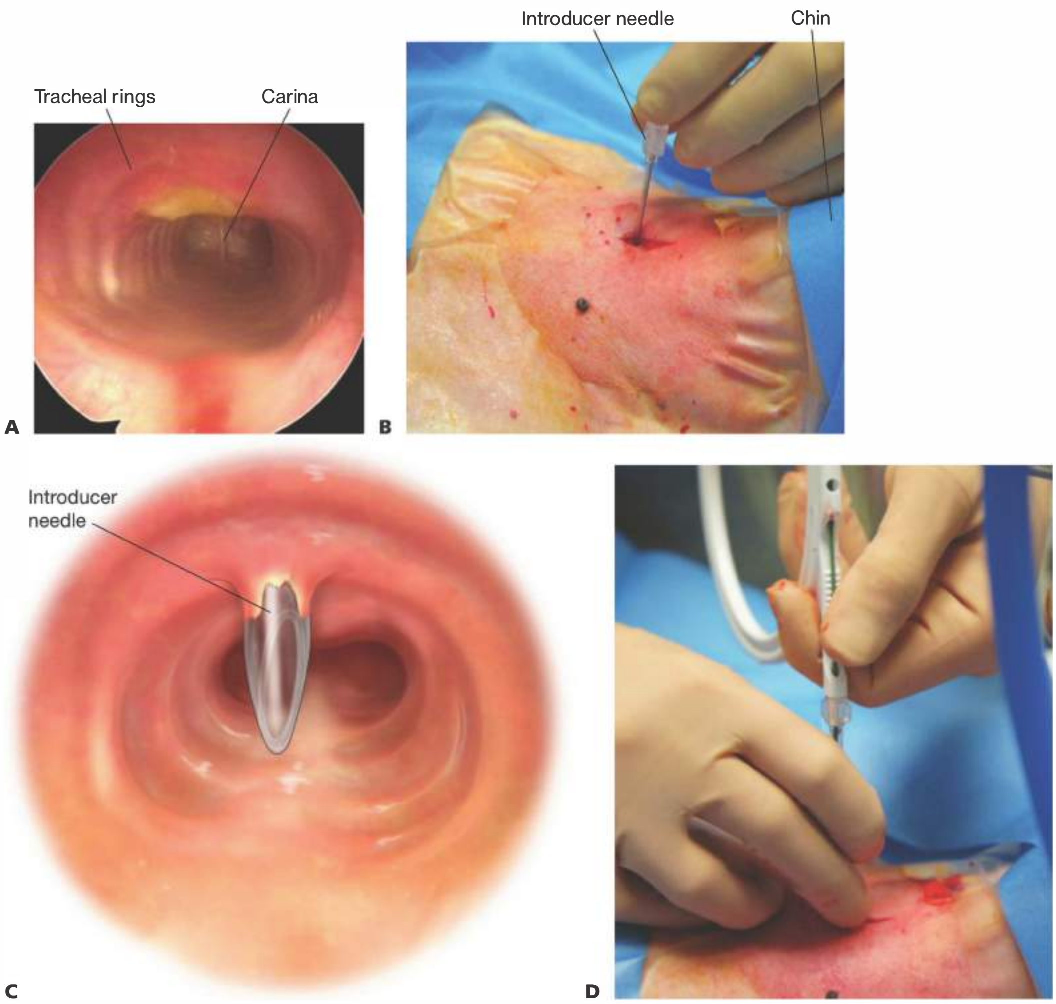

FIG 3 ● **A.** Image from the bronchoscope viewing the entire trachea. **B.** The needle is then used to apply pressure on the anterior wall of the trachea. **C.** Needle entry into the trachea under endoscopic vision. **D.** Guidewire insertion through the introducer needle from the external view. *(continued)*

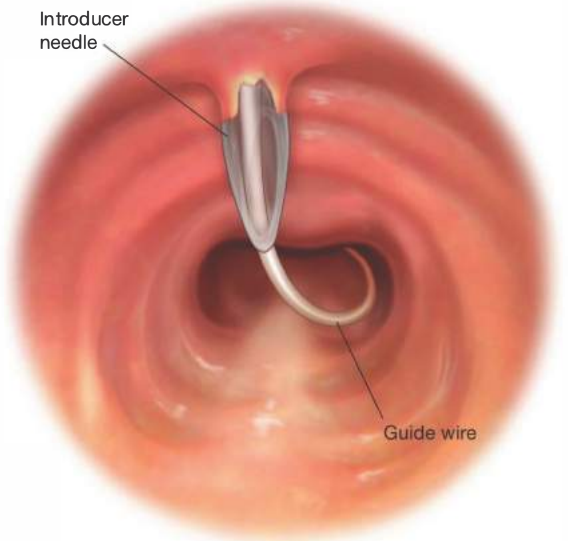


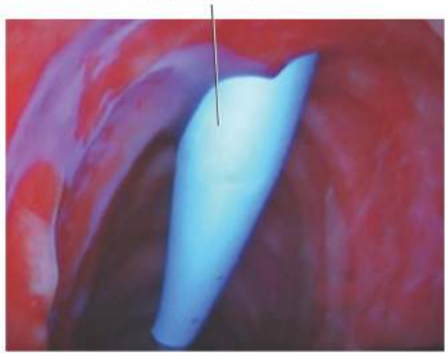
E

FIG 3 ● *(continued)* **E.** Guidewire insertion through the introducer needle from the endoscopic view.

DILATION

- The short, pretracheal dilator is then advanced over the guidewire, entering the trachea at 90 degrees to the trachea. As the dilator is entering into the trachea, a slight twist is applied to the dilator to aid with entry into the trachea (**FIG 4A,B**).
- Next, the tapered dilator and the guiding catheter are advanced as a unit over the guidewire. Once again, the catheters should enter the trachea at 90-degree angle to the trachea. The tapered dilator is advanced to dilate the trachea until the skin level mark on the dilator is at the skin incision. If the bronchoscope is not used, the endotracheal tube is withdrawn at this point by several centimeters as the respiratory therapist, who is holding the endotracheal tube, begins to feel the tapered dilator pull and hit the endotracheal tube (**FIG 4C,D**).
- The tapered dilator is removed from the guiding catheter and the guidewire, leaving the two of these in place.

A



B

FIG 4 ● **A.** Pretracheal dilator being passed over guidewire to perform pretracheal dilation. **B.** Endoscopic view of pretracheal dilator. *(continued)*

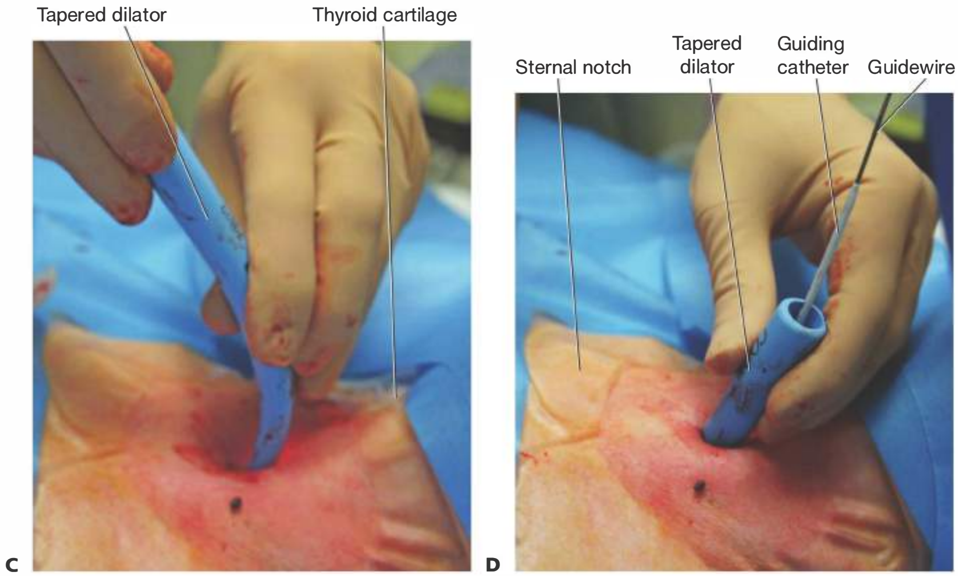


FIG 4 ● *(continued)* **C,D.** Tapered dilator being passed over guidewire and guidance catheter.

INSERTION OF TRACHEOSTOMY TUBE

- Finally, the loading dilator and the tracheostomy are loaded onto the guidewire and guidance catheter with caution to make sure the guidance catheter emerges from the distal end of the tracheostomy and loading dilator.
- Once the loading dilator is at the safety ridge of the guidance catheter, the guidance catheter, loading dilator, and tracheostomy tube are advanced as a unit into the trachea (**FIG 5A,B**).
- The guidewire, guidance catheter, and loading dilator are removed as a unit. The cuff of the tracheostomy tube is inflated. The inner cannula is then inserted into the tracheostomy. End-tidal carbon dioxide (CO_2) detection should be assessed as the patient is placed back on the ventilator or the bronchoscope should be quickly passed through the tracheostomy tube to confirm appropriate positioning of the tracheostomy tube.

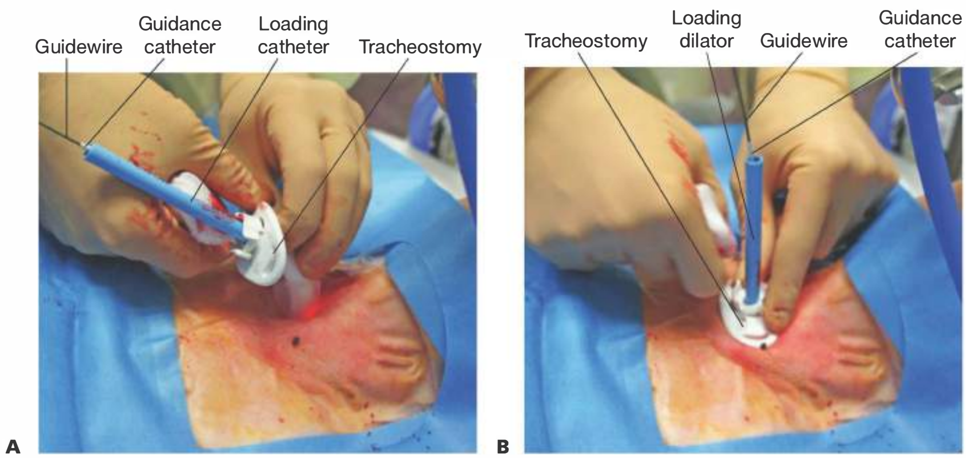

FIG 5 ● **A.** Tracheostomy tube being advanced into trachea over the guidewire, guidance catheter, and loading dilator. **B.** Completion of introduction of tracheostomy tube into trachea.

TECHNIQUES

COMPLETION OF THE PROCEDURE

- A 4 × 4 gauze should be cut to rest between the skin and tracheostomy tube for 24 hours, after which it is removed.
- The tracheostomy tube should be sewn to the neck with 2-0 Prolene sutures that remain in place for 7 to 10 days.
- A Velcro reinforcement collar also provides support to prevent accidental dislodgement prior to tract formation.
- A chest radiograph is routinely obtained postprocedure to evaluate for appropriate positioning of the tracheostomy tube, rule out pneumothorax, and evaluate for bronchial obstruction.
- The stylet of the tracheostomy tube should be taped to the wall above the patient's bed to be used for tracheostomy reinsertion should accidental dislodgement occurs.

PEARLS AND PITFALLS

Indications	■ In the obese patient, if a computed tomography (CT) scan is available, this can be used to measure the distance between the skin and trachea if an XLT tracheostomy tube is being considered.
Incision	■ If an anterior jugular vein is encountered in the incision (even if no injury is suspected), consider ligation proximally and distally as this is easiest to perform before the tracheostomy tube has been placed.
Cannulation	■ The introducing needle should be stabilized with the 1st and 2nd digits of the left hand while the 3rd–5th digits rest on the trachea to stabilize it; this helps prevent the needle from sliding off the lateral wall of the trachea. ■ The guidewire should pass easily through the introducer needle into the trachea.
Dilation	■ All catheters (pretracheal dilator, tapered dilator, and introducing catheter) should enter perpendicular to the trachea as to prevent pretracheal dissection or false passage.
Insertion of tracheostomy tube	■ Confirmation with bronchoscope should be performed if the bronchoscope is used or confirmation of end-tidal CO_2 if the bronchoscope is not used.

POSTOPERATIVE CARE

- The coagulopathic patient should be evaluated for bleeding, with platelets and/or blood products given if bleeding is present in the first 6 hours.
- A 4 × 4 gauze placed between the tracheostomy and skin should be removed 24 hours after placement.
- The initial tracheostomy tube should be exchanged between days 7 and 12 to help minimize secretions and decrease the ingrowth of granulation tissue.

COMPLICATIONS

- Rate of skin infection at surgical site: 2% to 3%
- Bleeding
- Tracheoinnominate fistula
- Tracheostomy dislodgement

Chapter 4

Tracheal Resection and Reconstruction

Alexander T. Hillel William Grist

DEFINITION

- Tracheal resection is usually performed for the external excision of tracheal stenosis or hypertrophic scarring of the trachea with critical obstruction of the airway. The term cricotracheal resection is used when the anterior section of the cricoid cartilage requires removal due to extension of the scar near the vocal folds. Tracheal resection is performed following failure of other surgical therapy, primarily endoscopic excision and dilation of tracheal stenosis. A successful tracheal resection allows the patient to avoid a lifelong tracheostomy tube.

DIFFERENTIAL DIAGNOSIS

- Tracheal stenosis is primarily due to postintubation injury, although autoimmune disease can also cause subglottic stenosis. Acquired stenosis is usually secondary to pathogenic wound healing, with the formation of permanent scar tissue in the airway.
- Tracheal neoplasms, including adenoid cystic and squamous cell carcinoma, or thyroid tumors with tracheal invasion are less frequent etiologies for segmental tracheal or cricotracheal resection.[1]

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be performed, including past medical history, past surgical history—including previous intubations or surgery on the trachea or esophagus, medications, allergies, and a family history of autoimmune disease.
- Patients with an idiopathic etiology, who have not undergone intubation, or those with a history/family history of autoimmune disease should have an autoimmune serum panel.
- A detailed medical history for comorbidities that could affect recovery following resection includes diabetes, coronary artery disease, and lung disease including chronic obstructive pulmonary disease (COPD) and tracheobronchial malacia. Severe COPD and tracheobronchial malacia may necessitate the need for tracheostomy even following successful resection.
- Patients who had multiple previous procedures, especially open tracheostomies or cervical tracheoesophageal fistula repair, may have extratracheal fibrosis, making dissection more challenging and increasing the risk of injury to the recurrent laryngeal nerve (RLN).
- Thorough evaluation of vocal fold mobility is recommended to document preoperative function. Patients often have multiple levels of stenosis, and glottic narrowing due to a second stenosis at level of vocal folds (relative contraindication) may limit the efficacy of successful tracheal resection.
- Accurate understanding of the length of stenosis will impact the necessity of surgical release maneuvers. These are rarely required for stenosis less than 5 cm.
- Contraindications for tracheal resection are listed in Table 1.

Table 1: Absolute and Relative Contraindications for Tracheal Resection

1. Active autoimmune diseases affecting the airway (Wegener's granulomatosis, relapsing polychondritis)
2. Stenosis extending to include the vocal folds
3. Stenosis greater than half the length of the trachea (relative contraindication)
4. Concurrent laryngeal stenosis (relative contraindication)—tracheostomy will need to remain in place until laryngeal stenosis is addressed.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Bronchoscopy is required to accurately map out the stenosis, including its length, width, and distance from the vocal folds and carina when appropriate. Bronchoscopy is usually performed in the operating room or endoscopy suite (**FIG 1**); however, with appropriate topical anesthesia, in-office bronchoscopy can provide similar results and avoid a trip to the operating room.
- As detailed in the preceding section, laryngoscopy or stroboscopy, when indicated, should be performed to assess preoperative vocal fold mobility and the presence of laryngeal stenosis.
- Computed tomography (CT) can provide key anatomic detail of the trachea, especially of the external trachea and adjacent vasculature. Three-dimensional CT provides excellent reconstructions of the tracheal and bronchial airways (**FIG 2**).
- If the patient complains of dysphagia, a modified barium swallow study may yield relevant results especially if the patient requires infra- or suprahyoid laryngeal release maneuvers, which will adversely affect swallowing postoperatively.

SURGICAL MANAGEMENT

Preoperative Planning

- When relevant, preoperative discussion between surgical teams about the extent of the stenosis is recommended. If the otolaryngologist represents the primary surgeon and repair of the stenosis may require a sternotomy, thoracic surgery should be consulted.

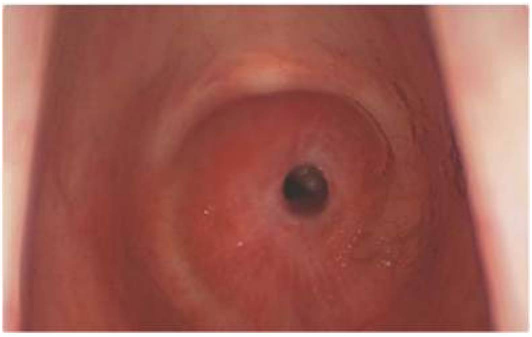

FIG 1 ● Bronchoscopic view of tracheal stenosis taken at the level of the vocal folds.

FIG 2 ● Three-dimensional sagittal CT image of cervical tracheal stenosis with dilated segment proximal to stenosis.

- Similarly, if it is a primary thoracic team performing surgery and the stenosis requires a suprahyoid release maneuver, preoperative inclusion of otolaryngology team is recommended.
- Use of an NIM™ RLN monitoring endotracheal tube (ETT) is recommended to allow for monitoring of the RLN during dissection.
- Having a second anesthesia circuit in a sterile sleeve allows for easy control of the airway when the anode tube is placed in the distal trachea following the tracheal cuts.

Positioning

- An inflatable shoulder roll should be inflated to provide complete neck extension and deflated prior to closure.
- Initial bronchoscopy may be performed with the bed rotated 90 degrees from the anesthesia team to allow the surgical team to dilate the stenosis in order to place an ETT.
- Following intubation, the bed should be rotated another 90 degrees to have the head 180 degrees from anesthesia. This allows for adequate room around the head and neck.
- If tracheostomy tube cannot be replaced with placement of an ETT following dilation, replace the tracheostomy tube with an anode tube to remove the flange from the operative field.

TECHNIQUES

BRONCHOSCOPY

- Initial bronchoscopy is recommended to assess the stenosis; dilate and place an ETT prior to resection. We encourage perioperative placement of an ETT in patients with tracheostomies to remove the tracheostomy tube from the surgical field.
- A key determination on bronchoscopy is the proximity of the stenosis to the vocal folds. If the proximal portion is within 2 cm of the superior aspect of the vocal folds, the cricoid will usually need to be included in the excision, which will influence the location of the initial tracheal incision.

PLACEMENT OF INCISION

- A low transverse neck incision should be placed in a neck crease below the cricoid cartilage extending from the anterior border of the sternocleidomastoid muscles on each side of the neck.
- If there is existing tracheostomy skin scar, the incision should include the scar around the tracheostomy site in an ellipse fashion.

SKIN INCISION AND RAISING OF FLAPS

- An incision is extended deep to the platysma, and inferior and superior subplatysmal flaps should be elevated from the sternal notch to the hyoid superiorly.
- The authors are proponents of the Mayfield thyroid retractor to provide adequate exposure.

EXPOSURE OF TRACHEA

- The sternohyoid and the sternothyroid muscles should be dissected and retracted laterally to expose the thyroid isthmus, which should be transected and reflected laterally.
- This provides exposure of the trachea, which should be skeletonized with blunt dissection to free up the anterior ligamentous attachments to just above the carina. This assists in for tension-free anastomosis. Lateral dissection should be limited to maintain the vascular supply.

SEPARATION OF COMMON PARTY WALL

- Following skeletonizing the anterior trachea, the trachea should be dissected circumferentially at the level of the stenosis. During exposure of tracheoesophageal groove, care should be taken with the dissection given proximity of RLNs. Given the greater ascending length of the left RLN, it tends to run in a more cranial–caudal course, whereas the right may be more oblique in a lateral to medial direction.
- Dissection may be used with a (Crile) clamp to separate the common party wall, separating the posterior membranous tracheal wall from the anterior wall of the esophagus (**FIG 3A**). This should be done at the level of stenosis, however, not superior to the 1st tracheal ring to prevent injury to the RLNs.
- Palpate the tip of the clamp on the contralateral side to gently dissect through the tissue plane. Tissue bunching up between clamp tip and finger suggesting the dissection is in wrong plane with the tissue is likely representing folded membranous tracheal wall or the esophagus.
- After the wall is separated, placement of a 1-inch thick Penrose drain maintains control (**FIG 3B**).

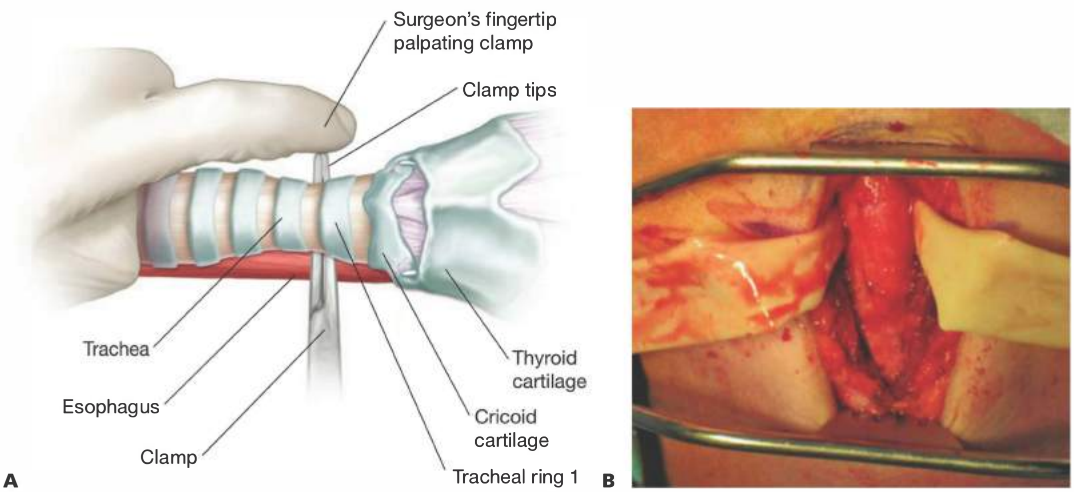

FIG 3 ● **A.** Blunt clamp dissection separating posterior tracheal wall from esophagus. **B.** Mayfield retractor providing cranial–caudal exposure of trachea after 1-in Penrose placed between trachea and esophagus.

TRACHEAL INCISION

- Prior to the tracheal incision, two retention sutures should be placed with 2-0 Vicryl sutures (on a CT-1 needle) around one or two tracheal rings below the planned inferior incision line. These are placed at 10 o'clock and 2 o'clock positions. This provides a substantial hold on the trachea should the trachea retract following the incision.
- The superior incision should be made first. If the subglottic stenosis is high, in proximity to the cricoid, the initial incision should be made at the inferior aspect of the cricothyroid membrane. A curved Mayo scissors is used to cut through anterolateral cricoid, angling the cut laterally in a superoinferior direction (**FIG 4A**). Usually, only 120 to 180 degrees of the anterior cricoid require excision; however, up to 240 degrees may be excised (**FIG 4B**).[2] If posterior cricoid remains thickened with concern for airway obstruction following anastomosis, it may be excised or ablated.
- For cervical tracheal stenosis, enter at top portion of the stenosis as estimated by bronchoscopy. Initially, favor the incision toward the stenosis so healthy trachea is not excised.
- If the ETT is interfering with the superior incision, it may be retracted by the anesthesia team and surgery may continue under intermittent apneic conditions. Tying a 2-0 silk suture through the Murphy's eye of the ETT will allow for easy advancement later in the procedure.
- Next, the posterior incision is made through the membranous trachea. This may be inferior to the anterior incision, resulting in a beveled cut.
- The inferior incision is made one ring below the inferior aspect of stenosis, again beveled inferiorly in an anterior–posterior direction to match the superior cut.
- At this point, a sterile anode tube on a second anesthesia circuit is placed into the open aspect of the trachea to ventilate the patient (**FIG 4C**). Close communication with the anesthesia team is paramount during placement and subsequent removal of the anode tube.

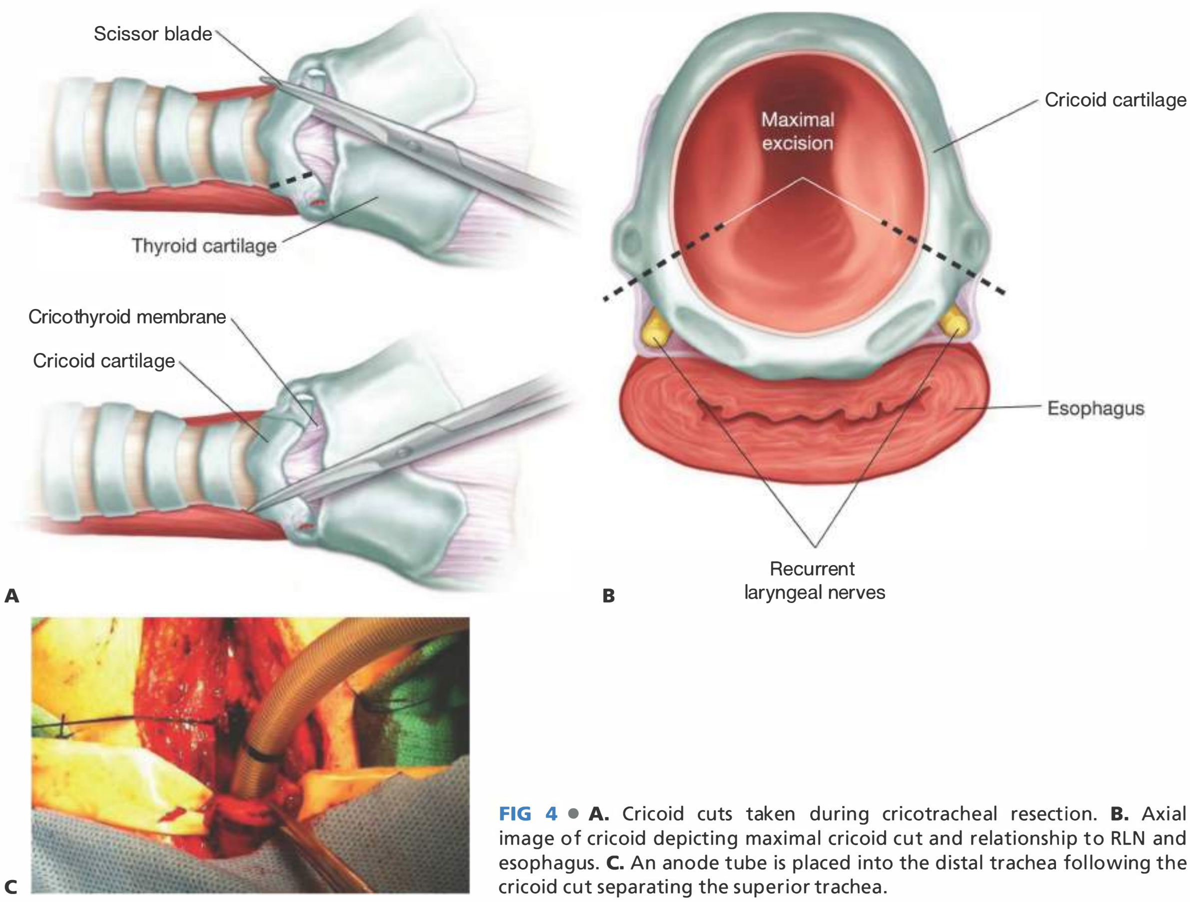

FIG 4 ● **A.** Cricoid cuts taken during cricotracheal resection. **B.** Axial image of cricoid depicting maximal cricoid cut and relationship to RLN and esophagus. **C.** An anode tube is placed into the distal trachea following the cricoid cut separating the superior trachea.

ANASTOMOSIS

- During the anastomosis, the anode tube is intermittently removed to place the sutures and replaced to ventilate.
- The posterior membranous wall should be lined up first with a 2-0 polydioxanone (PDS) suture placed at the corner bilaterally, leaving the suture knot external to the trachea (**FIG 5A,B**). If a central tracheal resection is performed, the suture spans from the corner of the membranous trachea inferiorly to the posterior aspect of the cricoid superiorly. Prior to tying the corner sutures, a running 2-0 PDS is used to close the membranous trachea. After the corner sutures are tied, the running suture is sutured to one side, pulled tight, and sutured to the contralateral corner suture (**FIG 5C**).
- Closure continues in a lateral to anterior direction from each corner using 3-0 Vicryl interrupted sutures with the suture knots kept outside the lumen (**FIG 5D,E**).
- Prior to placing the anterior sutures, the anode is ultimately removed and the ETT is advanced past the anastomosis. The cuff should be advanced beyond the anastomosis to prevent anterior sutures from including the cuff.
- If there is some concern for tension, the shoulder roll may be deflated and the head flexed to reduce tension.
- Superior retention sutures are placed through the thyroid cartilage superiorly at 10 o'clock and 2 o'clock positions and tied to the inferior stay sutures to release tension from the anastomosis (**FIG 5F,G**).[3]
- Finger dissection along anterior trachea is usually adequate for tension release in most cases (<5 cm). If extra length is needed, suprahyoid laryngeal release provides 1 to 2 cm in length with less risk of injury to the internal branch of the superior laryngeal nerve than infrahyoid release.[4] Hilar release is not usually performed for lengthy benign stenosis; instead, the substantially less morbid Tracheal T-Tube reconstruction is recommended.[2]
- After thoroughly irrigating the surgical bed, the anastomosis may be tested by filling the bed with saline, deflating the cuff, and having anesthesia provide positive pressure ventilation. If bubbles are appreciated, the leak should be localized and closed.

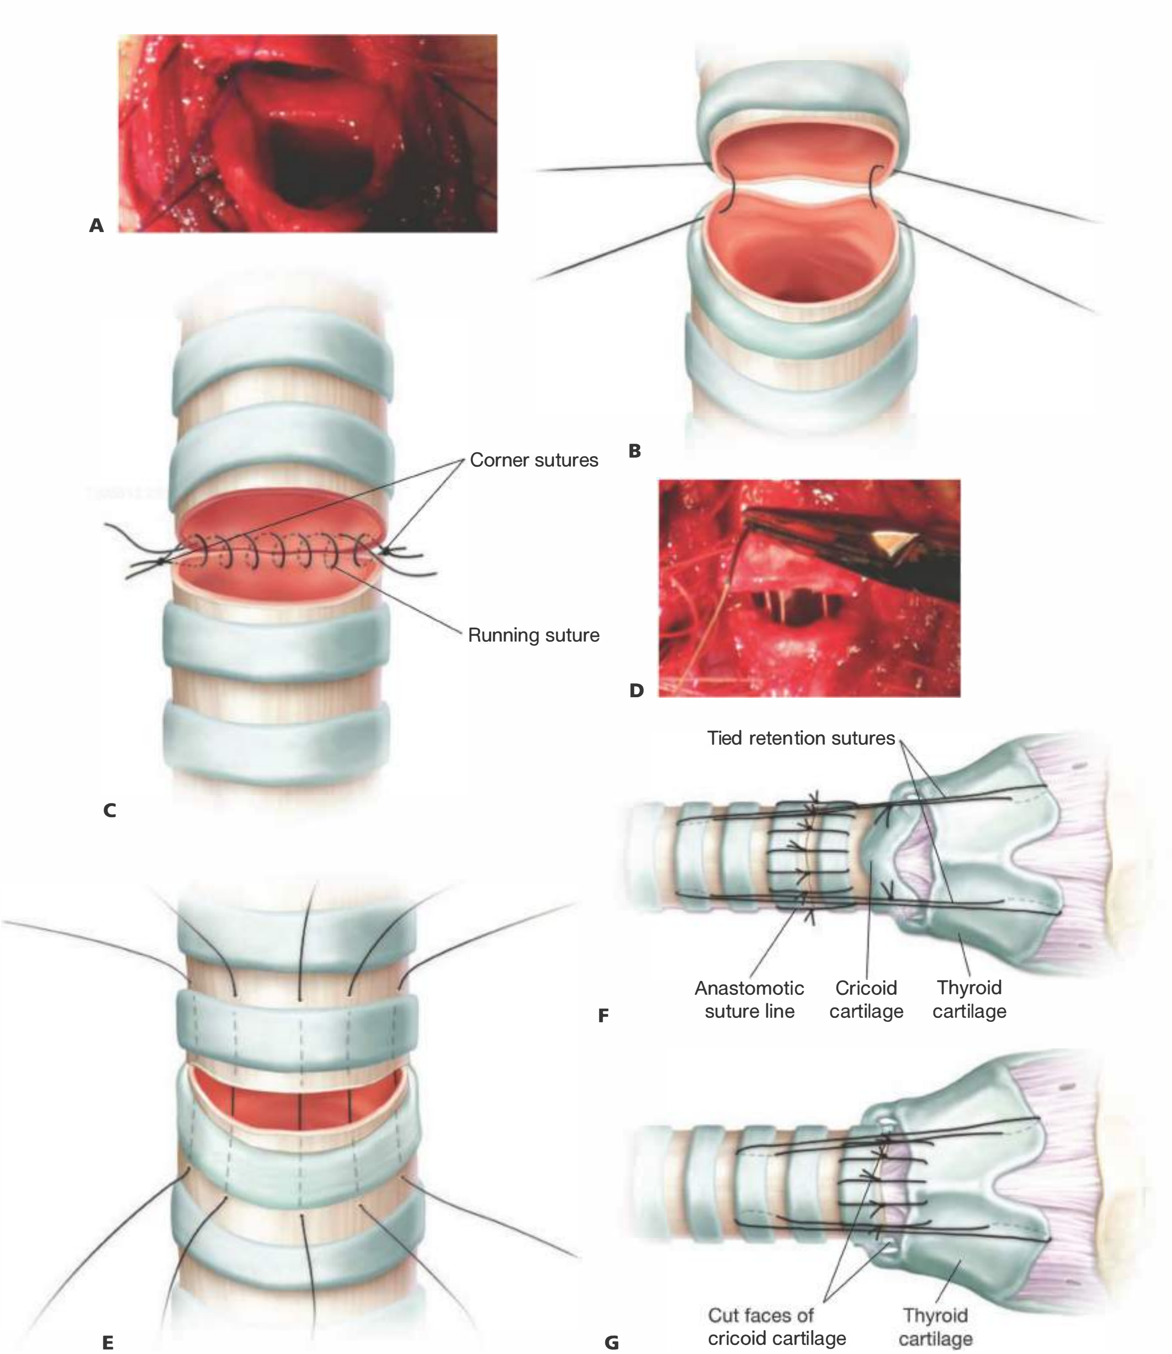

FIG 5 ● **A.** The anastomosis begins with sutures passed at each posterolateral corner of the membranous trachea inferiorly and the posterior cricoid using 2-0 dyed PDS suture. Panel **(B)** is an illustration of this step. **C.** Closure of membranous tracheal wall initially with two posterolateral corner sutures and then a running suture along the membranous wall. After all three are placed, the two corner sutures are tied, and then each end of the running suture is tied to the respective corner suture. All suture knots are kept outside the lumen. **D.** After the lateral trachea is approximated with interrupted Vicryl sutures, the ETT is advanced (ETT no pictured) and the anterior wall is closed. Panel **(E)** is an illustration of this step. **F.** Retention sutures are tied to relieve tension off the anastomotic suture line in a tracheal resection. **G.** The anastomosis in a cricotracheal resection, sutured to the thyroid anteriorly, showing the lateral presence of the cricoid, which is included in the anastomosis laterally (and posteriorly—not pictured).

TECHNIQUES

CLOSURE

- After hemostasis is verified, a Penrose drain may be placed deep to the strap muscles. We favor a Penrose drain because a negative pressure bulb drain may propagate a small tracheal dehiscence. The 3-0 Vicryl sutures are used to close the sternohyoid and sternothyroid muscles and to reapproximate the platysma layer. Finally, the epidermis is closed with a nylon suture.
- Grillo[2] proposed a "guardian" suture (Grillo stitch) passed through the skin of the submentum to the presternal skin as a reminder to the patient to prevent excessive neck extension and limit postoperative tension on the anastomosis. The placement of cartilaginous retention sutures creates a higher force requirement for tracheal anastomotic rupture beyond native tracheal rupture. This provides support for not placing a guardian suture, allowing patients to avoid the associated postoperative discomfort.[3,5]

PEARLS AND PITFALLS

Indications	■ A thorough history should be performed, including past medical, surgical, and family history along with preoperative bronchoscopy and imaging to assess if the patient is an appropriate surgical candidate. ■ Postintubation stenosis represents the primary indication along with tracheal neoplasms and, rarely, tracheoesophageal fistula. ■ Avoid operating on patients with active autoimmune disease.
Incision	■ A low transverse neck incision is usually placed in a neck crease just below the cricoid cartilage. ■ Existing tracheotomy scars should be excised.
Exposure	■ Subplatysmal flaps are elevated from the sternal notch inferiorly and superiorly to the thyroid cartilage for tracheal resection and hyoid cartilage for cricotracheal resection.
Excision	■ The posterior wall of the trachea should be separated from the esophagus with a clamp. ■ Inferior retention sutures prevent tracheal retraction. ■ Including a margin of one tracheal ring, when possible, is ideal to prevent restenosis.
Closure	■ Absorbable sutures reduce the risk of anastomotic restenosis. ■ Tying the superior and inferior retention sutures relaxes tension on the anastomosis. ■ A Penrose drain may be placed and an optional Grillo stitch may be used to remind the patient not to extend their neck.
Postoperative care	■ Extubation following the procedure is highly recommended.

POSTOPERATIVE CARE

- We are proponents of immediate extubation following tracheal resection. Close observation with the patient placed on proton pump inhibitors, antibiotics, and pain control is recommended. If there is no concern for esophageal injury, an initial soft diet may be advanced as tolerated. The patient should be instructed to limit neck extension.

OUTCOMES

- Long-term outcomes from tracheal resection are excellent with 95% of patients, maintaining a patent airway and mortality between 1% and 2%.[1,6] Anastomotic complications occur less than 10% of the time, with significant risk factors including reoperation, diabetes, lengthy resections (>4 cm), and laryngotracheal resection.[1]

COMPLICATIONS

- Anastomotic dehiscence
- Anastomotic granulation tissue and restenosis
- Infection (wound or pulmonary)
- Vocal fold paralysis
- Loss of high-pitched phonation (with sacrifice of cricothyroid muscles)
- Dysphagia (increased with superior release maneuvers)
- Hemorrhage

Chapter 5 Lobectomy: Open

Awad El-Ashry   Robert J. Cerfolio

DEFINITION

- Anatomic resection of one or more of the pulmonary lobes with ligation and resection of their respective bronchus, arterial supply, and venous drainage (**FIG 1**).

Indications

- Appropriately staged and selected patients with non–small cell lung cancer (NSCLC). For the purposes of this chapter, we will focus on oncologic resection of pulmonary lobe together with lymph node (LN) dissection (**FIG 2**).
- Destroyed lobe from chronic infections such as aspergillosis or tuberculosis (TB)

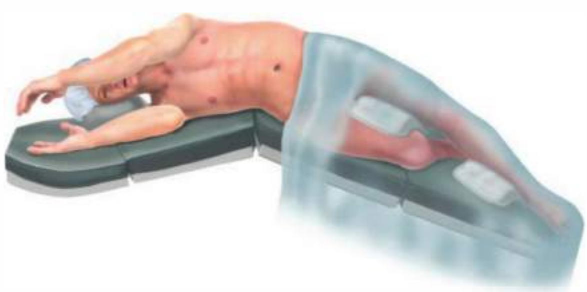

FIG 1 • Provides an overview of the surgical anatomy and related LN stations.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Growing nodules in a smoker
- Chronic cough and/or hemoptysis
- Dyspnea
- Age older than 50 years
- History of smoking
- Family or personal history of cancer
- Lymphadenopathy
- Horner's syndrome

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Chest x-ray: Plain films may show a pulmonary nodule and are also useful to evaluate for chronic lung conditions such as chronic obstructive pulmonary disease (COPD). Historically, the pattern of calcification of the nodule has been used to differentiate between benign and malignant lesions. However, this is not sensitive, as up to 20% of malignant nodules had benign appearance. Serial x-rays may be required to follow the lesion.
- Contrast-enhanced computed tomography (CT) scan: A solitary pulmonary nodule is most likely benign; however, high index of suspicion should prompt further investigation to rule out the possibility of malignancy. Typically, malignant nodules enhance more than 20 Hounsfield units (HU), whereas benign nodules are usually less than 15. CT is useful to identify the location (central vs. peripheral), size, characteristics, single versus multiple, presence or absence of direct

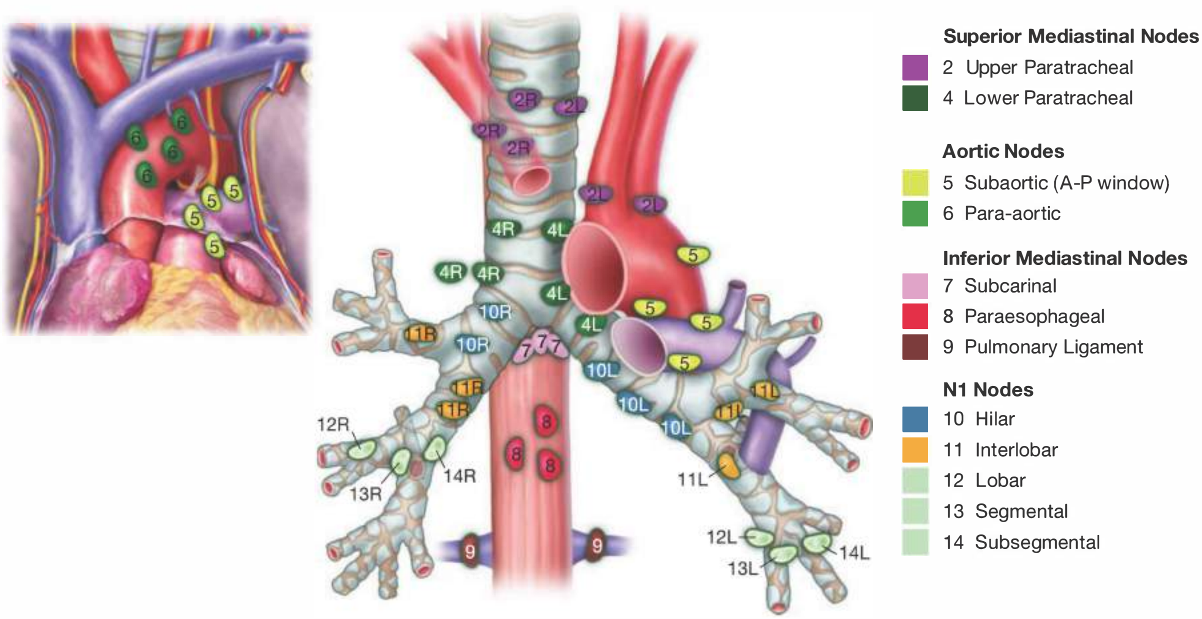

FIG 2 • Lymph node classification for lung cancer staging.

extension to mediastinal structures and/or chest wall, and presence or absence of suspicious LNs and their location.
- Positron emission tomography (PET) scan: The PET scan is less sensitive, however, more specific than CT in identifying malignant lesions. A lesion with standard uptake value (SUV) of 4.6 is associated with 96% likelihood of malignancy. An uptake of 0 to 2.5 is associated with 25% likelihood of malignancy. For staging purposes, PET scan helps identify the presence or absence of PET avid lymphatic and/or systemic metastasis.
- Mediastinoscopy for LN biopsy and staging
- Endobronchial ultrasound (EBUS) for LN status and biopsy of suspicious LNs
- Navigational bronchoscopy
- Pulmonary function test: with focus on forced expiratory volume (FEV_1) and diffusing capacity of the lung for carbon monoxide (DL_{CO}). These measures help predict the postresection pulmonary function.
- Video-assisted thoracoscopic surgery (VATS) biopsy if the diagnosis is still in doubt
- Brain and/or spine CT or magnetic resonance imaging (MRI) should be considered to identify possible metastasis, especially if the patient has neurologic symptoms. It was found that up to 18% of NSCLC has brain metastasis at presentation, with 10% asymptomatic.

SURGICAL MANAGEMENT—PULMONARY LOBECTOMY

Positioning and Preoperative Planning

- Position the patient supine.
- Intubate with a double lumen endotracheal tube.
- Perform complete bronchoscopy and confirm position of the double lumen tube for single-lung ventilation.
- Place a Foley catheter.
- After intubation, place the patient in full lateral decubitus position, the operated side exposed.
- Arms in swimmer's position to display the axilla
- Shoulder higher than hip
- Legs are positioned with the bottom leg bent and pillow in between to stabilize patient's lateral position.
- Break table (kidney bend/flex) and use additional reverse Trendlenburg to position the patient's lateral chest wall almost parallel to the floor and the legs are angled toward the floor.
- Pad pressure points and bony prominences; appropriately secure body position.
- A body warmer to prevent patient hypothermia can be applied.
- Curvilinear posterolateral incision at the 5th intercostal space is made starting midway between the medial edge of scapula and spine ending at the anterior axillary line, passing at a point two fingerbreadths below the scapular tip.
- We spare the rib as well as the serratus anterior muscle during dissection.
- Inject local anesthetic directly into the 5th and 6th intercostals nerve roots.
- Apply rib spreader retractor with gradual retraction.
- First inspect the pleural space and explore to ensure there are no metastatic lesions on the diaphragm or the parietal or visceral pleura.
- The hilum is identified after the lung is retracted posteriorly and inferiorly. The dissection is carried down between the hilar structures and the phrenic nerve.
- Sweep phrenic nerve gently down to remove the station 10R LN, avoiding the small phrenic vein that goes to the large station 10R LN that is routinely found in this area.
- Divide the inferior pulmonary ligament up to the level of the inferior pulmonary vein (IPV). Resect the LNs encountered in this area (stations 8 and 9) and clean the esophagus and vagus nerve of hilar tissue (**FIG 3**).

NOTE: It is important to place the patients flank exactly over the breaking point (flex or kidney break) of the table. We use the break table/flex function to maximize rib separation.

FIG 3 ● The inferior pulmonary ligament exposed by retracting the lung superiorly.

TECHNIQUES

RIGHT UPPER LOBECTOMY

- Develop the bifurcation between middle and upper lobe veins by bluntly dissecting it off of the underlying pulmonary artery (PA) (**FIG 4**).
- Continue en bloc dissection of the hilar tissue to clearly expose the main PA.
- Encircle the superior pulmonary vein with a vessel loop and retract it off the PA behind it. Using the vessel loop as a guide, the linear stapling device is passed across the right superior pulmonary vein and fired (**FIG 5A–C**).

FIG 4 ● Identification of superior PA.

FIG 5 ● Transection of right superior pulmonary vein: **(A)** vessel loop placed, **(B)** vessel loop guiding stapler, and **(C)** vein transected.

- Next, the anterior-apical trunk PA branch is encircled with a vessel loop and transected with a linear stapler in the same fashion as the vein (**FIG 6**).
- The right upper lobe (RUL) bronchus' anatomy is exposed. Its upper aspect is easily seen coming off the trachea. The dissection is continued inferiorly to expose the inferior edge of the RUL bronchus and free it from the bronchus intermedius (**FIG 7**).
- LN dissection (stations 10R and 11R, hilar and interlobar) is continued along the right main bronchus and the bifurcation between the bronchus intermedius with the upper lobe bronchus identified (**FIG 8**).
- Encircle the RUL bronchus with a vessel loop and transect with a linear stapler. Care must be taken to apply only minimal retraction on the specimen to avoid tearing of PA branches (**FIG 9**).
- Next, the posterior segment of the PA is exposed. The surrounding N1 nodes can be removed and the posterior artery can be encircled with a vessel loop and taken with a vascular stapler (**FIG 10**).
- Prior to stapling the fissure, the anterior aspect of the PA is carefully inspected to ensure there are no PA branches remaining. If so, these are usually quite small and can be easily torn and must be carefully ligated.
- The fissure between the RUL and the right middle lobe (RML) is now taken with a stapler (**FIG 11**). This is usually taken from anterior to posterior; however, it can also be taken from the back.
- As division of the fissure is completed, the main PA should be seen and the stapler should be placed just above it after ensuring that all small PA branches to the RUL have been taken. The RML PA branch can be easily seen and should be preserved, and the RUL must be lifted to ensure the bronchus is included in the resected specimen.
- To delineate the minor fissure, the upper lobe is retracted superiorly and the middle and lower lobe are pushed inferiorly (**FIG 12**).
- The minor fissure is divided with a linear stapler (**FIG 13**).
- The remaining LN dissection of stations 2R and 4R should be performed (**FIG 14**).

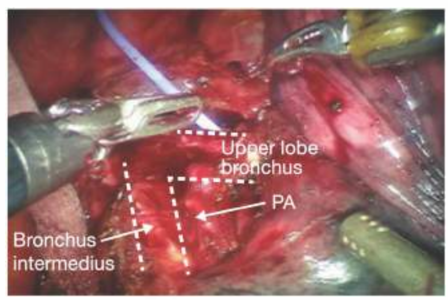

FIG 7 ● Identification of RUL bronchus, bronchus intermedius, and PA.

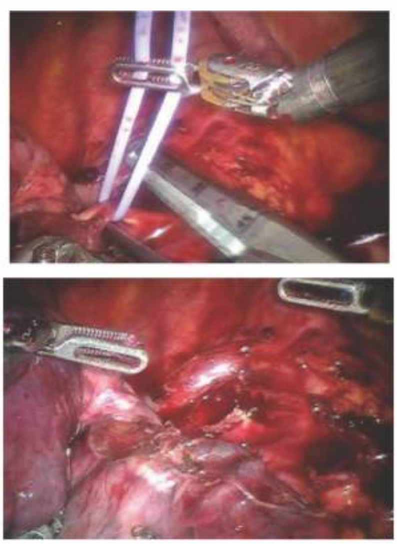

FIG 6 ● **A,B.** Transection of anterior-apical PA branch.

FIG 8 ● Removal of hilar and interlobar LN stations (10R and 11R).

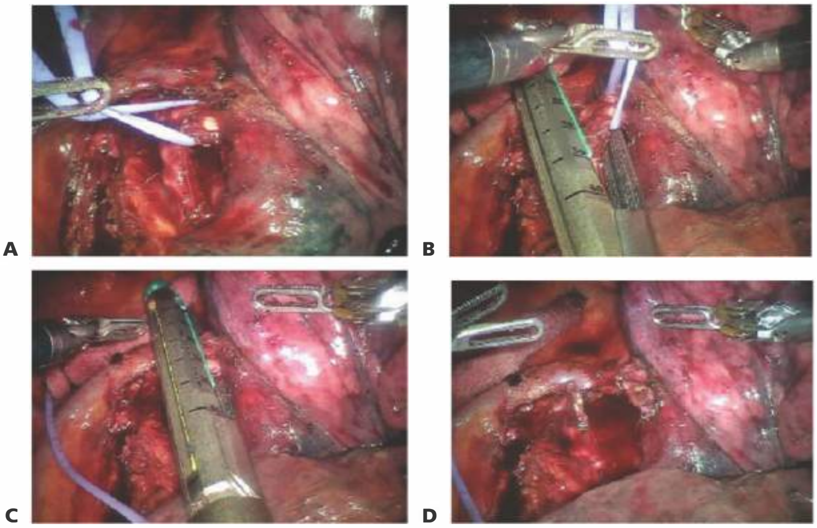

FIG 9 ● Transection of RUL bronchus: **(A)** vessel loop placed, **(B)** vessel loop guiding stapler, **(C)** stapler placed, and **(D)** bronchus transected.

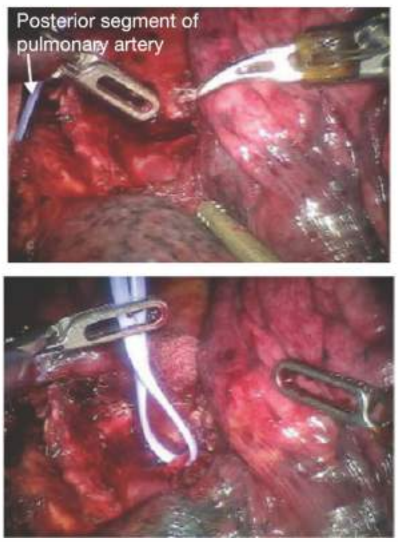

FIG 10 ● Identification of posterior segment of PA.

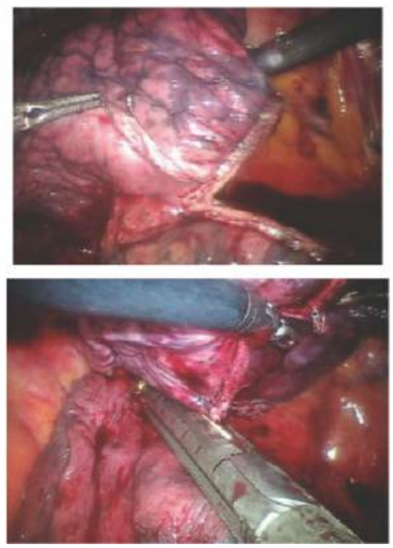

FIG 11 ● Transection of major fissure.

FIG 12 ● Minor fissure exposed for transection.

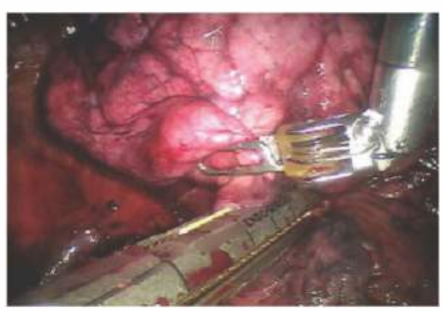

FIG 13 ● Transection of minor fissure.

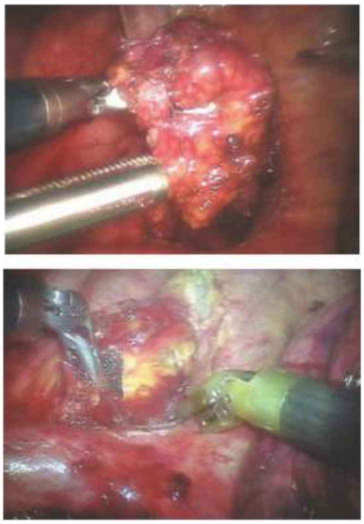

FIG 14 ● Removal of superior mediastinal LN stations (2R and 4R).

RIGHT MIDDLE LOBE RESECTION

- Bluntly dissect and identify the origin of the superior pulmonary vein. Continue the dissection inferiorly to view the RML vein branch. It can be a separate branch that drains into the left atrium, but most commonly, it joins the main trunk of the superior pulmonary vein.
- The RML vein is identified and cleaned circumferentially of hilar tissue. The LNs 10R is removed.
- A vessel loop is placed around the RML vein, and then, using the vessel loop as a guide, a linear vascular stapling device is passed across the vein and fired.
- Next, the anterior fissure between the RML and right lower lobe (RLL) is stapled.
- Care is taken to ensure the PA branches to the RLL are left intact and the RML bronchus is not injured as the dissection continues anterior to it. This will expose multiple LNs (11R and 12R) that surround the RML bronchus.
- Encircle the RML bronchus with a vessel loop and transect with a linear stapler.
- Expose the hilar tissue surrounding the arterial branches to the middle lobe and the origin of the RML bronchus.
- Identify the anterior PA branch to the RLL, and continue dissection along the top of the PA posteriorly until the superior segmental artery to the RLL is recognized.
- Dissect the hilar tissue (LN stations 10, 11, and 12R) from the interlobar portion of the arterial branches and then ligate the one or two RML PA branches. This is accomplished by first removing the LNs off of and between the PA branches and then encircling them with a vessel loop.
- The RML fissure is stapled; take care to avoid the RML vein.
- After the RML is free of all attachments, all of the N2 and N1 LNs should then be removed.
- Often, the LNs of stations 2R and 4R have not been removed yet and should be at this point. For completion of LN dissection in the subcarinal (station 7) and right and anterior mediastinal tissue (station 4R), the same exposure and dissection can be performed as with the upper lobe.

RIGHT LOWER LOBE RESECTION

- Divide the pleura enclosing the RLL anteriorly to the level of the RML vein branch. Continue the dissection in the plane between the superior and inferior pulmonary vein.
- Identify the junction between RUL bronchus and bronchus intermedius and resect the LN that is commonly found in this location.
- Encircle the IPV with a vessel loop and, using the vessel loop as a guide, the linear stapling device is passed across the right IPV and fired.
- Continue dissection on the inferior side of the bronchus intermedius into the carina removing the subcarinal LN station 7.
- Identify the superior segment of the lower lobe and develop the subadventitial plane of the right PA.
- At this point, all major vessel branches should be identified (RML artery, posterior recurring branch to the RUL, and the segmental vessels to the RLL).
- Next, the major fissure is stapled.
- Dissection is continued along the artery to circumferentially free the branches of the right PA supplying the lower lobe.
- Encircle the superior segmental artery with a vessel loop and transect with a linear stapler in the same fashion as the vein. Take care to not interfere with the takeoff of the posterior recurring branch to the RUL, because it can originate from the superior segmental artery.

- The bifurcation of the RML bronchus and bronchus intermedius is identified. A vessel loop can be passed around the bronchus intermedius to assist with exposure.
- Dissect the RLL bronchus circumferentially and confirm complete dissection by placing a vessel loop around it.
- Ensure the RML bronchus is seen and not kinked prior to stapling the RLL bronchus.
- Transect the RLL bronchus with a linear stapler. Care must be taken to apply only minimal retraction on the specimen to avoid tearing of pulmonary structures.
- The division of the remaining fissure is completed with a linear stapler.
- Residual LN stations 7, 8R, 9R, and 4R are dissected for completion of appropriate hilar nodal resection.

LEFT UPPER LOBECTOMY

- Dissection is started at the N2 mediastinal LNs. If the lung deflates well, the nodes 9, 8, and 7 can be completely removed. If the lung does not deflate sufficiently, it is best to start at station 7 and then move cephalad toward the trachea and remove the LN 10L plus 5 and 6.
- Removal of the LNs first exposes the anatomy and affords visual inspection of the N2 nodes.
- The dissection is continued between the hilar structures and in between the aorta and PA and posterior to the phrenic nerve.
- Identify the origin of the superior pulmonary vein and ensure there are two pulmonary veins and develop the space between the superior and the IPV.
- Because the fissure may be complete or incomplete, we recommend finding the PA posteriorly and then dissect along its surface to develop the fissure posteriorly.
- Identify the posterior segmental PA branch and encircle with a vessel loop. Using the vessel loop as a guide, the linear stapling device is used to divide the vessel.
- Next, staple the posterior fissure. Sometimes, the fissure may need to be taken before the posterior segmental PA can be divided.
- Continue the dissection following the PA anteriorly until all the branches are ligated and finally the lingular artery is stapled in the same fashion as the posterior segmental branch.
- Subsequently, the anterior fissure is encircled by placing a vessel loop from the divided lingular artery stump to the space between the two pulmonary veins and then transected with a linear stapler.
- The superior pulmonary vein is dissected off the bronchus and carefully encircled. Ensure the most superior aspect of the vein is dissected off of the main PA so when the stapler is passed around the vein, the artery is clearly seen.
- Using the vessel loop as a guide, the linear stapling device is passed across the vein and fired.
- The only vascular structures remaining are the anterior and apical branches of the PA to the left upper lobe (LUL).
- Therefore, remove the N1 LNs off of the LUL bronchus and encircle it with a vessel loop. Using the vessel loop as a guide, the linear stapling device is passed across the bronchus and fired. Care must be taken to apply only minimal retraction on the specimen to avoid tearing of PA branches.
- Once the LUL bronchus is transected, the final remaining branches of the PA are easily seen and stapled.
- The remaining LN stations are dissected.

LEFT LOWER LOBECTOMY

- Divide the inferior pulmonary ligament up to the level of the IPV. Resect the LNs encountered in this area (LN 9 first and then the periesophageal LN 8). Dissect the hilar tissue off the esophagus and vagus nerve (**FIG 3**), staying close to the pericardium to approach the subcarinal space.
- Continue the dissection toward the carina and remove subcarinal LN station 7 (**FIG 15A,B**).
- Next, the trajectory is changed and the left lower lobe is lifted anteriorly and cephalad to expose the origin of the IPV (**FIG 16**).
- Dissect the IPV off the underlying bronchus and free from hilar tissue (**FIG 17**).
- Encircle the IPV with a vessel loop and using the vessel loop as a guide, the linear stapling device is passed across the vein and fired (**FIG 18A–D**). Sometimes, it is best to take the vein later in the operation once the artery is dissected out and the fissure completed. This may help prevent the lobe from becoming edematous.
- The trajectory is changed back to expose the posterior aspect of the hilum and the arterial structures (**FIG 19**).

B

FIG 15 ● **A.** Exposing mediastinum for **(B)** removal of subcarinal LNs station 7.

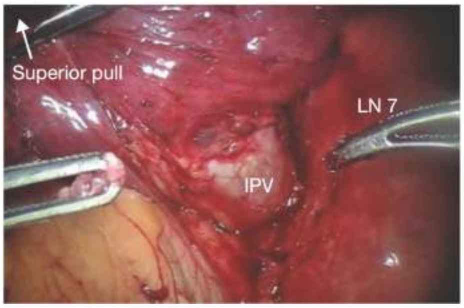

FIG 16 ● Identification of IPV.

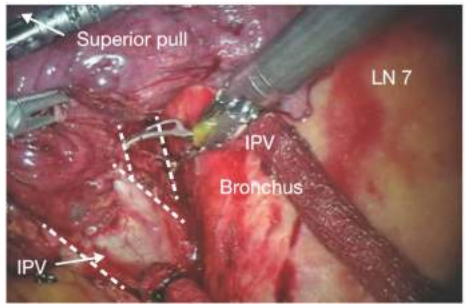

FIG 17 ● Peeling IPV off the bronchus and removal of hilar tissue.

- Identify the left PA posteriorly and then work along it to identify the major branches (superior segmental branch basilar PA (FIG 20).
- The superior segment of the PA is exposed as well as the remaining large basilar PA. The surrounding N1 nodes are removed from the arterial branches allowing them to be clearly exposed (FIG 21). The bronchial bifurcation of the upper and lower lobe can be identified below the PA in this location.
- The superior segmental PA is usually taken next using a vascular stapler (FIG 22).
- After the superior segmental artery is stapled, the remaining large basilar PA is stapled next.
- Now the IPV can be taken or the left lower lobe bronchus can be stapled and the vein divided last.
- The LN dissection (stations 11L and 12L) is continued along the lower lobe bronchus to free it circumferentially (FIG 23A–C).
- Encircle the left lower lobe bronchus with a vessel loop and transect with a linear stapler. Care must be taken to apply only minimal retraction on the specimen to avoid tearing of the lingular branch (FIG 24A–D).
- Next, the fissure between the LUL and the left lower lobe is exposed and taken with a linear stapler (FIG 25).
- The superior mediastinum is exposed and the removal of residual LN stations 5 and 6 is performed (FIG 26A,B).

TECHNIQUES

CLOSURE AND DRAINAGE

- The chest is filled with irrigation fluid and the remaining lung inflated to 20 cm H_2O to make certain there is no leak at the bronchial stump.
- If there is a leak, a 3-0 Prolene stitch on an RB needle is used to oversew the bronchial stump.
- Chest tube is employed per surgeon's standard routine.
- Rib approximation is achieved by drilling holes through the rib and passing the suture material through the holes.
- The muscle facial edges are approximated using absorbable running suture.
- Skin closed with subcuticular absorbable suture.
- The bronchial margin is sent for frozen section, and the tumor is sent for genetic testing and tumor markers.

PEARLS AND PITFALLS

Right upper lobectomy	■ Injuring the right main PA while getting circumferential control of the right superior pulmonary vein ■ Failure to identify the posterior ascending branch to the posterior segment of the RUL
Right middle lobectomy	■ Failure to identify the RLL bronchus while obtaining control of the RML bronchus ■ Injury of the posterior segmental vein while completing the fissure between the RUL and the RML
Right lower lobectomy	■ Injuring or kinking the RML bronchus while stapling the RLL bronchus
Left upper lobectomy	■ Injury to the anterior apical trunk of the LUL, with resultant massive bleeding ■ Failure to recognize the lingular artery
Left lower lobectomy	■ Failure to identify the superior segmental artery to the left lower lobe

POSTOPERATIVE CARE

- Postoperative pain management
  - Dispense pain medication per usual postoperative regimen.
  - The patient is placed on aspiration precautions (no oral intake until fully awake and able to sit upright).
  - *Inpatient hospital follow-up and discharge should be based on surgeon's experience and preference.*
  - Almost all patients should be extubated in the operating room.
  - Extubated patients are transferred to the recovery room and to the appropriate hospital inpatient setting (bed with monitoring until discharge).
  - No postoperative antibiotics are used.
  - Patients should be monitored with oximetry around-the-clock.
  - Chest drain removal once output is less than 450 mL per day
  - The patient is discharged from the hospital, if stable, most commonly on postoperative day 3 or 4.
- Outpatient follow-up
  - Follow-up visit 2 weeks postoperatively
  - In cases of malignancy following pathology review, counsel the patient concerning the need for additional therapy or adjuvant chemotherapy as indicated. Adjuvant therapy, even radiotherapy, which is rarely indicated, as soon as 3 to 6 weeks postoperative, depending on patient's performance status.

Chapter 6

Lobectomy: Thoracoscopic

Tyler Grenda Jules Lin

DEFINITION

- Video-assisted thoracic surgery (VATS) lobectomy is defined as an anatomic lobectomy in which bronchial and vascular ligation is performed with lymph node sampling or dissection through several small incisions while avoiding spreading of the ribs. VATS is an appealing alternative to thoracotomy but must follow the same principles with vascular ligation, resection with negative margins, and appropriate lymph node dissection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history and physical must be performed prior to any treatment including past medical and surgical history, allergies, medications, social, and family history.
- The patient's previous history of tobacco use as well as any chemical or asbestos exposures should be determined. Cessation of tobacco use preoperatively should be strongly encouraged for 4 weeks prior to any surgical intervention.
- The history should include the patient's current functional status and exercise tolerance.
- A complete physical examination should be performed with particular attention to auscultation of the heart and lungs and any evidence of cervical or supraclavicular lymphadenopathy or peripheral edema.
- Routine laboratory studies including a complete blood count and basic chemistry panel should be included as part of the preoperative evaluation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients typically present with abnormal chest radiograph (**FIG 1A**) or chest computed tomography (CT) findings. If available, the findings should be compared to previous imaging to determine any interval changes. Lesions that are stable for more than 2 years are generally considered benign. Indeterminate lesions less than 1 cm in size can be followed on serial imaging according to the recommendations of the Fleischner Society.[1]
- A chest CT (**FIG 1B**) should be obtained in all patients with a suspicious lung nodule to evaluate the size and characteristics of the nodule; proximity to the chest wall, vessels, airway, and mediastinum; additional pulmonary lesions; and hilar or mediastinal lymphadenopathy. The CT should include the upper abdomen to evaluate the liver and adrenal glands for metastatic disease.
- A positron emission tomography (PET) scan (**FIG 1C**) provides additional information regarding the metabolic activity of the pulmonary nodule and areas of uptake that are suspicious for regional nodal or distant metastatic disease

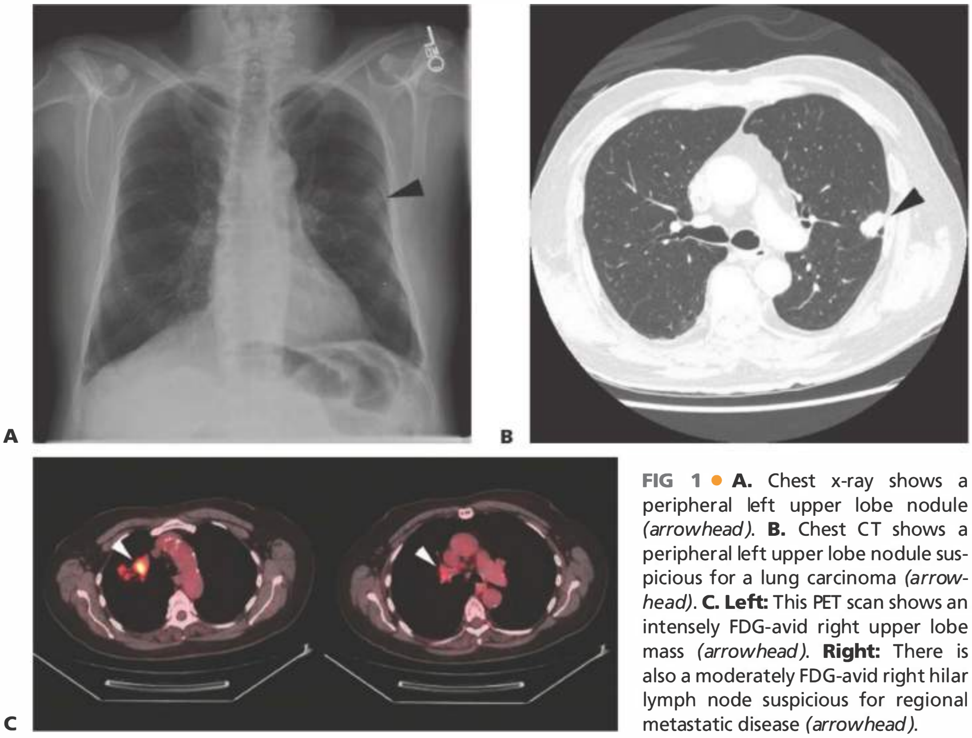

FIG 1 • **A.** Chest x-ray shows a peripheral left upper lobe nodule *(arrowhead)*. **B.** Chest CT shows a peripheral left upper lobe nodule suspicious for a lung carcinoma *(arrowhead)*. **C. Left:** This PET scan shows an intensely FDG-avid right upper lobe mass *(arrowhead)*. **Right:** There is also a moderately FDG-avid right hilar lymph node suspicious for regional metastatic disease *(arrowhead)*.

and should be obtained in all patients suspected of having a non–small cell lung carcinoma.[2] In patients with abnormal findings on fluorodeoxyglucose (FDG)-PET imaging, sampling of the abnormal lymph node should be performed prior to lung resection either by endobronchial ultrasound (EBUS) or mediastinoscopy.

- For patients with non–small cell lung carcinoma who are surgical candidates, anatomic lobectomy and mediastinal lymph node dissection for complete oncologic resection and staging is recommended.[3]
- Due to the low morbidity and mortality after wedge resection, our preference for nodules that are highly suspicious for lung carcinoma based on PET or serial imaging is to perform a VATS wedge resection for a tissue diagnosis. Needle biopsies are performed less often and are reserved for cases where the diagnosis is less clear or for central lesions that would require a lobectomy for diagnosis alone.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative risk assessment determines whether a patient will tolerate pulmonary resection based on pulmonary reserve (pulmonary function tests [PFTs]) and other comorbidities.[4] Patients with significant cardiovascular risk factors or symptoms should undergo preoperative cardiac evaluation.
- Patients with a preoperative forced expiratory volume in 1 second (FEV_1) of more than 60% predicted and diffusing capacity of lung for carbon monoxide (DLCO) of more than 50% predicted are candidates for lobectomy. Patients not meeting these criteria should undergo further evaluation with a quantitative ventilation perfusion scan to determine their postoperative predicted pulmonary function with a minimum postoperative value of 40% predicted.
- Cardiopulmonary exercise testing is occasionally helpful in patients whose symptoms do not correlate with the severity of their pulmonary function results.
- For patients who will not tolerate an anatomic lobectomy, alternatives include a sublobar resection such as a segmentectomy or wedge resection, stereotactic body radiation therapy (SBRT), radiofrequency ablation (RFA), or definitive chemoradiation. These patients are best discussed in a multidisciplinary setting.
- Relative contraindications for VATS lobectomy are listed in Table 1.
- In the preoperative area, the history and physical should be reviewed and consent should be obtained. The operative side should be appropriately marked.

Table 1: Relative Contraindications to Thoracoscopic Lobectomy

Complete resection unable to be achieved with a lobectomy (Need for sleeve resection or pneumonectomy)
A central lesion making it difficult to staple the bronchus or pulmonary arterial branches
Chest wall or mediastinal invasion (T3 or T4)
Nodal disease adherent to the vessels
Neoadjuvant chemoradiation
Positive N3 disease
Patient unable to tolerate single-lung ventilation

- Once in the operating room, a flexible bronchoscopy should be performed to verify airway anatomy and rule out any endobronchial lesions.
- Single-lung ventilation is achieved with a left-sided double lumen endotracheal tube, which is generally preferable to a bronchial blocker.

Positioning

- The patient should be placed in the lateral decubitus position, tilted slightly posteriorly. The bed is flexed taking care to drop the hips out of the way of the camera port (**FIG 2**). The arms should be positioned in an arm holder in neutral position. The patient should then be secured and all pressure points padded.
- Following positioning, the endotracheal tube position should be confirmed again by the anesthesiologist.

FIG 2 ● The patient is placed in the lateral decubitus position. It is important to drop the hip out of the way of the camera, which is placed in the most inferior port.

TECHNIQUES

PLACEMENT OF INCISIONS

- Port placement is important to obtain the ideal angles for stapler placement and lung retraction. Our general port placement for a VATS lobectomy is shown (**FIG 3**).
- Port 1 is placed just below the inframammary crease in the 6th intercostal space in the anterior axillary line. A 5-mm, 30-degree angled scope is preferable to decrease compression of the intercostal nerve. The remaining ports can be placed under direct visualization.
- Port 2 is placed posteriorly in the auscultatory triangle in the 6th intercostal space. Placing this incision one interspace lower is helpful for an upper lobectomy in passing the stapler when dividing the superior pulmonary vein.
- Port 3 is placed in the 8th or 9th intercostal space in the posterior axillary line, taking care to avoid injuring the diaphragm.
- An access incision (<10 cm) is placed in the 4th intercostal space in the midaxillary line (directly above the superior

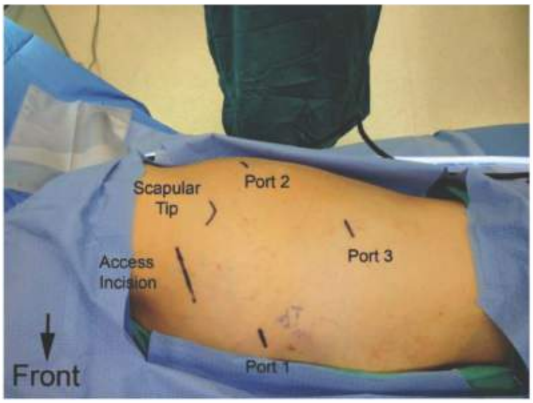

FIG 3 ● Standard port placement for a VATS lobectomy. Port 1 is placed just below the inframammary crease in the 6th intercostal space in the anterior axillary line. Port 2 is placed posteriorly in the auscultatory triangle in the 6th intercostal space. Port 3 is placed in the 8th or 9th intercostal space in the posterior axillary line. An access incision (<10 cm) is placed in the 4th intercostal space in the midaxillary line. The surgeon operates through port 1 and the access incision while the assistant retracts the lung using Foerster clamps in port 2. The camera is placed in the most inferior port 3. (The *arrow* indicates the front of the patient.)

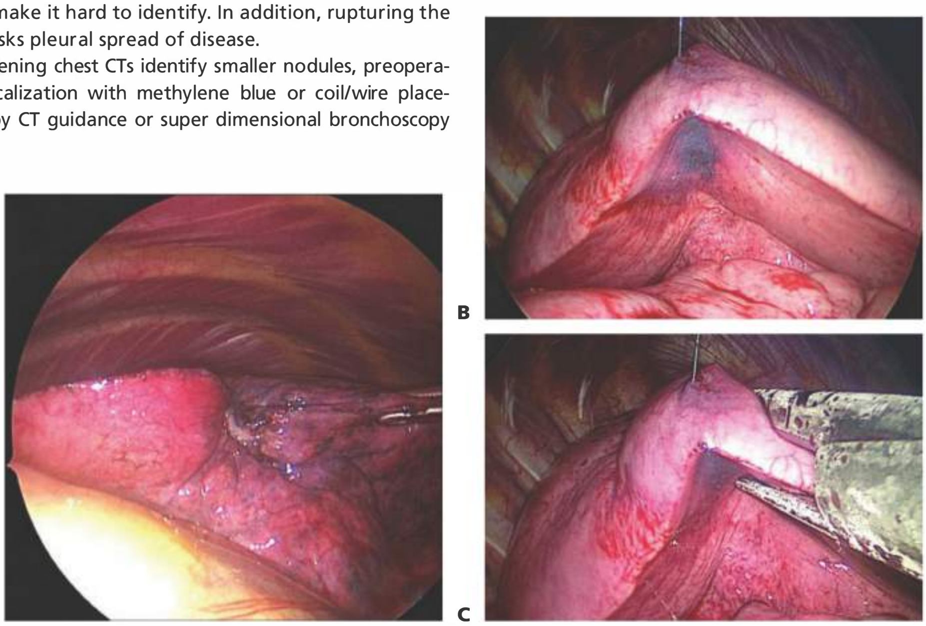
pulmonary vein for an upper lobectomy or one space lower for a middle or lower lobectomy) for dissection and retrieval of the specimen. A Weitlaner retractor is used to hold the incision open to prevent suction from reexpanding the lung. In the event of bleeding, a sponge stick can be quickly inserted through the access incision to hold pressure.

- The surgeon operates through port 1 and the access incision while the assistant positions the lung using Foerster clamps in port 2. The camera is placed in the most inferior port 3.
- Thoracoscopic exploration should be performed looking for any effusion, pleural lesions, or unexpected nodules in the remainder of the lung.
- If the lung is not adequately collapsed, suction should be applied to the appropriate lumen of the endotracheal tube.

LOCALIZATION OF THE LUNG NODULE

- The nodule is localized by correlating the chest CT with the visualized anatomy. The nodule is then palpated with either the surgeon's finger or an instrument (**FIG 4A**). Care should be taken not to crush the nodule, which could make it hard to identify. In addition, rupturing the mass risks pleural spread of disease.
- As screening chest CTs identify smaller nodules, preoperative localization with methylene blue or coil/wire placement by CT guidance or super dimensional bronchoscopy may be helpful in identifying ground glass nodules (<1 cm), small nodules (<5 mm), or nodules deep to the pleural surface intraoperatively (**FIG 4B**).
- A Foerster clamp can be used to compress the lung below the nodule to help with passage of the stapler if needed.



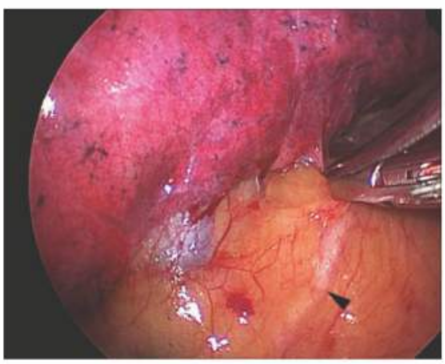
A B C

FIG 4 ● **A.** The nodule is located by visualization as well as palpation with a finger or instrument. **B.** Small or ground glass nodules can be localized preoperatively with dye injection and wire/coil placement. **C.** A wedge resection is performed and sent for frozen section for a tissue diagnosis.

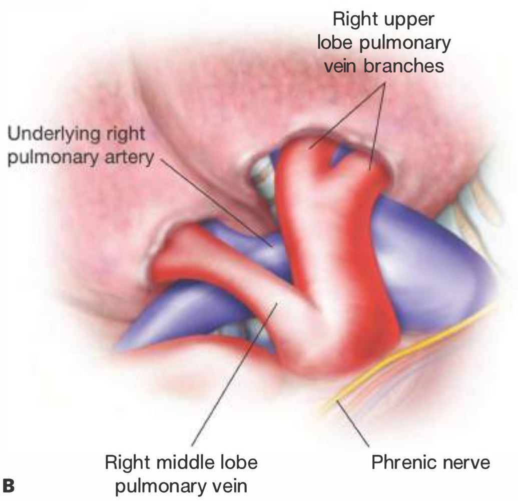
- A stapler (Ethicon, Inc, San Antonio, TX or Covidien, Inc, Mansfield, MA; purple load Endo GIA 3.0- to 4.0-mm stapler height) is used to perform the wedge resection (**FIG 4C**).
- The specimen is placed in a bag to prevent port site recurrence.
- If the specimen is benign, cultures are sent and the procedure is terminated.
- If cancer is confirmed, the access incision is made in the 4th intercostal space and a thoracoscopic lobectomy is performed.

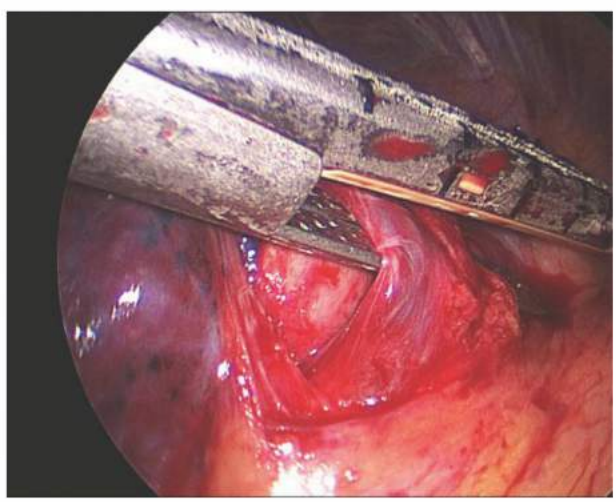
RIGHT UPPER LOBECTOMY

- The major and minor fissures should be inspected, and the location of the tumor in the right upper lobe should be confirmed. The lung is retracted posteriorly to expose the hilum.
- The dissection is performed from anterior to posterior as opposed to the traditional fissure dissection used in an open lobectomy.
- The anterior mediastinal pleura is opened sharply to avoid injuring the phrenic nerve using thoracoscopic Metzenbaum scissors and pickups (**FIG 5A**).
- The superior pulmonary vein is dissected bluntly with a long coronary tip suction. The division between the upper lobe and middle lobe venous branches must be identified (**FIG 5B**). The minor fissure can be followed anteriorly to ensure that the middle lobe vein is preserved. Attention must also be taken to avoid injury to the underlying right pulmonary artery.
- The upper lobe venous branches are isolated and divided using a vascular beige load stapler (2.0- to 3.0-mm stapler height) through the posterior incision (**FIG 5B**). If needed, the vessels can be encircled with a silk tie for traction or a curved-tip stapler can be used to assist in passage of the stapler.
- Following division of the pulmonary vein, the pulmonary artery is then exposed. The truncus anterior branch of the pulmonary artery is then carefully isolated and divided using a beige load stapler through the posterior incision (**FIG 5C**).
- Once the truncus anterior has been divided, the right upper lobe bronchus is exposed. The lung is then retracted anteriorly, and the pleura is opened posteriorly. The branch point between the upper lobe bronchus and the bronchus intermedius is identified (**FIG 5D**). Stations 10R and 11R lymph nodes are often taken at this time, which helps with the dissection.



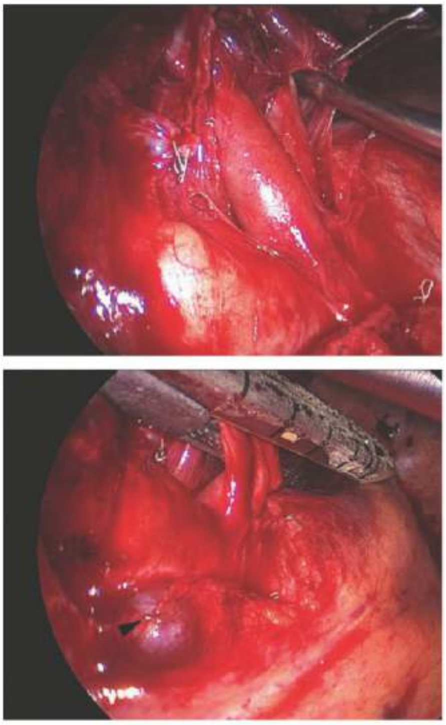
A



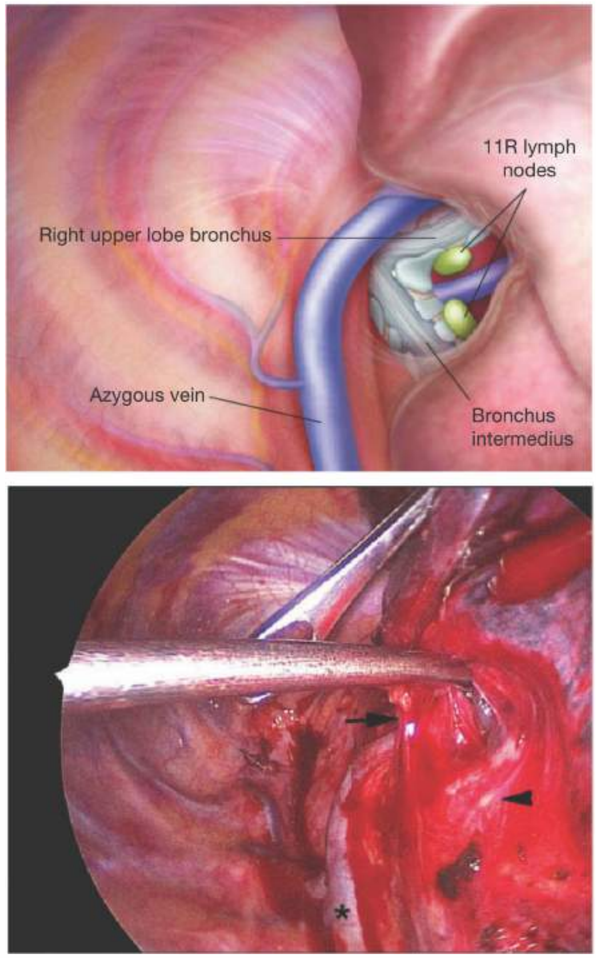


B

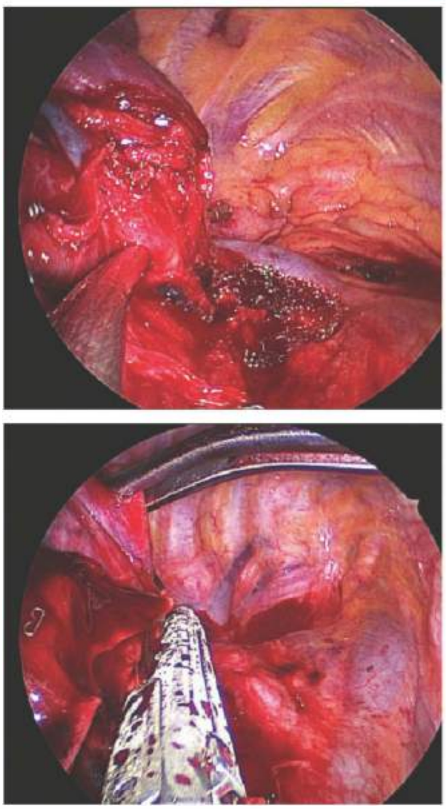
FIG 5 ● **A.** The anterior mediastinal pleura is opened sharply, taking care to preserve the phrenic nerve *(arrowhead)*. **B. Left:** The right upper lobe branches of the superior pulmonary vein are dissected free. Care is taken to identify and preserve the right middle lobe vein. Attention must also be taken to avoid injury to the underlying right pulmonary artery. **Right:** The upper lobe pulmonary vein branches are divided with a beige load stapler passed from the posterior port. *(continued)*



C

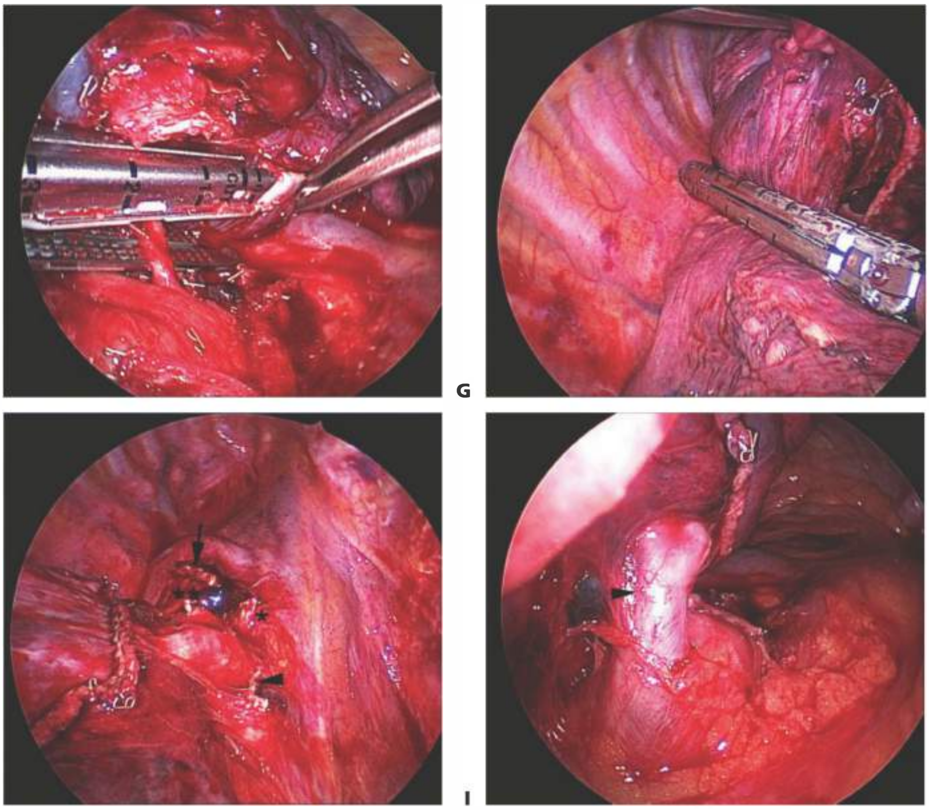


D



E

FIG 5 ● *(continued)* **C.** The truncus anterior branches **(top)** of the pulmonary artery are dissected free and divided with a beige load stapler **(bottom)**. The pulmonary vein stump is in the foreground *(arrowhead)*. **D.** With the lung retracted anteriorly, the posterior pleura is opened and the bifurcation between the upper lobe bronchus *(arrow)* and the bronchus intermedius *(arrowhead)* is dissected free. An 11R lymph node is usually removed, and care is taken not to injure the posterior ascending pulmonary arterial branch, which is often just behind this lymph node (azygous vein, *asterisk*). **E. Top:** The right upper lobe bronchus is dissected free anteriorly, and any 11R lymph nodes are sent for pathology. **Bottom:** The right upper lobe bronchus is clamped with a purple load stapler passed from the anterior port. The right middle and lower lobes are briefly inflated to confirm that the bronchus intermedius is patent before firing the stapler. *(continued)*



F G H I

FIG 5 ● *(continued)* **F.** The posterior ascending pulmonary artery branch is divided with a beige load stapler passed from the posterior port. **G.** The fissure is completed with a purple load stapler. Care is taken to preserve the middle lobe pulmonary vein and the underlying pulmonary artery. **H.** The right upper lobe pulmonary vein *(arrowhead)*, bronchial *(arrow)*, and truncus anterior *(asterisk)* and posterior ascending *(double asterisk)* pulmonary arterial stumps are checked for hemostasis. **I.** It is important to examine the middle lobe vein *(arrowhead)* to confirm that there is no middle lobe torsion.

- The lung is then retracted posteriorly. The upper lobe bronchus is isolated and clamped flush with the bronchus intermedius. The lung is gently reinflated with a hand breath to ensure that the bronchus intermedius is patent before dividing the upper lobe bronchus using a purple load (size of staple) stapler through the anterior incision (**FIG 5E**).
- The posterior ascending arterial branch to the right upper lobe (**FIG 5F**) is then dissected free and divided using a beige load stapler through the posterior incision.
- A purple load stapler through the anterior incision is then used to divide the minor fissure to complete the resection of the right upper lobe (**FIG 5G**). Care should be taken to preserve the middle lobe vein and underlying pulmonary artery.
- Once the dissection has been completed, the specimen should be removed using a protective retrieval bag (Cook Urological, Bloomington, IN; LapSac).
- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is evidence of an air leak, endoscopic or open suturing of the bronchial stump using interrupted 4-0 Vicryl may be required. The vascular stumps are checked for hemostasis (**FIG 5H**).
- Prior to closure, chest tubes are placed anteriorly and posteriorly through the anterior and inferior incisions. The lung is reinflated under direct vision to ensure that there is no torsion of the middle lobe (**FIG 5I**).
- The remaining port sites are closed in layers using a running 2-0 Vicryl for the muscle and subcutaneous layers and 4-0 Monocryl to reapproximate the skin.

RIGHT MIDDLE LOBECTOMY

- The minor and major fissures should be inspected and the tumor location in the right middle lobe confirmed.
- The right middle lobe is retracted posteriorly. The anterior mediastinal pleura is opened sharply to avoid injuring the phrenic nerve using thoracoscopic Metzenbaum scissors and pickups.
- The superior pulmonary vein branches to the middle and upper lobes are identified. The minor fissure can be followed anteriorly to ensure that the upper lobe veins are preserved. The middle lobe vein (**FIG 6A**) is dissected free and divided using a beige load stapler through the posterior incision.
- The right middle lobe bronchus is exposed (**FIG 6B**), and any 10R or 11R lymph nodes are obtained. The middle lobe bronchus is then clamped flush with the origin of the lower lobe bronchus. The lung is gently reinflated with a hand breath to ensure that the right lower lobe inflates before dividing the middle lobe bronchus using a purple load stapler through the posterior incision.
- The right middle lobe artery (**FIG 6C**) is then divided using a beige load stapler through the posterior incision. A second middle lobe arterial branch may be present and is divided in a similar fashion.
- The major fissure between the middle and lower lobes and the minor fissure separating the middle and upper lobes (**FIG 6D**) are then divided using a purple load stapler passed through the anterior incision. Care is taken to preserve the upper lobe veins.
- The specimen is then removed using a retrieval bag.

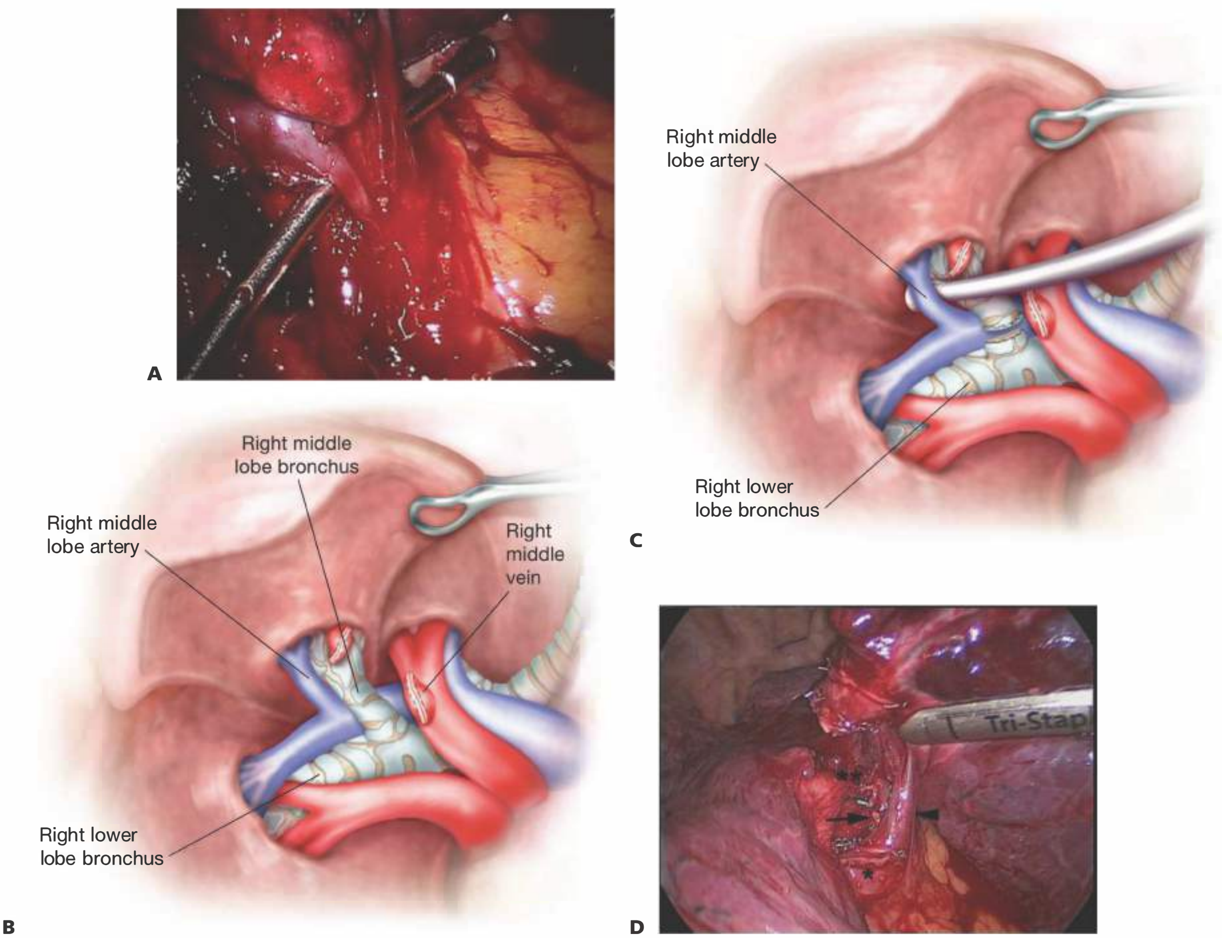


FIG 6 ● **A.** The right middle lobe vein is dissected free. Care is taken to identify and preserve the right upper lobe vein branches before dividing the middle lobe vein with a beige load stapler passed from the posterior port. **B.** The right middle lobe bronchus is dissected free. Before dividing the bronchus, a purple load stapler is passed from the posterior port and clamped. The right lower lobe is briefly inflated to confirm that the lower lobe bronchus is patent. **C.** The right middle lobe arterial branches are dissected free and divided with a beige load stapler passed from the posterior port. **D.** The minor fissure is completed with a purple load stapler. Care is taken to preserve the upper lobe veins *(arrowhead)*. The middle lobe vein *(asterisk)*, bronchial *(arrow)*, and middle lobe pulmonary arterial *(double asterisk)* stumps are checked for hemostasis.

- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is evidence of an air leak, endoscopic or open suturing of the bronchial stump may be required with interrupted 4-0 Vicryl sutures.
- Prior to closure, chest tubes are placed anteriorly and posteriorly. The lung is reinflated under direct vision to confirm that there is no lobar torsion.

RIGHT LOWER LOBECTOMY

- The location of the tumor in the right lower lobe is confirmed.
- The inferior pulmonary ligament is taken down while retracting the lower lobe superiorly, exposing the inferior pulmonary vein (**FIG 7A**). Level 9R lymph nodes are obtained.
- The anterior and posterior mediastinal pleural reflections are then divided sharply to avoid injuring the phrenic nerve using thoracoscopic Metzenbaum scissors and pickups.
- The inferior pulmonary vein is dissected free. With the lung retracted anteriorly, level 7 lymph nodes may be obtained at this time. The lung is then retracted posteriorly, and the vein is divided using a beige load stapler from the anterior incision (**FIG 7B**). Care is taken to identify and preserve the middle lobe vein.

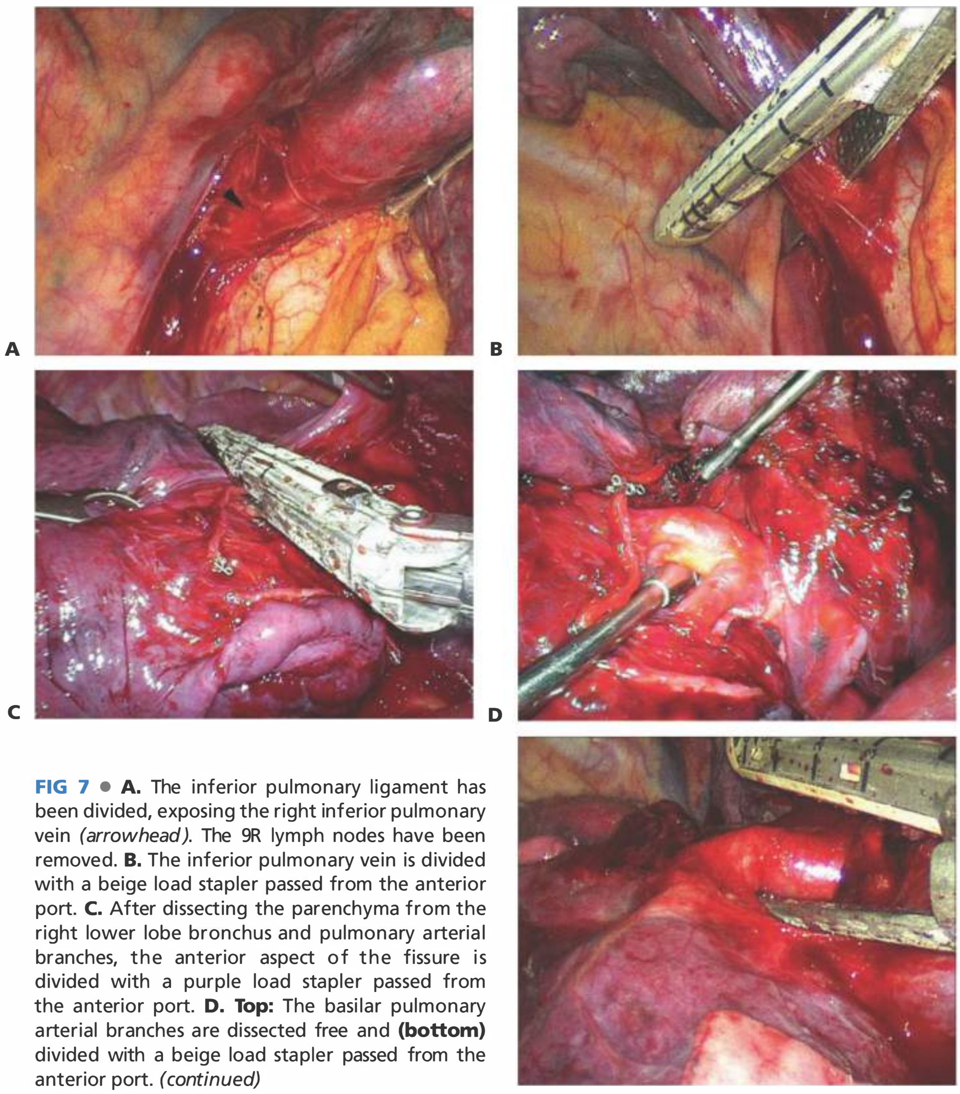

FIG 7 ● **A.** The inferior pulmonary ligament has been divided, exposing the right inferior pulmonary vein *(arrowhead)*. The 9R lymph nodes have been removed. **B.** The inferior pulmonary vein is divided with a beige load stapler passed from the anterior port. **C.** After dissecting the parenchyma from the right lower lobe bronchus and pulmonary arterial branches, the anterior aspect of the fissure is divided with a purple load stapler passed from the anterior port. **D. Top:** The basilar pulmonary arterial branches are dissected free and **(bottom)** divided with a beige load stapler passed from the anterior port. *(continued)*

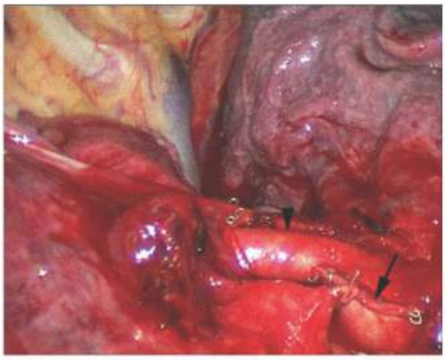
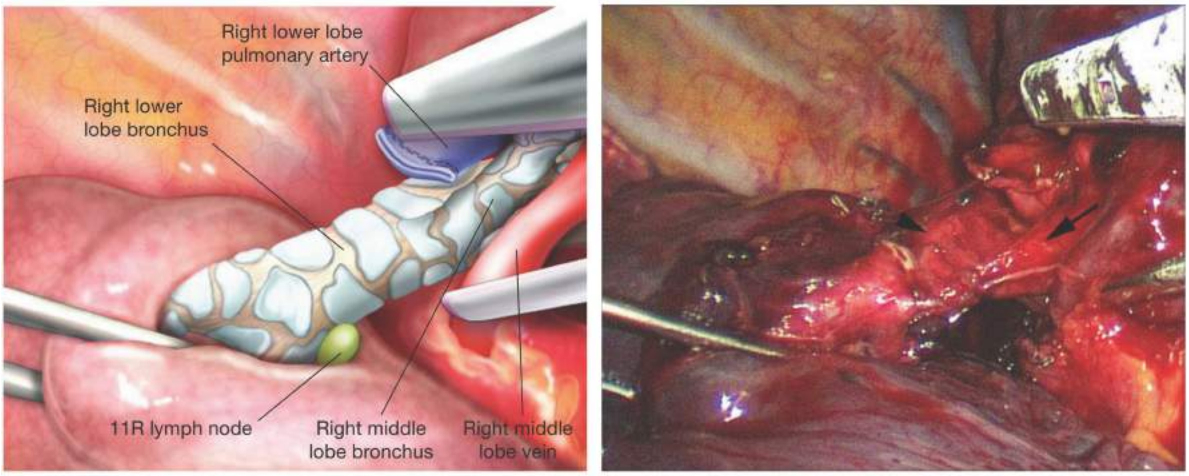
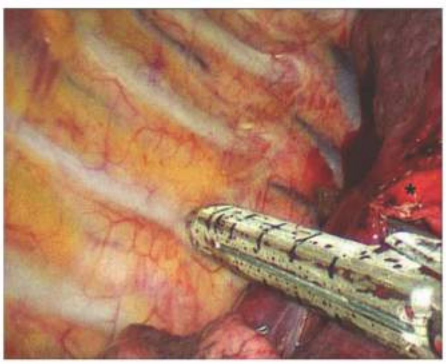


E

FIG 7 ● *(continued)* **E.** The superior segment pulmonary artery *(arrowhead)* is dissected free and divided with a beige load stapler passed from the anterior port (basilar pulmonary artery stump, *arrow*). **F.** The right lower lobe bronchus *(arrowhead)* is dissected free at the branch point with the right middle lobe bronchus *(arrow)*. The 11R lymph nodes are removed and sent to pathology. Before dividing the bronchus, a purple load stapler passed from the anterior port is clamped, and the right middle lobe is briefly inflated to confirm that the middle lobe bronchus is patent. **G.** The posterior fissure is completed with a purple load stapler passed from the anterior port (superior segment pulmonary artery stump, *asterisk*). **H.** The pulmonary arterial *(asterisk)*, right lower lobe bronchial *(arrow)*, and inferior pulmonary vein stumps *(arrowhead)* are checked for hemostasis. The right middle lobe vein *(double asterisk)* is examined to ensure that there is no lobar torsion.



F



G

H

- Working outward from the hilum, the parenchyma in the major fissure is dissected off the lower lobe bronchus and the lower lobe pulmonary artery branches.
- The fissure is then divided keeping the purple load stapler above the bronchovascular structures, passing the stapler from the anterior port (**FIG 7C**).
- The basilar pulmonary arterial branches (**FIG 7D**) are then dissected free and divided either together or individually with a beige load stapler passed from the anterior incision. After dividing additional fissure in a similar fashion, the superior segment pulmonary arterial branch is dissected free and divided with a beige load stapler passed from the anterior incision (**FIG 7E**).
- The lower lobe bronchus is then isolated and clamped flush with the origin of the middle lobe bronchus. The lung is gently reinflated with a hand breath to ensure that the middle lobe bronchus is patent before dividing the lower lobe bronchus using the purple load stapler through the anterior incision (**FIG 7F**).
- The posterior aspect of the major fissure is completed with a purple load stapler passed from the anterior incision (**FIG 7G**). The specimen is then removed using a retrieval bag.

- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is evidence of an air leak, endoscopic or open suturing of the bronchial stump may be required using interrupted 4-0 Vicryl sutures. The vascular stumps are checked for hemostasis (**FIG 7H**).
- Prior to closure, chest tubes are placed anteriorly and posteriorly.

ALTERNATIVE APPROACH—FISSURE DISSECTION

- If there is a complete fissure, a fissure dissection can be performed, similar to the approach taken during an open lobectomy through a posterolateral thoracotomy. The advantage of this approach is that the arterial branches are divided before the veins, decreasing pulmonary congestion.
- The fissure is opened sharply using thoracoscopic Metzenbaum scissors and pickups. It is important to dissect down to the correct plane on the wall of the pulmonary artery (**FIG 8A**).
- The basilar and superior segment pulmonary arterial branches in the fissure are then dissected free and divided using a beige load stapler through the anterior incision (**FIG 8B**).
- The inferior pulmonary vein and lower lobe bronchus are divided as described earlier.

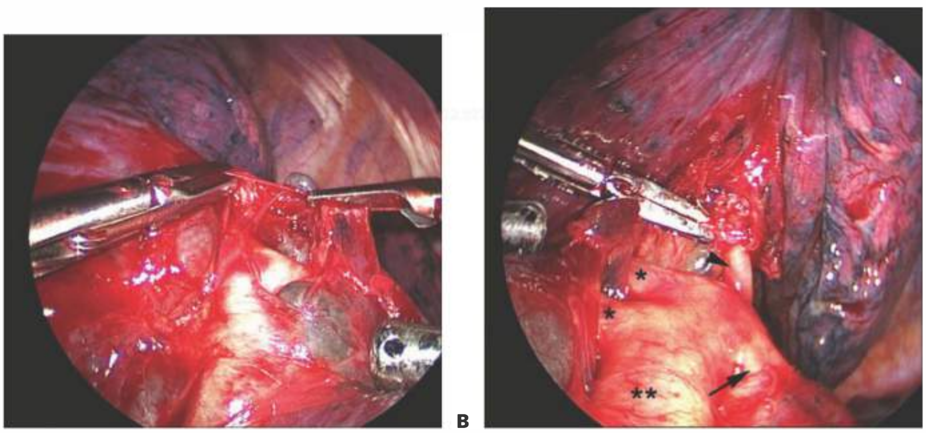


FIG 8 ● **A.** With a complete fissure, an alternative approach is to open the fissure sharply using a thoracoscopic pickup and scissors. **B.** This figure shows a completed fissure dissection on the left showing multiple pulmonary arterial branches, including a posterior segmental branch *(arrowhead)* and two lingular branches *(asterisks)* as well as the superior segmental *(arrow)* and basilar branches *(double asterisk)* to the left lower lobe.

LEFT UPPER LOBECTOMY

- The major fissure should be inspected and the tumor should be localized in the left upper lobe.
- The left upper lobe is retracted posteriorly and the anterior mediastinal pleura is opened sharply to avoid injuring the phrenic nerve using thoracoscopic Metzenbaum scissors and pickups.
- The branches of the left superior pulmonary vein are dissected free (**FIG 9A**) and divided using a beige load stapler through the posterior incision. There are usually three branches, although there can be more.
- The pleura superior to the hilum is then opened sharply. Levels 5 and 6 lymph nodes are obtained. The pulmonary arterial anatomy to the left upper lobe is the most variable and there are often multiple small branches.
- The apical and anterior pulmonary arterial branches are dissected free and divided using a beige load stapler through the anterior incision (**FIG 9B**).
- Working outward from the hilum, the parenchyma in the major fissure is dissected off the lingular pulmonary arterial branches and the bronchus.
- The fissure is then divided, keeping the purple load stapler above the bronchovascular structures passing the stapler from the anterior port.
- The lingular pulmonary arterial branches are then dissected free and divided using a beige load stapler through the anterior incision (**FIG 9C**).
- Retracting the lung superiorly, the branch point between the upper and lower lobe bronchi is identified (**FIG 9D**). Any 11L lymph nodes are removed. The bronchus is then clamped flush with the origin of the lower lobe bronchus.

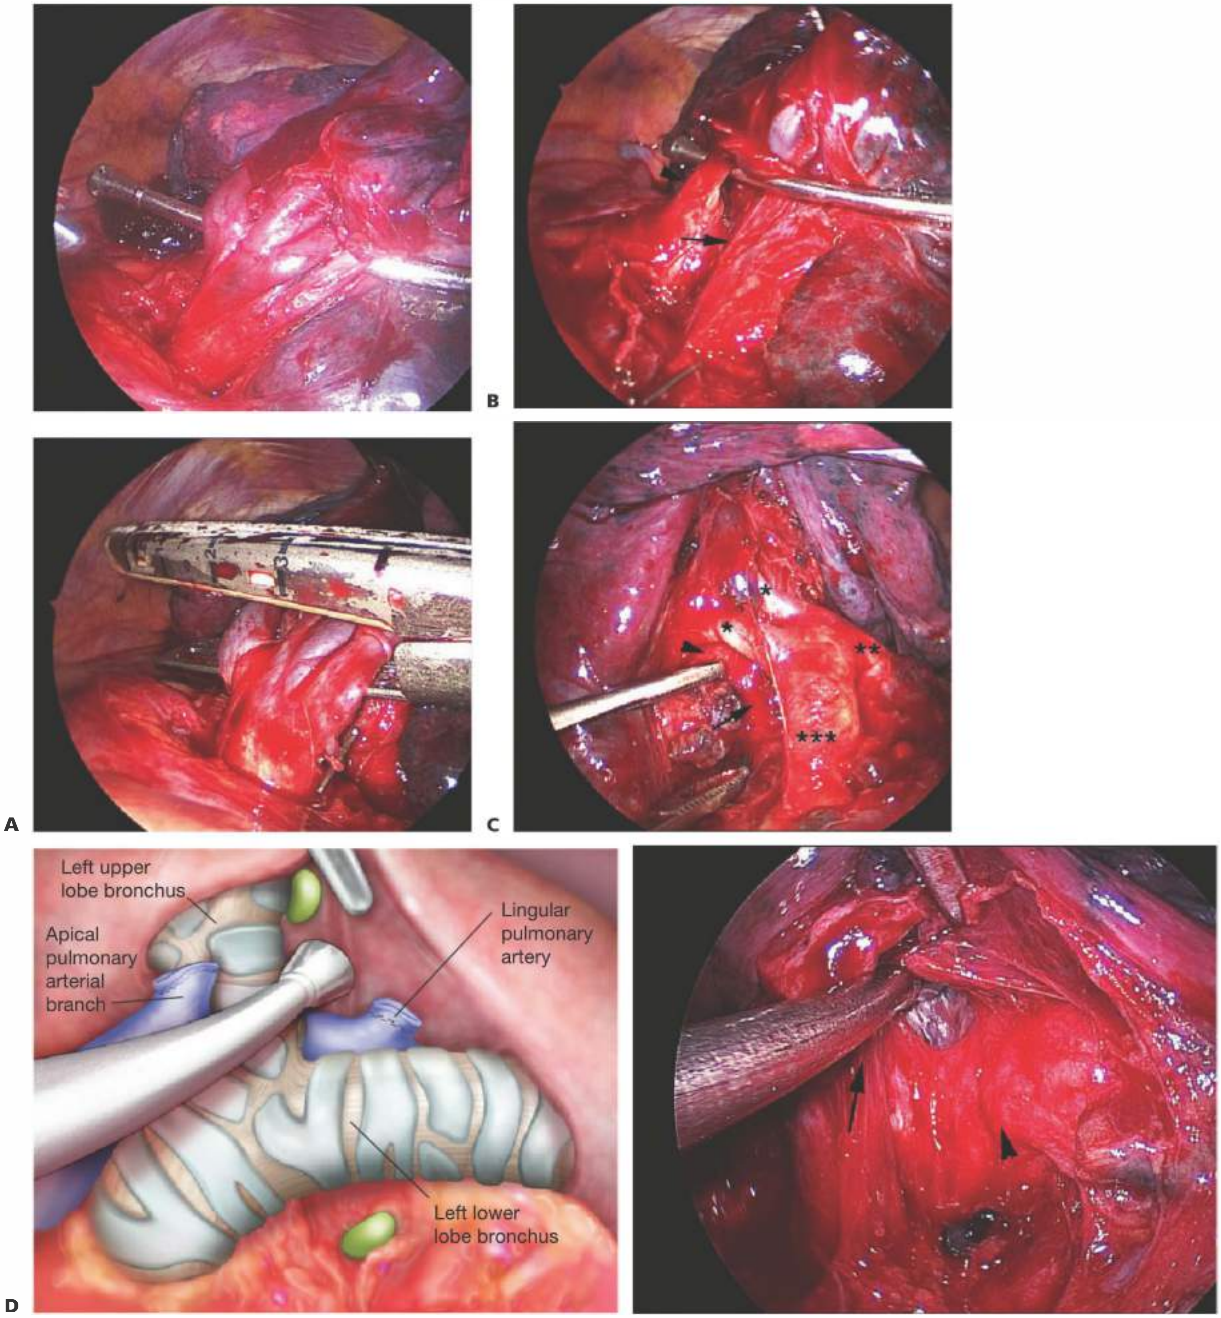

FIG 9 ● **A. Top:** There are multiple left upper lobe superior pulmonary vein branches that are **(bottom)** divided with a beige load stapler passed from the posterior port. **B.** The apical pulmonary arterial branch *(arrowhead)* is dissected free and divided with a beige load stapler passed from the anterior port (left upper lobe bronchus, *arrow*). **C.** The parenchyma has been dissected from the pulmonary artery and left upper lobe bronchus *(arrowhead)*. The anterior fissure has been divided with a stapler. This figure shows the left lower lobe bronchus *(arrow)* and the left lower lobe basilar *(triple asterisk)* and superior segmental *(double asterisk)* pulmonary arterial branches. The lingular branches *(asterisks)* are divided with a beige load stapler passed from the anterior port. **D.** The left upper lobe bronchus *(arrow)* is dissected free at the branch point with the lower lobe bronchus *(arrowhead)*. The 11L lymph nodes are removed and sent to pathology. *(continued)*

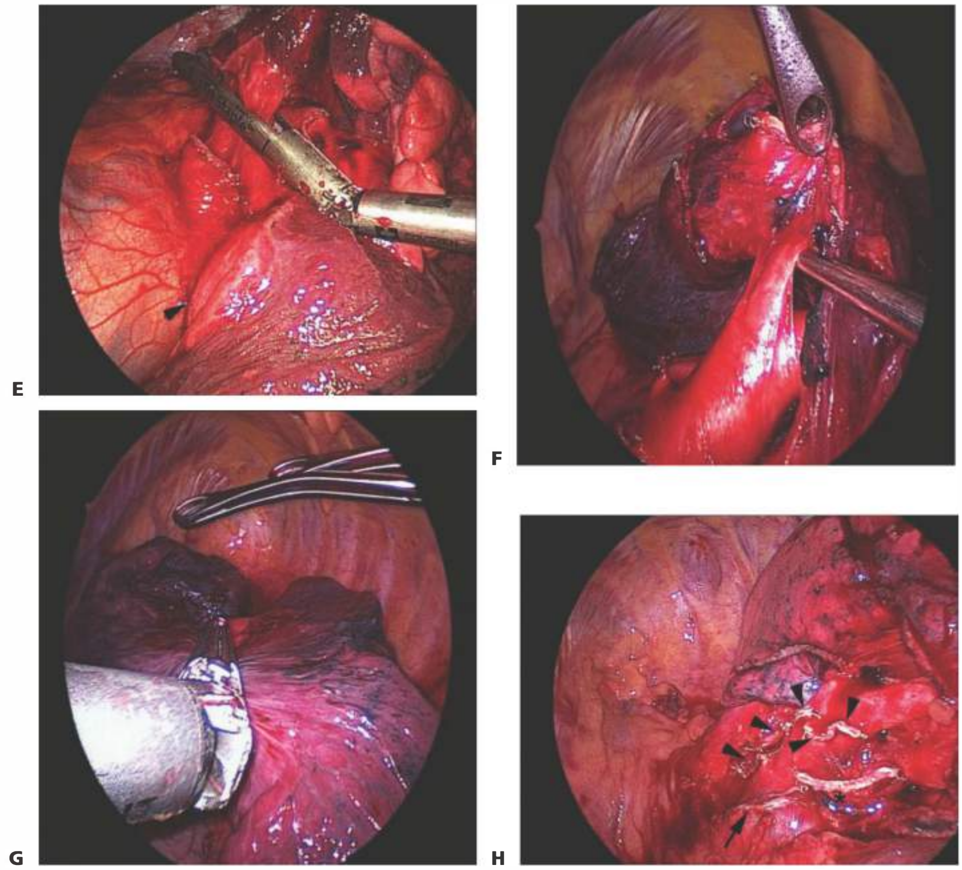

FIG 9 ● *(continued)* **E.** Before dividing the left upper lobe bronchus, a purple load stapler passed from the posterior port is clamped, and the left lower lobe is briefly inflated to confirm that the lower lobe bronchus is patent *(arrowhead)*. **F.** The remaining pulmonary arterial branches are divided with a beige load stapler. **G.** The posterior fissure is completed with a purple load stapler passed from the anterior port. **H.** The left upper lobe pulmonary arterial anatomy is the most variable, and there are frequently multiple short branches. The pulmonary arterial *(arrowheads)*, superior pulmonary vein *(arrow)*, and left upper lobe bronchial *(asterisk)* stumps are checked for hemostasis.

The lung is gently reinflated with a hand breath to ensure that the left lower lobe inflates before dividing the upper lobe bronchus using a purple load stapler passed through the posterior incision (**FIG 9E**).

- The remaining upper lobe pulmonary arterial branches are then dissected free and divided using a beige load stapler through the anterior incision (**FIG 9F**).
- The fissure is then completed with the purple load stapler through the anterior incision (**FIG 9G**). The specimen is removed using a retrieval bag.
- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is evidence of an air leak, endoscopic or open suturing of the bronchial stump may be required using interrupted 4-0 Vicryl sutures. The vascular stumps are checked for hemostasis (**FIG 9H**).
- Prior to closure, chest tubes are placed anteriorly and posteriorly.

ALTERNATIVE APPROACHES—FISSURE DISSECTION

- If there is a complete fissure, a fissure dissection can be performed. The advantage of this approach is that the arterial branches are taken before the veins, decreasing pulmonary congestion.
- The fissure is opened sharply using thoracoscopic Metzenbaum scissors and pickups (**FIG 8A**). It is important to dissect down to the correct plane on the wall of the

pulmonary artery. The left main pulmonary artery can also be identified just posterior to the fissure and followed anteriorly (**FIG 10**).

- The pulmonary arterial branches in the fissure are then dissected free and divided individually using a beige load stapler through the anterior incision (**FIG 8B**).
- The superior pulmonary vein branches and left upper lobe bronchus are then divided as described earlier.

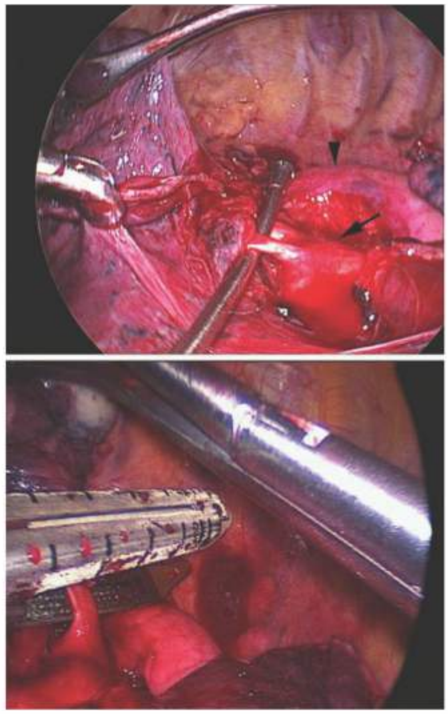

FIG 10 ● **A.** The left main pulmonary artery *(arrow)* can also be identified posteriorly behind the fissure by opening the posterior mediastinal pleura and the posterior aspect of the fissure. The *arrowhead* shows the aortic arch. Two posterior segmental arteries are being dissected free. **B.** The first branch is divided with a curved tip stapler, which can be useful in passing the stapler when there is another structure directly behind the artery; in this case, another pulmonary arterial branch.

LEFT LOWER LOBECTOMY

- A left lower lobectomy is performed in a similar fashion to a right lower lobectomy as described earlier.

MEDIASTINAL LYMPH NODE DISSECTION

- Patients undergoing resection for non–small cell lung carcinoma should have systematic mediastinal lymph node sampling or dissection performed intraoperatively.[3]
- The dissection can be performed during the lobectomy as the vessels and bronchus are taken or following lung resection.
- Paratracheal lymph nodes (levels 2R and 4R) are taken after opening the pleura superior to the azygous vein between the trachea and the superior vena cava (**FIG 11A**). Care is taken to preserve the phrenic and vagus nerves. The nodal tissue between the superior vena cava and the trachea up to the level of the innominate artery is removed.
- For the subcarinal node dissection (level 7), the pleura is incised posteriorly between the inferior pulmonary vein and the bronchus intermedius on the right and the mainstem bronchus on the left (**FIG 11B**). The nodal packet is dissected from the pericardium, bronchus, and esophagus. Care is taken to protect the esophagus and the vagus nerve.
- The inferior pulmonary ligament is divided, and level 9 lymph nodes are obtained adjacent to the inferior pulmonary vein (**FIG 11C**).
- The paratracheal lymph nodes are not easily accessible on the left where aortopulmonary window (level 5) and paraaortic (level 6) lymph nodes are obtained after incising the pleura in between the aorta and pulmonary artery. Again, care must be taken to preserve the left phrenic and recurrent laryngeal nerves (**FIG 11D**).

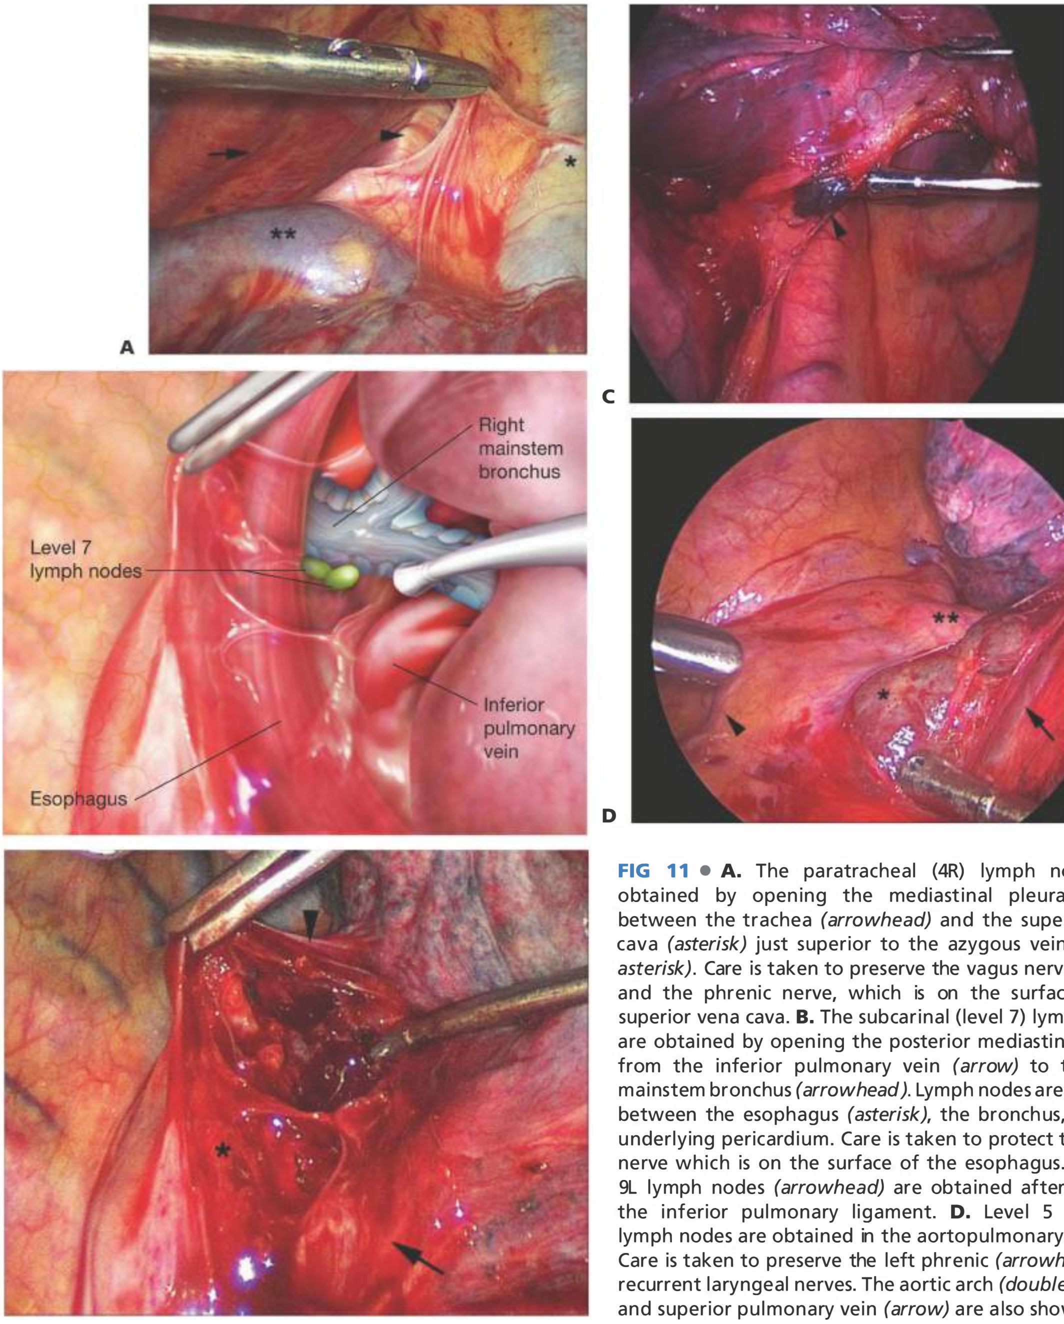

FIG 11 ● **A.** The paratracheal (4R) lymph nodes are obtained by opening the mediastinal pleura sharply between the trachea *(arrowhead)* and the superior vena cava *(asterisk)* just superior to the azygous vein *(double asterisk)*. Care is taken to preserve the vagus nerve *(arrow)* and the phrenic nerve, which is on the surface of the superior vena cava. **B.** The subcarinal (level 7) lymph nodes are obtained by opening the posterior mediastinal pleura from the inferior pulmonary vein *(arrow)* to the right mainstem bronchus *(arrowhead)*. Lymph nodes are removed between the esophagus *(asterisk)*, the bronchus, and the underlying pericardium. Care is taken to protect the vagus nerve which is on the surface of the esophagus. **C.** Level 9L lymph nodes *(arrowhead)* are obtained after dividing the inferior pulmonary ligament. **D.** Level 5 *(asterisk)* lymph nodes are obtained in the aortopulmonary window. Care is taken to preserve the left phrenic *(arrowhead)* and recurrent laryngeal nerves. The aortic arch *(double asterisk)* and superior pulmonary vein *(arrow)* are also shown.

PEARLS AND PITFALLS

Preoperative evaluation	■ Patients with a hilar mass or those unable to tolerate single-lung ventilation should undergo open lobectomy. ■ For ground glass or small nodules (<5 mm) requiring a wedge resection, localization with methylene blue injection or coil/wire placement should be considered.
Positioning	■ Patients should be flexed and positioned to drop the hip out of the way of the camera port. ■ Single-lung ventilation should be started when prepping the patient to allow time for the lung to collapse especially in patients with emphysema.
Incisions	■ Incisions should be placed to allow for optimal visualization and angles for stapler placement for vascular ligation.
Dissection	■ Careful identification and exposure of hilar structures is imperative prior to division. ■ Care must be taken to preserve the right middle lobe vein during a right upper lobectomy. ■ The phrenic and recurrent laryngeal nerves are protected during the mediastinal lymph node dissection. ■ The bronchial stump should be tested for an air leak following division. ■ The hilar structures should be examined to ensure there is no torsion of the remaining lung, particularly the right middle lobe after an upper lobectomy.
Closure	■ Placing chest tubes to water seal may result in quicker resolution of air leaks as long as the lung is well expanded on chest x-ray (CXR).

POSTOPERATIVE CARE

- Following VATS lobectomy, a chest x-ray should be obtained. The chest tubes should be placed to water seal unless the lung is not fully inflated on suction. Chest tubes may be removed on postoperative day 2 or once any air leaks have resolved and drainage has decreased to less than 100 mL per shift.
- Patients should be given an adequate pain control regimen and encouraged to ambulate and use the incentive spirometer.

OUTCOMES

- There are no large, randomized studies of VATS compared to open lobectomy. However, in the two largest series published to date, with more than 500 patients each, the conversion rate was 1.6% to 2.5%, mortality 0.8% to 1.2%, and morbidity 15.3%[5,6] The median length of stay was 3 days.
- VATS lobectomy results in less pain,[7] improved pulmonary function in the postoperative period, and an increased chance of completing adjuvant chemotherapy.[8]
- VATS lobectomy, when performed by experienced thoracic surgeons, is a safe procedure with comparable or better results than open lobectomy via thoracotomy.

COMPLICATIONS

- Prolonged air leak
- Bleeding
- Infection
- Atrial fibrillation
- Pneumonia
- Phrenic or recurrent laryngeal nerve injury
- Myocardial infarction
- Bronchopleural fistula
- Right middle lobe torsion is a rare complication following right upper lobectomy. The lung should be reinflated under direct vision to ensure that there is no lobar torsion.

Chapter 7

Lobectomy: Robotic

Tyler Grenda Jules Lin

DEFINITION

- Robotic-assisted thoracoscopic lobectomy is defined as an anatomic lobectomy performed with the assistance of robotic technology in which bronchial and vascular ligation is performed with lymph node dissection or sampling through several small incisions while avoiding spreading of the ribs. The technique is a minimally invasive alternative to thoracoscopic lobectomy and must be performed with the same oncologic principles as an open lobectomy including vascular ligation, resection with negative margins, and appropriate lymph node dissection.

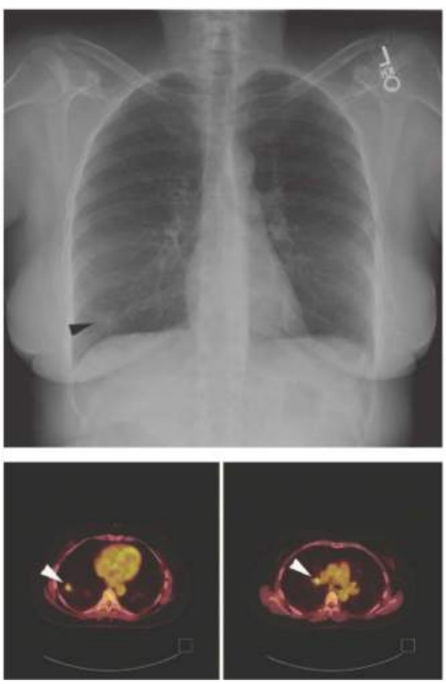
PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history and physical must be performed including past medical and surgical history, allergies, medications, social, and family history.
- A detailed social history is important to determine the patient's previous history of tobacco use as well as any chemical or asbestos exposures. Smoking cessation for 4 weeks preoperatively should be strongly encouraged prior to surgery.
- The patient's current functional status and exercise tolerance must also be assessed to determine their fitness for surgery.
- A complete physical examination should be performed with auscultation of the heart and lungs and evaluation for any cervical or supraclavicular lymphadenopathy or peripheral edema. Any abnormal findings on physical examination should be evaluated prior to surgery.
- Routine laboratory studies including a complete blood count and basic chemistry panel should be included as part of the preoperative evaluation.

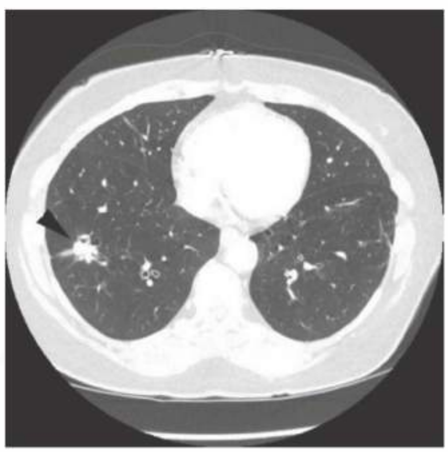
IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients generally present with abnormalities on chest radiograph (**FIG 1A**) or chest computed tomography (CT) (**FIG 1B**). The lung nodule should be compared to previous imaging when available. Nodules that have been stable for more than 2 years are generally benign. Indeterminate lesions less than 1 cm in size should be followed with serial imaging according to the recommendations of the Fleischner Society.[1]
- A chest CT (**FIG 1B**) should be obtained in all patients with a suspicious lung nodule on chest x-ray (CXR)[2,3] to evaluate the size and characteristics of the lesion; any potential involvement of the chest wall, vessels, airway, and mediastinum; additional pulmonary nodules; and hilar or mediastinal lymphadenopathy. The upper abdomen should be included to evaluate the liver and adrenal glands for any metastatic disease.
- A positron emission tomography (PET) scan (**FIG 1C**) is a functional study that evaluates the metabolic activity of the pulmonary lesion and areas of uptake that are suspicious for regional nodal or distant metastatic disease and should be obtained in patients suspected of having a non–small cell lung carcinoma.[3] Sampling of any abnormal lymph nodes

A



B



C

FIG 1 ● **A.** Chest x-ray shows a peripheral right lower lobe nodule *(arrowhead)*. **B.** Chest CT shows a spiculated right lower lobe nodule suspicious for a lung carcinoma *(arrowhead)*. **C. Left:** PET scan shows an intensely fluorodeoxyglucose (FDG)-avid right lower lobe nodule *(arrowhead)* with a hypermetabolic right hilar lymph node (**right**; *arrowhead*).

should be performed prior to lung resection by endobronchial ultrasound (EBUS) or mediastinoscopy.

- Due to the low morbidity and mortality of a thoracoscopic wedge resection, for nodules that are highly suspicious for lung carcinoma on PET or serial imaging, our preference is to perform a video-assisted thoracic surgery (VATS) wedge resection for a tissue diagnosis. CT or super dimensional needle biopsies are performed when the diagnosis is less clear or for central lesions that would require a lobectomy for diagnosis alone.
- Once the cancer diagnosis is confirmed, an anatomic lobectomy and mediastinal lymph node dissection for complete oncologic resection and staging is performed in patients who are surgical candidates.[4]
- As screening chest CTs identify smaller lesions, preoperative localization with methylene blue or coil/wire placement by CT guidance or super dimensional bronchoscopy may be useful in identifying small (<5 mm) or ground glass nodules (<1 cm) and nodules that are deep to the pleural surface intraoperatively.

SURGICAL MANAGEMENT

Preoperative Planning

- All patients undergoing lung resection should undergo preoperative pulmonary function testing (PFT) to determine if they have adequate pulmonary reserve.[5] Preoperative cardiac evaluation should be performed in patients with significant cardiovascular risk factors or symptoms.
- Patients with a preoperative forced expiratory volume in 1 second (FEV_1) of more than 60% predicted and diffusing capacity of lung for carbon monoxide (DLCO) of more than 50% predicted are candidates for lobectomy. Patients not meeting these criteria should undergo further testing with a quantitative ventilation perfusion scan to determine the postoperative predicted pulmonary function with a minimum postoperative value of 40% predicted.
- Cardiopulmonary exercise testing can be helpful in patients whose symptoms do not correlate with the severity of their pulmonary function results.
- For patients who are not candidates for an anatomic lobectomy, alternatives include a sublobar resection such as a segmentectomy or wedge resection, stereotactic body radiation therapy (SBRT), radiofrequency ablation (RFA), or definitive chemoradiation. These patients should be discussed in a multidisciplinary setting.
- In the preoperative area, the history and physical should be reviewed and consent should be obtained from the patient. The operative side should be marked.
- Once in the operating room (OR), a flexible bronchoscopy is performed to verify airway anatomy and the location of any endobronchial lesions.
- A left-sided double lumen endotracheal tube is generally preferable to a bronchial blocker in achieving single-lung ventilation, especially on the right where the mainstem bronchus is shorter.
- It is important to recognize the lack of tactile feedback when using the robot. Practice in the robotic simulator prior to the case is useful.
- The OR team must be familiar with emergency de-docking, and a sponge stick should be immediately available in case of bleeding.
- The dual console is useful when working with residents and allows both surgeons to switch instruments as needed. Pressing the camera pedal stops all the arms from moving, increasing safety.

Positioning

- The robot is draped sterilely (**FIG 2A**). The surgeon operates with arms 1 and 2 while arm 3 is used for retraction. The joint of the camera arm should be placed opposite of arm 3 to minimize bumping of the robotic arms.
- The surgeon sits at the console (**FIG 2B**), whereas an experienced bedside assistant changes the robotic instruments, passes the staplers, and suctions when needed.
- The patient should be placed in the lateral decubitus position, tilted slightly posteriorly (**FIG 3A**). The robotic camera is much larger than the standard thoracoscopic camera, and the bed is flexed taking care to drop the hips out of the way of the camera port. The patient should be secured to the bed, and all pressure points are padded. The arms are positioned in the neutral position in an arm holder.
- The position of the endotracheal tube should be confirmed again once positioning is complete.

FIG 2 ● **A.** The robot is draped sterilely. For a left-sided resection, arm 3 is placed as shown while arm 3 is moved to the opposite side for a right-sided resection. The surgeon operates with arms 1 and 2 while arm 3 is used for retraction. The joint of the camera arm *(arrowhead)* should be placed opposite of arm 3 to minimize bumping of the robotic arms. **B.** The surgeon sits at the console, whereas an experienced bedside assistant changes the robotic instruments, passes the staplers, and suctions when needed.

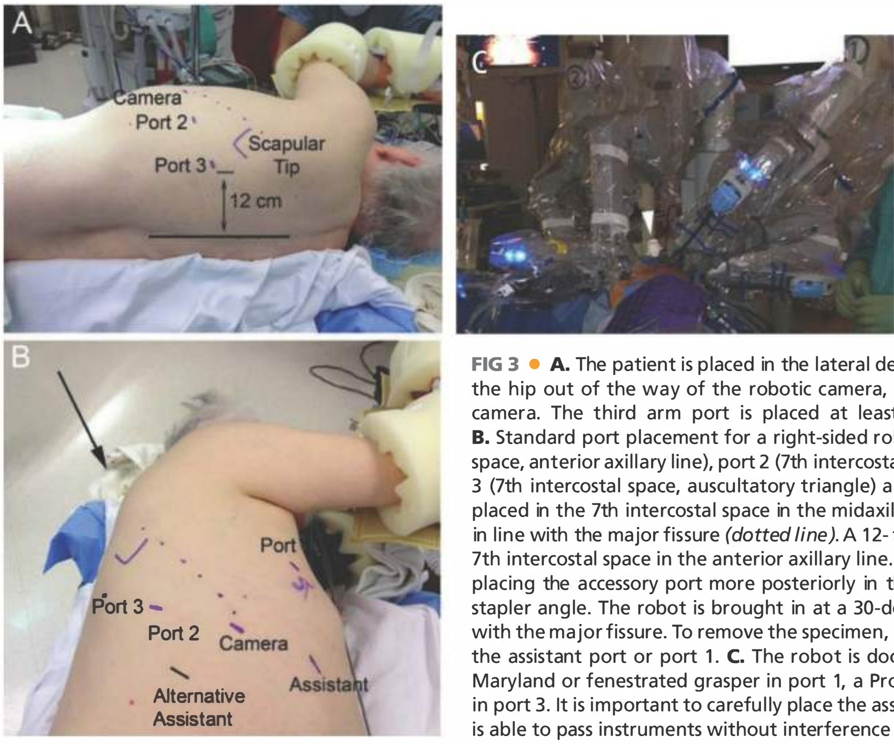


FIG 3 • **A.** The patient is placed in the lateral decubitus position. It is important to drop the hip out of the way of the robotic camera, which is larger than the thoracoscopic camera. The third arm port is placed at least 12 cm from the level of the spine. **B.** Standard port placement for a right-sided robotic lobectomy. Port 1 (5th intercostal space, anterior axillary line), port 2 (7th intercostal space, posterior axillary line), and port 3 (7th intercostal space, auscultatory triangle) are placed as shown. The camera port is placed in the 7th intercostal space in the midaxillary line, so the camera will be directed in line with the major fissure *(dotted line)*. A 12- to 15-mm accessory port is placed in the 7th intercostal space in the anterior axillary line. For a right upper or middle lobectomy, placing the accessory port more posteriorly in the 8th intercostal space offers a better stapler angle. The robot is brought in at a 30-degree angle to the back *(arrow)* in line with the major fissure. To remove the specimen, a 10-cm access incision is made at either the assistant port or port 1. **C.** The robot is docked to the ports with either a bipolar Maryland or fenestrated grasper in port 1, a ProGrasp in port 2, and a Caudier grasper in port 3. It is important to carefully place the assistant port so that the bedside assistant is able to pass instruments without interference from the robotic arms.

PLACEMENT OF INCISIONS

- Port placement is important in obtaining the ideal angles for stapler placement and avoiding the robotic arms interfering with each other or the bedside assistant's port. Our general port placement for a robotic lobectomy is shown (**FIG 3B**).
- Port 1 is placed in the 5th intercostal space in the anterior axillary line. A 5-mm, 30-degree angled standard thoracoscope is inserted, so the remaining ports can be placed under direct visualization.
- Port 2 is placed in the 7th intercostal space in the posterior axillary line. Port 3 is placed in the 7th intercostal space in the auscultatory triangle and should be placed at least 12 cm from the spine. The camera port is placed in the 7th intercostal space in the midaxillary line, so the camera will be directed in line with the major fissure.
- A 12- to 15-mm assistant port is placed in the 7th intercostal space in the anterior axillary line. It is important to carefully place the assistant port so that the bedside assistant is able to pass instruments without interference from the robotic arms (**FIG 3C**). For a right upper or middle lobectomy, placing the assistant port more posteriorly in the 8th intercostal space offers a better stapler angle. Early in the surgeon's experience, the 15-mm port is useful, so standard thoracoscopic instruments such as the Foerster clamp and long coronary tip suction can be used.
- Carbon dioxide (CO_2) insufflation to 5 mmHg can be useful for a lower lobectomy to help push the diaphragm out of the way. It is important to communicate with the anesthesiologist at the start of insufflation to watch for hypotension and adjust the CO_2 insufflation as warranted.
- A 10-cm access incision can be made instead of the assistant port at the beginning of the case. If CO_2 insufflation is used, the access incision is made at either the assistant port or port 1 at the end of the case to remove the specimen. In the event of bleeding, a sponge stick can be quickly inserted through the access incision or the 15-mm port to hold pressure.
- The robot is brought in at a 30-degree angle to the back in line with the major fissure (**FIG 3B**).
- The robot is docked to the ports with either a bipolar Maryland or fenestrated grasper in port 1 for dissection. A ProGrasp is placed in port 2 and is used to provide counter tension as vessels and other structures are dissected free. A Caudier grasper is placed in port 3 and is used to retract and position the lung. A 30-degree, 8.5-mm camera (angled down) is used to decrease compression of the intercostal nerve.
- Following port placement, a thoracoscopic exploration is performed to evaluate for any effusion, pleural lesions, or additional pulmonary nodules.
- Adequate lung isolation is important, and if the lung is not adequately collapsed, suction should be applied to the appropriate lumen of the endotracheal tube.

RIGHT UPPER LOBECTOMY

- The location of the nodule in the right upper lobe should be confirmed. The lung is retracted posteriorly to expose the hilum.
- The dissection is performed from anterior to posterior. The anterior mediastinal pleura is opened sharply to avoid injuring the phrenic nerve using scissors or the bipolar Maryland grasper (**FIG 4A**).
- The superior pulmonary vein branches are dissected bluntly with the bipolar fenestrated grasper. The division between the upper lobe and middle lobe venous branches must be identified (**FIG 4B**). The minor fissure can be followed anteriorly to ensure that the middle lobe vein is preserved. Care must be taken to avoid injury to the underlying right pulmonary artery.
- The upper lobe superior venous branches are divided using a vascular stapler (Ethicon Inc, San Antonio, TX or Covidien, Mansfield, MA; beige load Endo GIA, 2.0- to 3.0-mm stapler height) through the assistant port (**FIG 4C**). If needed, the vessels can be encircled with a silk tie for traction or a curved-tip stapler (Covidien) can be used to assist in passage of the stapler.
- The truncus anterior branch of the pulmonary artery is then dissected free and divided using a beige load stapler through the assistant port (**FIG 4D**).
- With the lung retracted anteriorly, the posterior pleura is opened. The bifurcation between the upper lobe bronchus and the bronchus intermedius is dissected free (**FIG 4E**). An 11R lymph node is often removed, and care must be taken not to injure the posterior ascending pulmonary artery branch, which is just behind this lymph node.
- The lung is again retracted posteriorly, and the right upper lobe bronchus is dissected free (**FIG 4F**). Stations 10R and 11R lymph nodes are obtained for pathology. The right upper lobe bronchus is then clamped flush with the bronchus intermedius with a purple load stapler passed from the assistant port (**FIG 4G**). The right middle and lower lobes are partially inflated to confirm that the bronchus intermedius is patent before firing the stapler.
- The posterior ascending arterial branch (**FIG 4H**) is then dissected free and divided using a beige load stapler through the assistant port.
- A purple load stapler (3.0- to 4.0-mm stapler height) through port 1 is then used to divide the minor fissure to complete the resection of the right upper lobe (**FIG 4I**).
- Once the dissection has been completed, the specimen should be removed using a protective retrieval bag (Cook Urological, Bloomington, IN; LapSac).

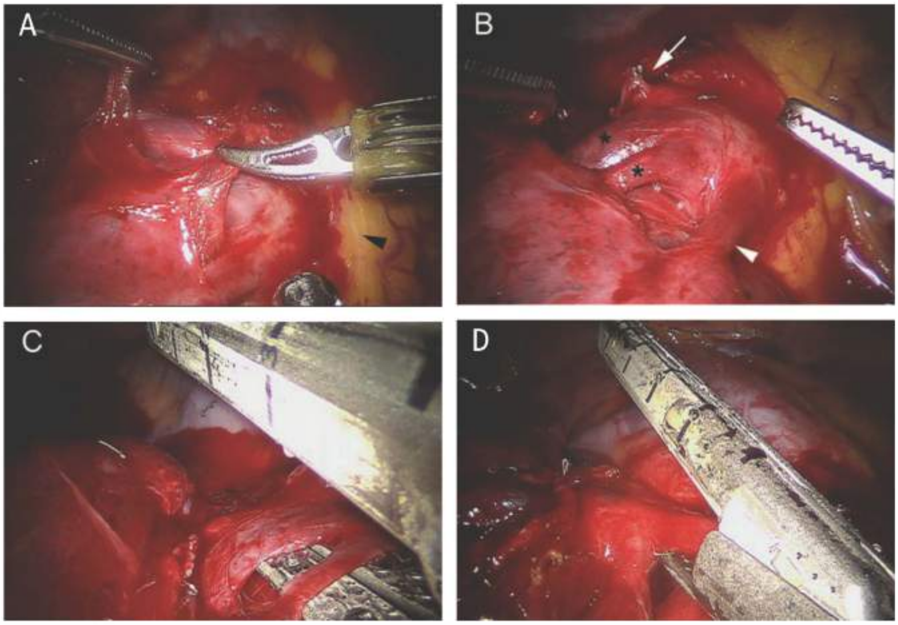

FIG 4 ● **A.** The anterior mediastinal pleura is opened with either scissors or bipolar Maryland grasper. Care is taken to preserve the right phrenic nerve *(arrowhead)*. **B.** The right upper lobe branches *(asterisks)* of the superior pulmonary vein are dissected free. The most superior branch *(arrow)* has already been divided. Care is taken to preserve the right middle lobe vein *(arrowhead)*. Attention must also be taken to avoid injuring the underlying right pulmonary artery. **C.** The upper lobe branches are divided with a beige load stapler passed from the assistant port. **D.** The truncus anterior branch of the pulmonary artery is dissected free and divided with a beige load stapler. *(continued)*

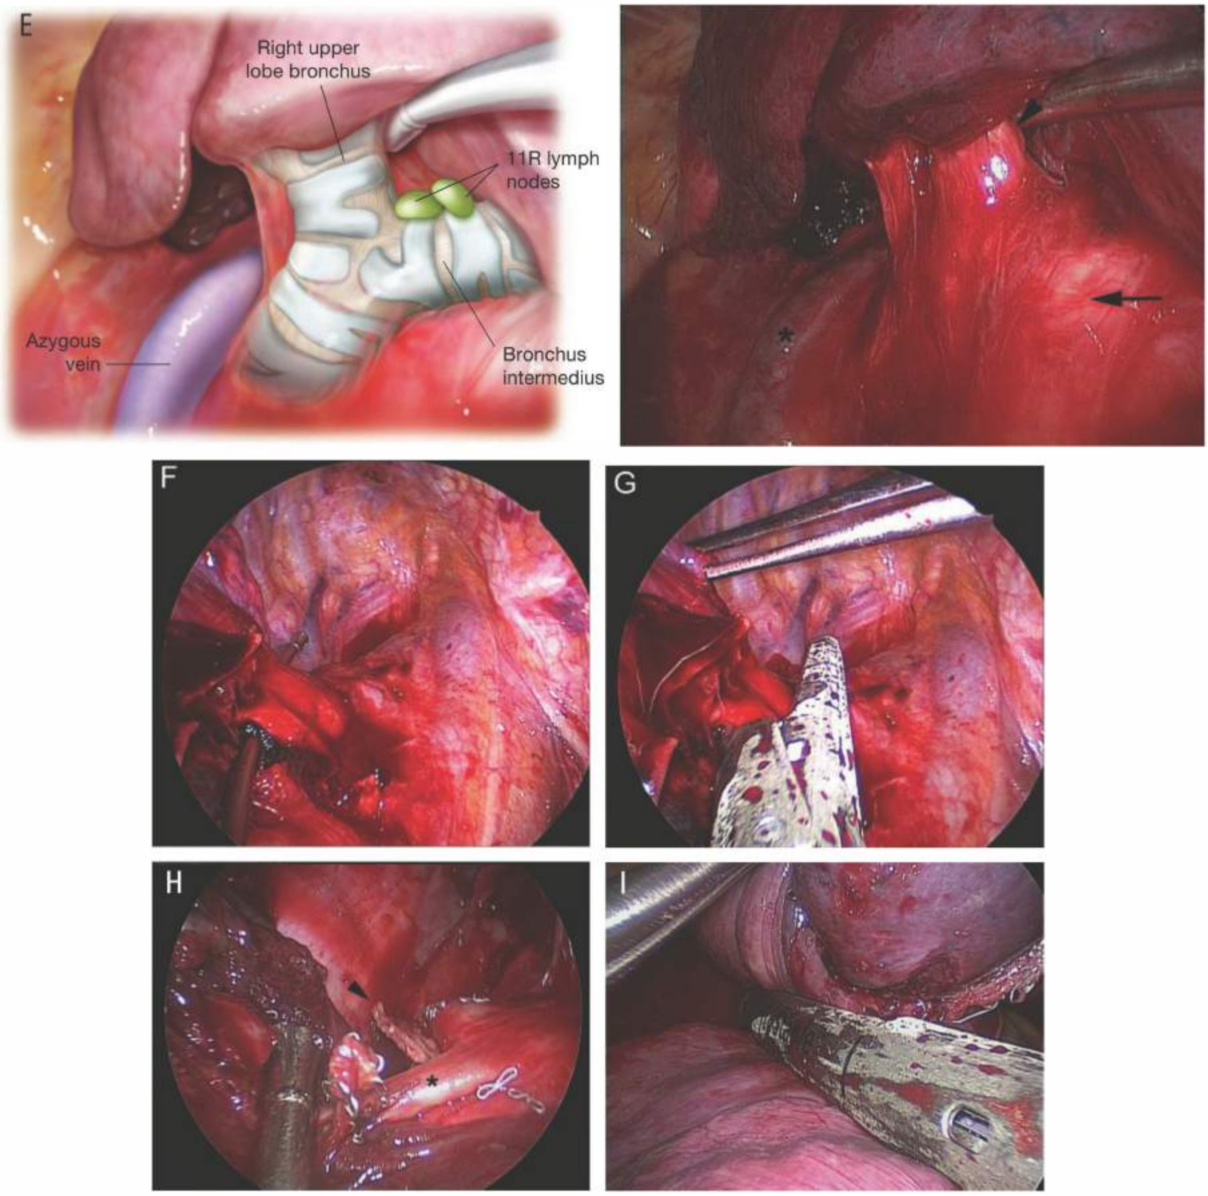

FIG 4 ● *(continued)* **E.** With the lung retracted anteriorly, the posterior pleura is opened. The bifurcation between the upper lobe bronchus *(arrowhead)* and the bronchus intermedius *(arrow)* is dissected free. An 11R lymph node is often removed, and care is taken not to injure the posterior ascending pulmonary artery branch, which is just behind this lymph node (azygous vein, *asterisk*). **F.** The right upper lobe bronchus is dissected free anteriorly, and 11R lymph nodes are sent for pathology. **G.** The right upper lobe bronchus is clamped with a purple load stapler passed from the assistant port. The right middle and lower lobe are partially inflated to confirm that the bronchus intermedius is patent before firing the stapler. **H.** The posterior ascending pulmonary artery branch *(asterisk)* is dissected free and divided with a beige load stapler passed from the assistant port. The right upper lobe bronchial stump is shown *(arrowhead)*. **I.** The fissure is completed with a purple load stapler through port 1. Care is taken to preserve the middle lobe pulmonary vein and the underlying pulmonary artery. *(continued)*

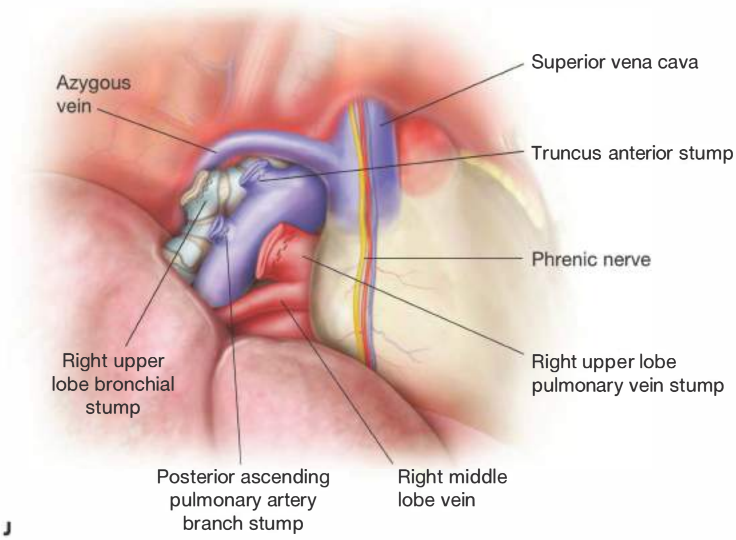

FIG 4 ● *(continued)* **J.** The right upper lobe pulmonary and bronchial veins and truncus anterior and posterior ascending pulmonary arterial stumps are checked for hemostasis. It is important to examine the middle lobe vein to confirm that there is no middle lobe torsion.

- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is an air leak, robotic or open suturing of the bronchial stump is performed using interrupted 4-0 Vicryl sutures. The vascular stumps are checked for hemostasis (**FIG 4J**).
- Chest tubes are placed anteriorly and posteriorly through the port 1 and camera port incisions. The lung is reinflated under direct vision to ensure that there is no torsion of the middle lobe (**FIG 4J**).
- The remaining port sites are closed in layers using running 2-0 Vicryl for the muscle and subcutaneous layers and 4-0 Monocryl to reapproximate the skin.

RIGHT MIDDLE LOBECTOMY

- The tumor location in the right middle lobe is confirmed. The right middle lobe is retracted posteriorly. The anterior mediastinal pleura is opened sharply to avoid injuring the phrenic nerve using scissors or the bipolar Maryland grasper.
- The right middle lobe vein is identified. Care is taken to preserve the right upper lobe vein branches (**FIG 5A**). The minor fissure can be followed anteriorly to ensure that the upper lobe veins are preserved. The right middle lobe vein is dissected with a bipolar fenestrated grasper and divided with a beige load stapler passed from the assistant port (**FIG 5B,C**).
- The major fissure is opened with a combination of dissection with the bipolar Maryland grasper and the purple load stapler taking care to protect the underlying right lower lobe branches of the pulmonary artery.
- The right middle lobe bronchus is dissected free with the bipolar fenestrated grasper at the branch point with the right lower lobe bronchus (**FIG 5D,E**). Any 10R or 11R lymph nodes are obtained for pathology. The right middle lobe bronchus is then clamped with a purple load stapler passed through the assistant port, flush with the origin of the lower lobe bronchus. The lung is gently reinflated to ensure that the right lower lobe bronchus is patent before dividing the middle lobe bronchus.
- The right middle lobe pulmonary arterial branches are dissected free with a bipolar fenestrated grasper and divided with a beige load stapler passed from the assistant port (**FIG 5F**). A second middle lobe arterial branch may be present and is divided in a similar fashion.
- The major and minor fissures (**FIG 5G**) are completed with a purple load stapler passed from port 1. Care is taken to preserve the upper lobe veins.
- The specimen is then removed using a retrieval bag.
- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is evidence of an air leak, robotic or open suturing of the bronchial stump with interrupted 4-0 Vicryl may be performed.
- Prior to closure, chest tubes are placed anteriorly and posteriorly. The lung is reinflated under direct vision to confirm that there is no lobar torsion.

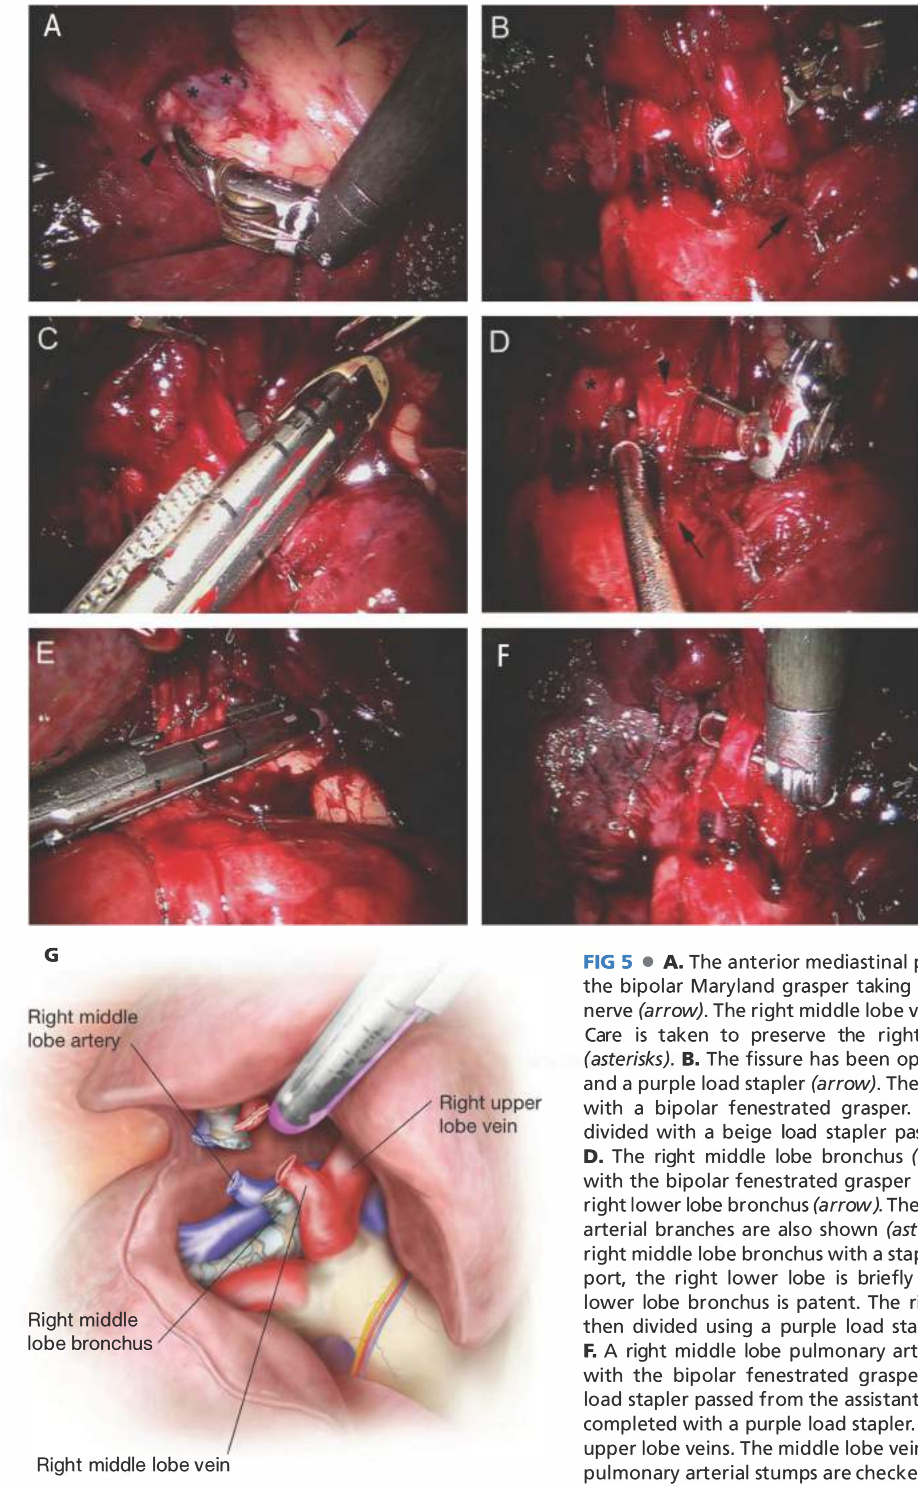

FIG 5 ● **A.** The anterior mediastinal pleura has been opened with the bipolar Maryland grasper taking care to preserve the phrenic nerve *(arrow)*. The right middle lobe vein is identified *(arrowhead)*. Care is taken to preserve the right upper lobe vein branches *(asterisks)*. **B.** The fissure has been opened with bipolar dissection and a purple load stapler *(arrow)*. The middle lobe vein is dissected with a bipolar fenestrated grasper. **C.** The middle lobe vein is divided with a beige load stapler passed from the assistant port. **D.** The right middle lobe bronchus *(arrowhead)* is dissected free with the bipolar fenestrated grasper at the branch point with the right lower lobe bronchus *(arrow)*. The right middle lobe pulmonary arterial branches are also shown *(asterisk)*. **E.** After clamping the right middle lobe bronchus with a stapler passed from the assistant port, the right lower lobe is briefly inflated to ensure that the lower lobe bronchus is patent. The right middle lobe bronchus is then divided using a purple load stapler from the assistant port. **F.** A right middle lobe pulmonary arterial branch is dissected free with the bipolar fenestrated grasper and divided with a beige load stapler passed from the assistant port. **G.** The minor fissure is completed with a purple load stapler. Care is taken to preserve the upper lobe veins. The middle lobe vein, bronchial, and middle lobe pulmonary arterial stumps are checked for hemostasis.

RIGHT LOWER LOBECTOMY

- The location of the tumor in the right lower lobe is confirmed.
- With the lower lobe retracted superiorly, the inferior pulmonary ligament is divided to expose the right inferior pulmonary vein (**FIG 6A**). The 9R lymph nodes are removed.
- The anterior and posterior mediastinal pleural are opened sharply to avoid injuring the phrenic nerve using scissors or the bipolar Maryland grasper.
- The inferior pulmonary vein is then dissected bluntly with the bipolar fenestrated grasper. With the lung retracted anteriorly, level 7 lymph nodes may be obtained. The lung is then retracted posteriorly, and the inferior pulmonary vein is divided with a beige load stapler through port 1 (**FIG 6B**).
- Performing a fissure dissection is easier using the robotic bipolar Maryland grasper compared to thoracoscopy (**FIG 6C**). Once the plane overlying the pulmonary arterial branches is identified, the parenchyma is dissected from the arterial branches with the bipolar fenestrated grasper.
- If the fissure is incomplete, a standard thoracoscopic anterior to posterior approach is performed. Working outward from the hilum, the parenchyma in the major fissure is dissected from the lower lobe bronchus and the basilar pulmonary artery branches.
- The anterior fissure is completed with a purple load stapler passed from the assistant port, exposing the right lower lobe bronchus and pulmonary arterial branches (**FIG 6D**).
- The basilar pulmonary arterial branches (**FIG 6E**) are then dissected free and divided either together or individually with a beige load stapler passed from the assistant port.
- The superior segment pulmonary arterial branch is dissected free and divided with a beige load stapler passed from the assistant port.
- The right lower lobe bronchus is dissected free at the junction with the right middle lobe bronchus (**FIG 6F**). The right lower lobe bronchus is clamped with a purple load stapler and the right middle lobe briefly inflated to ensure patency of the right middle lobe bronchus before firing the stapler.
- The posterior fissure is completed with a purple load stapler (**FIG 6G**). The specimen is then removed using a retrieval bag.
- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is evidence of an air leak, robotic or open suturing of the bronchial stump with interrupted 4-0 Vicryl may be performed. The vascular stumps are checked for hemostasis.
- Prior to closure, chest tubes are placed anteriorly and posteriorly.

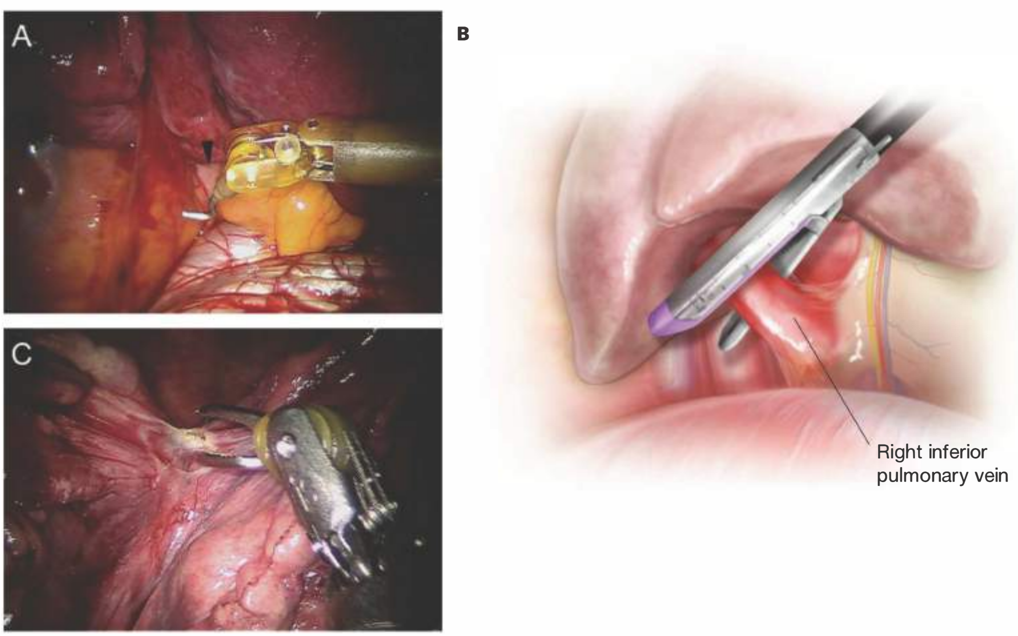

FIG 6 ● **A.** The inferior pulmonary ligament is divided to expose the right inferior pulmonary vein *(arrowhead)*. The 9R lymph nodes are removed. **B.** The inferior pulmonary vein is divided with a stapler passed from port 1. **C.** The right lower lobe fissure is opened with the bipolar Maryland grasper. *(continued)*

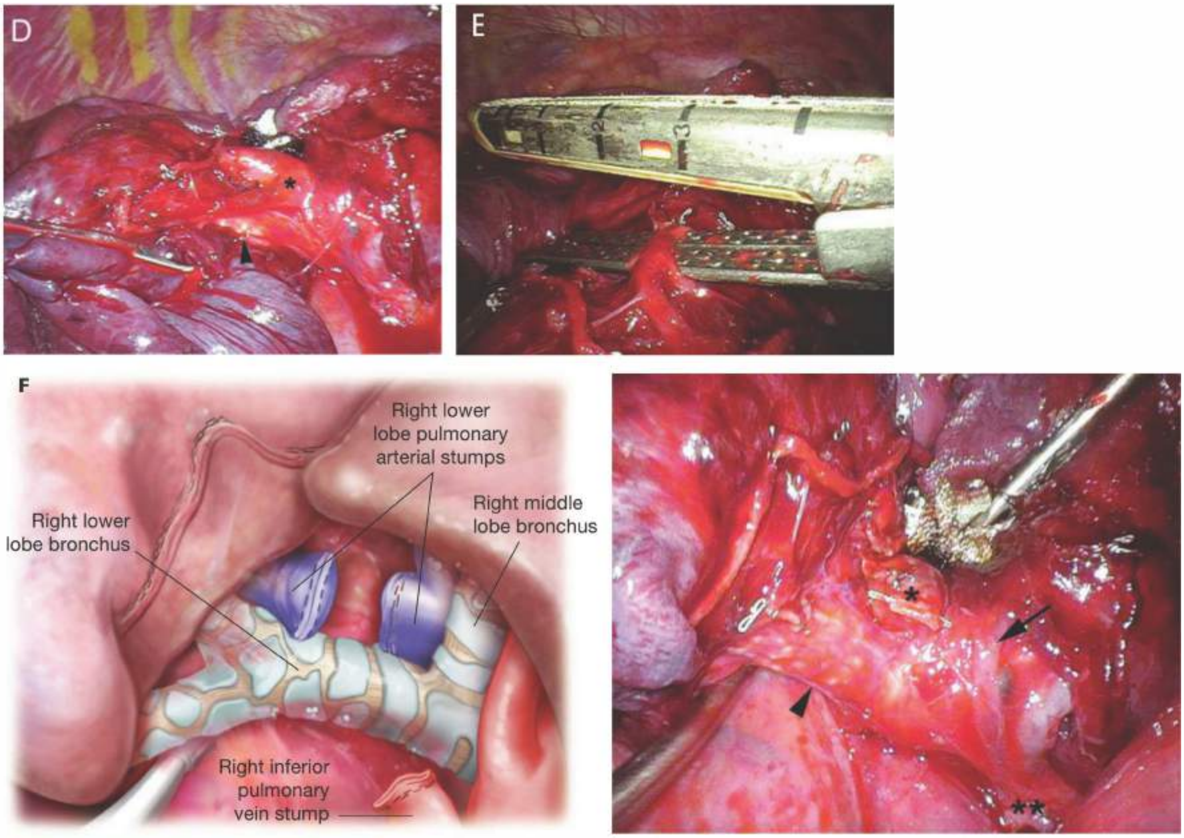

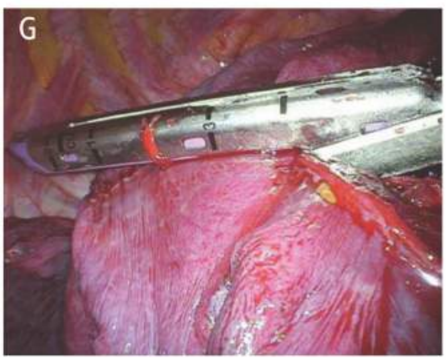

FIG 6 ● *(continued)* **D.** Staying in the plane overlying the pulmonary arterial branches, the anterior fissure has been completed with a purple load stapler passed from the assistant port, exposing the right lower lobe bronchus *(arrowhead)* and pulmonary arterial branches *(asterisk)*. **E.** A right lower lobe basilar branch is divided with a beige load stapler passed from the assistant port. **F.** The right lower lobe bronchus *(arrowhead)* is dissected free at the junction with the right middle lobe bronchus *(arrow)*. The right lower lobe bronchus is clamped with a purple load stapler and the right middle lobe briefly inflated to ensure patency of the right middle lobe bronchus before firing the stapler. The right lower lobe pulmonary arterial *(asterisk)* and inferior pulmonary vein stumps are shown *(double asterisk)*. **G.** The posterior fissure is completed with a purple load stapler.

LEFT UPPER LOBECTOMY

- The major fissure should be inspected, and the tumor should be localized in the left upper lobe.
- The left upper lobe is retracted posteriorly, and the anterior mediastinal pleura is opened sharply to avoid injuring the phrenic nerve using scissors or the bipolar Maryland grasper.
- The left superior pulmonary vein branches are dissected free and divided with a beige load stapler passed from port 2 (**FIG 7A**). There are usually three branches, although there can be more.
- The pleura superior to the hilum is then opened sharply. Levels 5 and 6 lymph nodes are obtained for pathology.
- The left upper lobe pulmonary arterial anatomy is the most variable, and there are often multiple, small branches.
- The apical pulmonary arterial branch is dissected free and divided with a beige load stapler passed from the assistant port (**FIG 7B**).
- Performing a fissure dissection is easier using the robotic bipolar Maryland grasper compared to thoracoscopy. Once the plane overlying the pulmonary arterial branches is identified, the parenchyma is dissected

from the arterial branches with the bipolar fenestrated grasper (**FIG 7C**).

- If the fissure is incomplete, the dissection is continued anterior to posterior as is generally used for a thoracoscopic lobectomy.
- Working outward from the hilum, the parenchyma in the major fissure is dissected off the lingular pulmonary arterial branches and the bronchus.
- The fissure is then divided, keeping the purple load stapler above the bronchovascular structures passing the stapler from port 1.
- The lingular pulmonary arterial branches are then dissected free and divided using a beige load stapler through the anterior incision.
- The junction of the left upper and lower lobe bronchi is dissected free while retracting the upper lobe superiorly (**FIG 7D,E**). Level 11L lymph nodes are obtained for pathology. The bronchus is then clamped with a purple load stapler passed from port 2 flush with the origin of the lower lobe bronchus. The left lower lobe is briefly inflated to confirm that the lower lobe bronchus is patent before firing the stapler.
- The remaining pulmonary arterial branches (**FIG 7F**) are divided with a beige load stapler passed from the assistant port.
- The remaining fissure is divided using a purple load stapler from port 1. The specimen is removed using a retrieval bag.
- A mediastinal lymph node dissection is performed as described in the following text.
- The hemithorax is then irrigated with warm water, and the bronchial stump is inspected for evidence of an air leak with a Valsalva to 25 cm H_2O. If there is evidence of an air leak, robotic or open suturing of the bronchial stump with interrupted 4-0 Vicryl may be performed. The vascular stumps are checked for hemostasis (**FIG 7G**). The lung is reinflated under direct vision to ensure that there is no lobar torsion.
- Prior to closure, chest tubes are placed anteriorly and posteriorly.

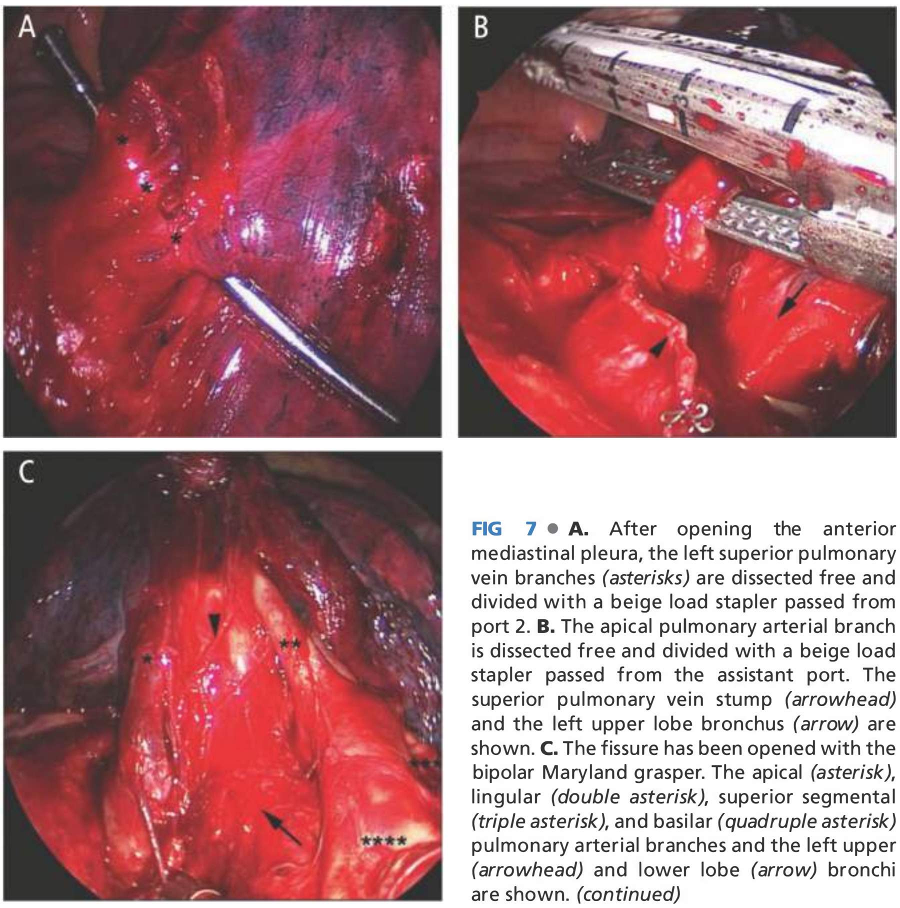

FIG 7 ● **A.** After opening the anterior mediastinal pleura, the left superior pulmonary vein branches *(asterisks)* are dissected free and divided with a beige load stapler passed from port 2. **B.** The apical pulmonary arterial branch is dissected free and divided with a beige load stapler passed from the assistant port. The superior pulmonary vein stump *(arrowhead)* and the left upper lobe bronchus *(arrow)* are shown. **C.** The fissure has been opened with the bipolar Maryland grasper. The apical *(asterisk)*, lingular *(double asterisk)*, superior segmental *(triple asterisk)*, and basilar *(quadruple asterisk)* pulmonary arterial branches and the left upper *(arrowhead)* and lower lobe *(arrow)* bronchi are shown. *(continued)*

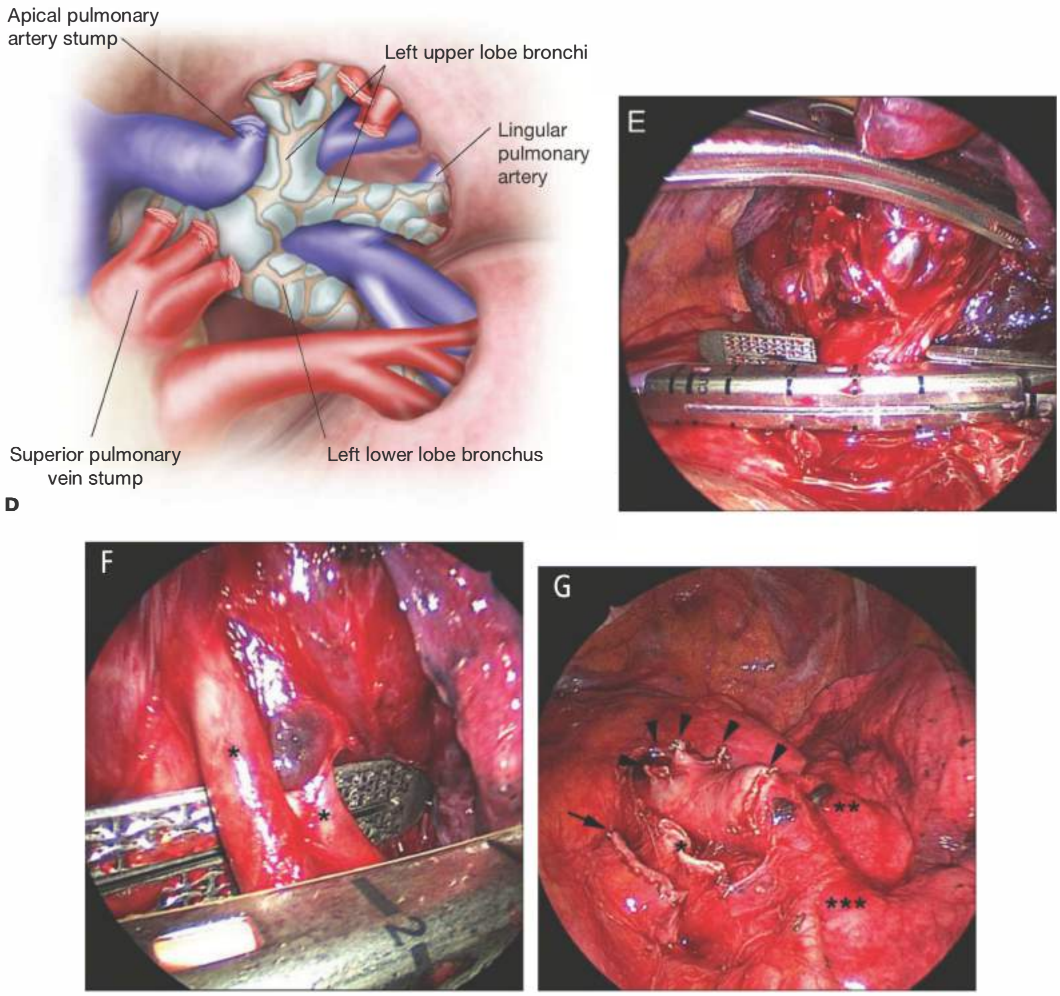

FIG 7 ● *(continued)* **D.** This illustration shows the junction of the left upper and lower lobe bronchi. The 11L lymph nodes are removed and sent to pathology. **E.** Before dividing the left upper lobe bronchus, the bronchus is clamped with a purple load stapler passed from port 2, and the left lower lobe is briefly inflated to confirm that the lower lobe bronchus is patent. **F.** The remaining pulmonary arterial branches *(asterisks)* are divided with a beige load stapler. **G.** The left upper lobe pulmonary arterial anatomy is the most variable, and there are often multiple, short branches. The pulmonary arterial *(arrowheads)*, superior pulmonary vein *(arrow)*, and left upper lobe bronchial *(asterisk)* stumps are checked for hemostasis. The superior segmental *(double asterisk)* and basilar pulmonary arterial branches *(triple asterisk)* are shown.

LEFT LOWER LOBECTOMY

- A left lower lobectomy is performed in a similar fashion to a right lower lobectomy as described earlier.

MEDIASTINAL LYMPH NODE DISSECTION

- Patients undergoing resection for non–small cell lung carcinoma should have systematic mediastinal lymph node sampling or dissection performed intraoperatively.[4]
- The dissection can be performed during the lobectomy as the vessels and airway are dissected or following lung resection.
- The paratracheal (2R and 4R) lymph nodes are obtained by opening the mediastinal pleura sharply between the trachea and the superior vena cava just superior to the azygous vein (**FIG 8A**). Care is taken to preserve the vagus and phrenic nerves. Nodal tissue is removed between the superior vena cava and the trachea up to the level of the innominate artery.

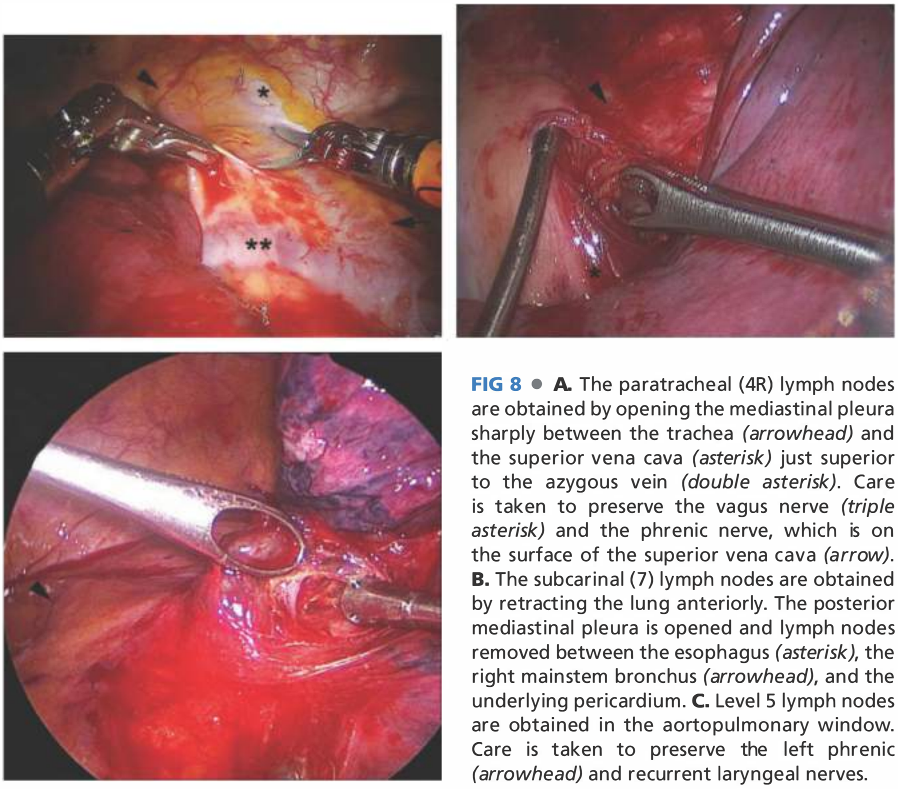

FIG 8 ● **A.** The paratracheal (4R) lymph nodes are obtained by opening the mediastinal pleura sharply between the trachea *(arrowhead)* and the superior vena cava *(asterisk)* just superior to the azygous vein *(double asterisk)*. Care is taken to preserve the vagus nerve *(triple asterisk)* and the phrenic nerve, which is on the surface of the superior vena cava *(arrow)*. **B.** The subcarinal (7) lymph nodes are obtained by retracting the lung anteriorly. The posterior mediastinal pleura is opened and lymph nodes removed between the esophagus *(asterisk)*, the right mainstem bronchus *(arrowhead)*, and the underlying pericardium. **C.** Level 5 lymph nodes are obtained in the aortopulmonary window. Care is taken to preserve the left phrenic *(arrowhead)* and recurrent laryngeal nerves.

- The subcarinal (level 7) lymph nodes are obtained by retracting the lung anteriorly. The posterior mediastinal pleura is opened and lymph nodes are removed between the mainstem bronchus, the esophagus, and the underlying pericardium (**FIG 8B**).
- Level 9 lymph nodes are obtained after dividing the inferior pulmonary ligament and are found adjacent to the inferior pulmonary vein.
- The paratracheal lymph nodes are not easily accessible on the left where aortopulmonary window (level 5) and paraaortic (level 6) lymph nodes are obtained after incising the pleura in between the aorta and pulmonary artery (**FIG 8C**). Care must be taken to preserve the left phrenic and recurrent laryngeal nerves.

PEARLS AND PITFALLS

Preoperative evaluation	■ Patients with a hilar mass or those unable to tolerate single-lung ventilation should undergo open lobectomy. ■ For ground glass or small nodules (<5 mm) requiring a wedge resection, localization with methylene blue injection or coil/wire placement should be considered.
Positioning	■ Patients should be flexed in the lateral decubitus position to drop the hip out of the way of the camera port. ■ Single-lung ventilation should be started when prepping the patient to allow time for the lung to collapse especially in patients with emphysema. ■ The robot should be brought in at 30 degrees from the back in line with the major fissure to decrease the robotic arms from interfering with each other.
Incisions	■ The third arm port should be placed at least 12 cm from the spine. ■ Placing the assistant port more posteriorly provides a better stapler angle for right upper and middle lobectomies. ■ It is important to place the assistant port so that the bedside assistant is able to pass instruments without interference from the robotic arms.

Dissection	▪ The OR team must be familiar with emergency de-docking, and a sponge stick should be immediately available in case of bleeding. ▪ The dual console is useful when working with residents and allows both surgeons to switch instruments as needed. Pressing the camera pedal stops all arms from moving, increasing safety. ▪ Careful identification and exposure of hilar structures are essential prior to division. ▪ The lobar bronchus should be test clamped prior to division and the ipsilateral lung gently inflated to confirm that the remaining airway is patent. ▪ The bronchial stump should be tested for an air leak following division. ▪ The hilar structures should be examined to ensure there is no torsion of the remaining lung, particularly the right middle lobe after an upper lobectomy.
Closure	▪ Placing chest tubes to water seal may result in quicker resolution of air leaks as long as the lung is well expanded on CXR.

POSTOPERATIVE CARE

- A CXR should be obtained immediately following the procedure.
- The chest tubes should be placed to water seal unless the lung is not fully inflated on suction. Chest tubes may be removed on postoperative day 2 or once any air leaks have resolved and drainage has decreased to less than 100 mL per shift.
- Patients should be given an adequate pain control regimen and encouraged to ambulate and use the incentive spirometer.

OUTCOMES

- Robotic technology continues to evolve and provides the advantage of three-dimensional visualization and wristed instruments with seven degrees of freedom. However, it is also important to recognize the limitations of the technology with the lack of tactile feedback and the need for an experienced bedside assistant.
- The surgeon must assess his or her comfort level and skill as he or she gains experience with the robotic simulator and performing simpler procedures such as robotic resection of a mediastinal mass prior to attempting more advanced cases, such as a robotic lobectomy. In several series, the number of robotic lobectomies felt to be needed before the surgeon and nursing teams were considered proficient was at least 20 cases.[6–8]
- When comparing long-term oncologic outcomes in 325 patients undergoing robotic pulmonary resection, overall and stage-specific survival for early non–small cell lung cancer is comparable for robotic and thoracoscopic lobectomy.[9]
- Louie et al.[10] compared 53 robotic to 35 thoracoscopic pulmonary resections and found that the postoperative outcomes were similar with significantly shorter narcotic use and earlier return to normal activities.
- Although randomized trials are not available, results after robotic lobectomy appear to be comparable to VATS lobectomy, although the costs are currently higher. In the largest series published to date with 100 to 325 patients each, the median operating time ranged from 90 to 220 minutes. The conversion rate was 0% to 13%. The median length of stay was 3 to 5 days with a morbidity rate of 21% to 27% and 30-day mortality of 0% to 3%.[6,7,9,11,12]
- Robotic lobectomy can be performed safely by experienced thoracic surgeons. However, larger series and more widespread use and experience will be required before definitive conclusions can be made regarding any benefits of robotic lobectomy in terms of length of stay or postoperative pain.

COMPLICATIONS

- Prolonged air leak
- Bleeding
- Infection
- Atrial fibrillation
- Pneumonia
- Phrenic or recurrent laryngeal nerve injury
- Myocardial infarction
- Bronchopleural fistula
- Right middle lobe torsion

Chapter 8

Pneumonectomy: Open

Christopher R. Morse Cameron T. Stock

DEFINITION

- Pneumonectomy is the complete removal of a lung. A pneumonectomy is most often performed for bronchogenic carcinomas that are central and unable to be removed via a lesser (lobectomy, segmentectomy) resection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be obtained on all patients presenting with a new lung mass. Patients may have symptoms of dyspnea, cough, hemoptysis, or weight loss. Some patients, however, may present with a mass or hilar fullness discovered incidentally on routine chest x-ray.
- The history should focus on signs and symptoms of local or distant metastases. Patients should be asked about recent onset of headaches or other neurologic symptoms, which should arouse suspicion for distant metastases. Patients should also be questioned about new chest wall or back pain, suggesting local tumor invasion or distant bony metastases.
- It is essential to establish the patient's functional status prior to pneumonectomy. There are several scales that can be used to quantify a patient's performance status including the Zubrod and Karnofsky scales. Poor functional status is a contraindication to pneumonectomy. Age is not a contraindication to pneumonectomy; however, older patients must be carefully selected as increasing age has been associated with increased postoperative complications. Patients should also be asked about significant cardiac history and other medical comorbidities.
- A history of smoking or significant exposure to secondhand smoke should be noted in the patient's history or significant environmental exposures such as to silicon, asbestos, or radon. Active smokers are often not considered operative candidates.
- On physical exam, auscultation of the lungs revealing diminished breath sounds suggests a near obstructing lesion or a significant pleural effusion. Findings of Horner's syndrome suggest involvement of the sympathetic ganglion. Hoarseness can indicate invasion of the recurrent laryngeal nerve (RLN). Evaluation of the supraclavicular and cervical lymph nodes (LNs) should be performed with enlarged nodes suggesting metastatic disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Routine chest x-rays may reveal a hilar mass or hilar fullness. Chest x-rays are limited, however, they may show lobar collapse, pleural effusions suspicious for a malignant effusion, or elevation of the diaphragm suggesting phrenic nerve involvement.
- A computed tomography (CT) scan of the chest should be obtained for all patients being evaluated for possible pneumonectomy (**FIG 1**). If available, prior CT scans should be used for comparison. A CT scan of the chest can be used to assess staging of the primary lesion, degree of local chest wall, or mediastinal invasion. The presence of hilar or mediastinal lymphadenopathy should be noted. CT may understage mediastinal LN by missing LNs positive for metastatic disease that are not enlarged or greater than 1 cm. Therefore, a CT chest alone is not sufficient for preoperative staging.
- Positron emission tomography (PET)/CT should be performed to confirm metabolic activity in the primary lesion, to assess for distant metastases, and to increase the ability to detect nodal involvement. PET/CT has a high false-positive rate; therefore, suspicious lesions on PET should be confirmed with a tissue diagnosis.
- Magnetic resonance imaging (MRI) of the brain is used to assess for distant metastases that are not able to be imaged on PET/CT and should be obtained for all patients with central lesions.
- Pulmonary function tests (PFTs) are necessary to define the patient's ability to tolerate a pneumonectomy. In general, postoperative calculated forced expiratory volume (FEV_1) of less than 40% predicted or a diffusing capacity of the lung for carbon monoxide (DL_{CO}) less than 40% predicted are significant predictors of morbidity and mortality following pneumonectomy and should be used to guide candidate selection.
- In patients with marginal PFTs, a ventilation-perfusion (V/Q) scan should be obtained. Patients with large proximal tumors compromising lung function may have compensated through shunting and therefore may better tolerate a pneumonectomy than would be predicted based on their preoperative PFTs. Other cardiopulmonary testing such as maximum oxygen consumption (VO_{2max}) can be used to evaluate patients who are marginal candidates for resection.

FIG 1 ● CT scan of chest demonstrating a right hilar mass causing partial lobar collapse of the right upper lobe.

Patients with a Vo_{2max} less than 15 mL/kg/min and a postoperative predicted FEV_1 and DL_{CO} less than 40% are at high risk for postoperative complications.[1]

- A cardiac workup including an electrocardiogram (EKG) and an echocardiogram and stress test in patients with significant risk factors for coronary artery disease should be performed. Patients with signs of right heart failure or pulmonary hypertension are at high risk for mortality postoperatively.
- Routine lab work including liver function tests and alkaline phosphatase should be obtained.
- A tissue diagnosis of the primary lesion is helpful in the preoperative planning and staging for a lung resection. Patients with small cell lung cancer lesions are not candidates for pneumonectomy. Due to proximity to hilar structures, a CT-guided fine needle aspiration (FNA) may be technically challenging. When tumors are intraluminal and visible on flexible bronchoscopy, biopsies can easily be obtained. Other modalities such as endobronchial ultrasound (EBUS) FNA or navigational bronchoscopy can be used to biopsy a hilar mass if not visible on flexible bronchoscopy.
- Mediastinoscopy and LN biopsy should be performed on all patients considered for pneumonectomy. Patients with enlarged mediastinal LN on CT or have increased metabolic activity on PET/CT have a high likelihood of having mediastinal LN metastases. Mediastinal LN involvement (N2 disease) may lead to neoadjuvant chemoradiotherapy.

SURGICAL MANAGEMENT

Preoperative Planning

- Active smokers should be counseled to quit smoking weeks in advance, as smoking has been found to be an independent risk factor for adverse outcomes.[2]
- A thoracic epidural catheter should be placed prior to surgery unless there is a contraindication.
- Prior to surgery, all patients should undergo flexible bronchoscopy by the operating surgeon to assess resectability. On flexible bronchoscopy, the location of the tumor with respect to the trachea and main bronchus should be assessed (**FIG 2**). Copious respiratory secretions may warrant a course of antibiotics to treat pneumonia prior to pneumonectomy.
- CT chest images should be reviewed, and final planning for the procedure should occur.
- The patient should have an active type and screen and have blood available in the blood bank, and antibiotics should be administered prior to skin incision.
- An arterial line should be placed prior to incision.
- Communication between the surgeon and anesthesiologist is critical. Excessive intravenous (IV) fluid administration in the perioperative period (particularly intraoperative and postoperative) is associated with acute lung injury in patients undergoing pneumonectomy.
- High tidal volumes during single-lung ventilation have been linked to increased rates of respiratory failure postoperatively. Low tidal volume ventilation (5 to 6 mL/kg) to prevent barotrauma is preferred with peak inspiratory pressures not to exceed 35 cm H_2O and plateau pressures to remain below 25 cm H_2O.[3]

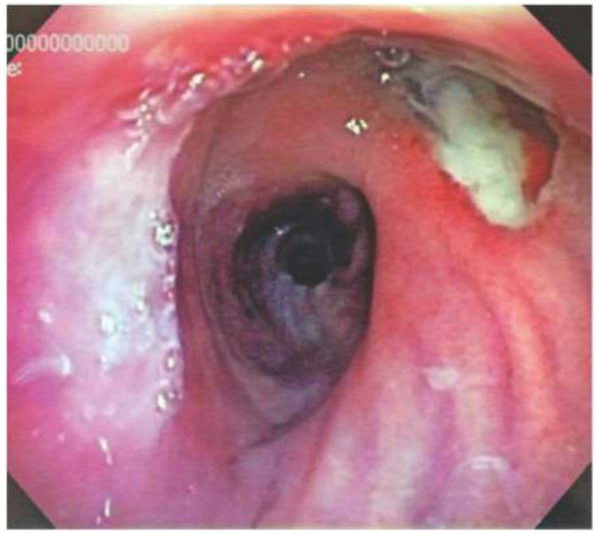

FIG 2 • Preoperative flexible bronchoscopy demonstrating an adenocarcinoma involving the right upper lobe bronchus.

Positioning

- Patients are intubated with a double lumen tube and positioned in the lateral decubitus position with the surgery side up. Rolled blankets or a "beanbag" are used to hold the patient upright. An arm board or ether screen can be used to support the arms. All pressure points should be well padded with particular attention paid to the common peroneal nerve. An axillary roll may be used to support the axilla. The bed is flexed and the patient should be secured to the bed with heavy tape and a belt (**FIG 3**).

FIG 3 • Patient positioned in the left lateral decubitus position for a right pneumonectomy.

RIGHT PNEUMONECTOMY

Posterolateral Thoracotomy

- A standard posterolateral thoracotomy incision is made 1 to 2 cm below the scapula. The latissimus dorsi muscle is divided. The serratus is mobilized along its posterior border and retracted anteriorly. The 4th intercostal space is entered on top of the 5th rib. If an intercostal muscle flap will be used to cover the bronchial stump, it should be created during the entry into the pleural space. The 5th rib is shingled by dividing it at the border of the paraspinous muscles and removing a small segment. A chest retractor is placed in the rib space and the lung hilum is exposed.

Assessment of Resectability

- The visceral and mediastinal pleura are examined initially for signs of pleural spread. The right lower lobe is grasped and retracted cephalad and the inferior pulmonary ligament is divided with cautery. Level 9 LNs are excised during this step or are swept into the specimen. Assessment of the lung hilum is performed by identifying the phrenic nerve and dividing the mediastinal pleura lateral to the nerve (**FIG 4**). The landmarks for dissection are the inferior border of the azygous vein to the inferior pulmonary vein. The lung is retracted caudally and medially, and dissection of the mediastinal pleura is carried over the superior aspect of the hilum and posterior to the bronchus. Care is taken to separate the right main bronchus from the esophagus. Resection of the subcarinal LN packet can be performed at this time. The tumor should be readily palpated at this point, and the degree of vascular invasion as well as invasion of surrounding structures should be assessed. The need for pneumonectomy should be reassessed and consideration should be given to a lesser pulmonary resection if oncologically feasible. Tumor that extends onto the pulmonary artery or the pulmonary veins and cannot be safely taken with a stapler may require an intrapericardial ligation of the vascular structure. This should be determined at this time.

Division of Pulmonary Veins

- There is no specific order to the division of the lung hilar structures, and division of the vascular structures may proceed according to which are most convenient for division. With the mediastinal pleura open and the inferior pulmonary ligament divided, the inferior and superior pulmonary veins are readily visualized. The lung is retracted cephalad and laterally, exposing the inferior pulmonary vein. Careful blunt dissection is used to dissect the inferior vein from the mediastinum. Prior to division of the veins, they should be reassessed for tumor involvement. Division of the vein is most commonly accomplished using a vascular stapler. The superior pulmonary vein is exposed by lateral retraction of the lung. The superior vein lies in close proximity to the pulmonary artery and this must be accounted for during dissection of the posterior aspect of the vein. Once the vein is completely dissected and able to be encircled, it is divided with a vascular stapler (**FIG 5**). If either the superior or inferior veins are invaded by the tumor, the pericardium can be entered and an additional 1 to 2 cm of vein can be exposed.

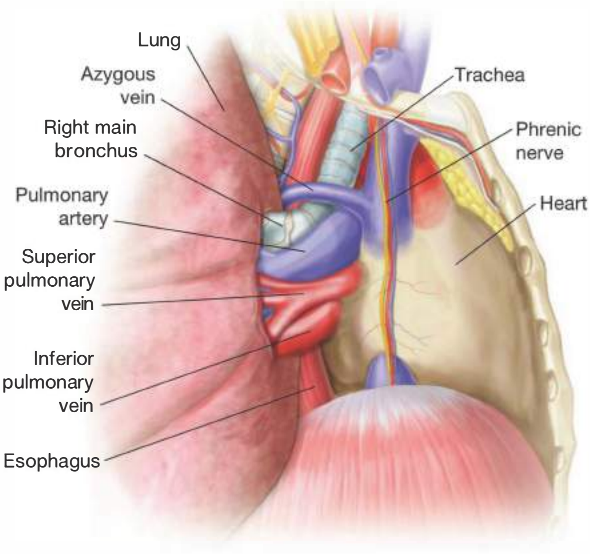

FIG 4 ● Right pneumonectomy. Exposure of the right hilar structures. Initial dissection of the right hilum proceeds with division of the mediastinal pleura lateral to the phrenic nerve.

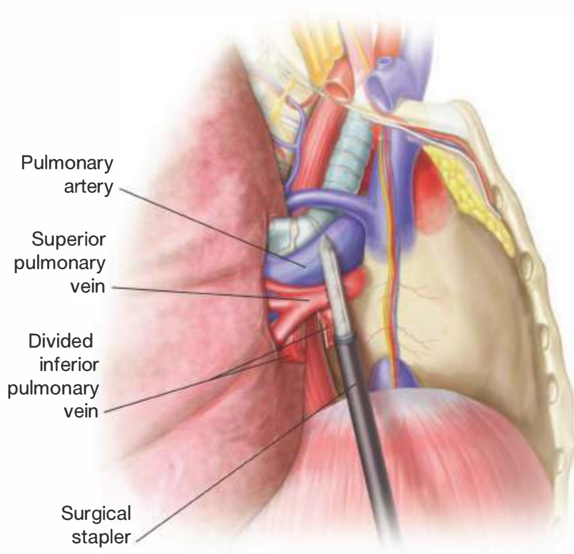

FIG 5 ● Right pneumonectomy. Division of the superior pulmonary vein is performed using a vascular stapler. The inferior pulmonary vein has already been divided.

Division of Pulmonary Artery

- With the mediastinal pleura divided and the lung retracted laterally, the pulmonary artery is visible cephalad and posterior to the superior pulmonary vein. The artery should be assessed for tumor invasion by palpation after it is carefully dissected. The pulmonary artery must be handled carefully during dissection as it is relatively thin walled compared to the pulmonary veins and can tear easily resulting in potentially catastrophic hemorrhage. Therefore, all dissection should be blunt around the artery and cautery should be used sparingly if at all. In patients who are borderline candidates for resection, that is, those who have elevated pulmonary arterial pressures, we prefer to dissect the pulmonary artery first and perform a test clamp of the artery prior to division of any hilar structure. If the patient has significant negative hemodynamic changes with the test clamp, the procedure is aborted. In our institution, we typically use a vascular stapler to divide the artery (**FIG 6**); however, some surgeons prefer to clamp the artery with a vascular clamp and oversew the artery with a nonabsorbable suture after it has been divided. As with the pulmonary veins, if the tumor invades or is adherent to the artery and it is unclear if a margin can be obtained on the vessel, the pericardium can be entered away from the tumor to provide an extra 1 to 2 cm of length to safely divide the artery.

Division of Bronchus

- The lung is retracted medially to reveal the membranous trachea (**FIG 7**). From the right side, the carina is visible after excision of the subcarinal LNs. When preparing to divide the bronchus, it must be remembered to minimize proximal dissection on the trachea and to divide the bronchus as close to the carina as possible. This serves to preserve the blood supply to the bronchial stump and prevents the pooling of secretions leading to stump breakdown and bronchopleural fistula formation. In our institution, we typically divide the bronchus using a thick tissue surgical stapler. Alternately, the bronchus may be divided sharply and the trachea closed with a series of interrupted 4-0 absorbable sutures (**FIG 8**). The right

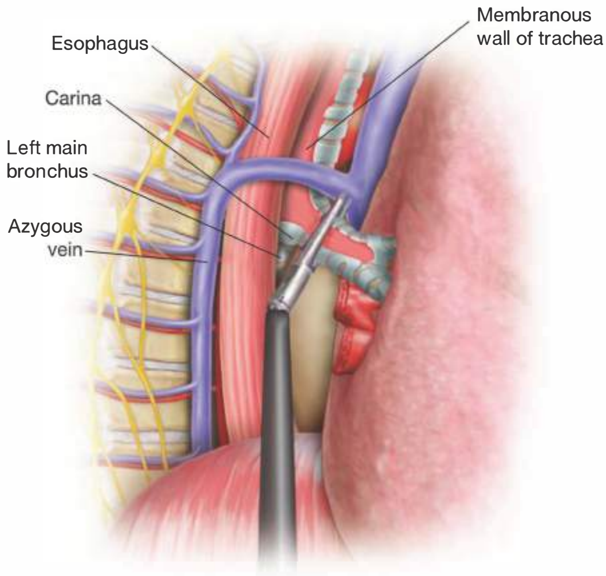

FIG 7 • Right pneumonectomy. Division of the right main bronchus. The lung is retracted medially and the membranous trachea is exposed. A thick tissue stapler is used to divide the bronchus as close to the carina as possible.

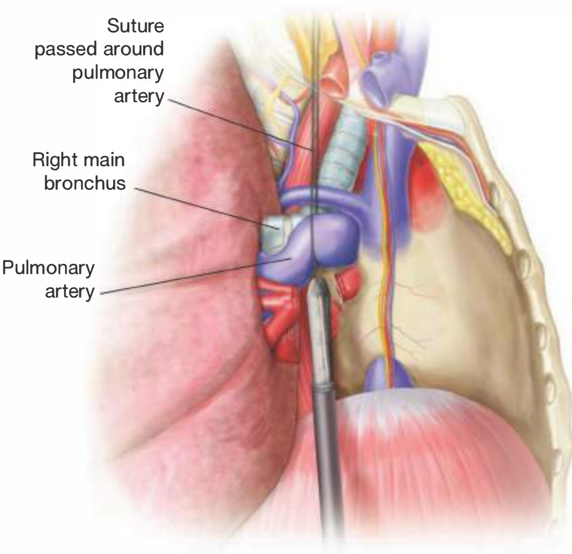

FIG 6 • Right pneumonectomy. The pulmonary artery is carefully dissected and encircled with a tie. After palpating the artery for involvement with tumor, it is divided using a vascular stapler.

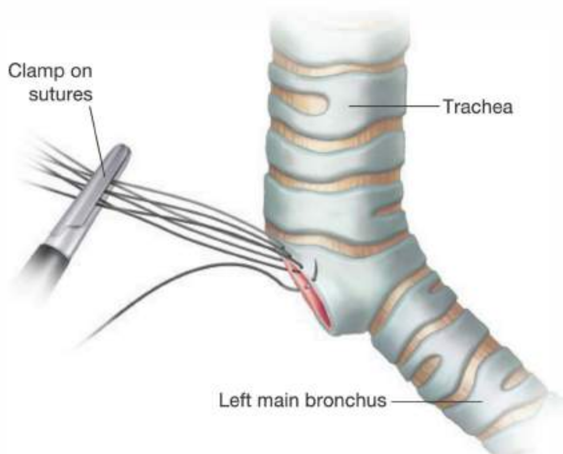

FIG 8 • Right pneumonectomy. Suture closure of the right bronchus. The bronchial stump may be alternatively closed with a series of interrupted 4-0 absorbable sutures.

bronchial stump is at high risk for stump breakdown and fistula formation. This is thought to be due to the lack of soft tissue coverage on the right side as compared to the left. In our institution, we cover all bronchial stumps with vascularized tissue. Due to its robust vascular supply, we prefer to use an intercostal muscle flap, although others have described using pericardial fat, parietal pleura, or pericardium to cover the bronchial stump. The pleural cavity should be filled with warm saline and the stump tested for a leak under water at pressures of 20 to 25 cm H_2O.

LEFT PNEUMONECTOMY

Exposure and Assessment of Resectability

- The exposure and dissection for a left pneumonectomy proceeds in a similar sequence as for a right pneumonectomy. The patient is placed in the right lateral decubitus position and a standard left thoracotomy is performed. During dissection, consideration must be made for the course of the left RLN. On the left side, the RLN passes around the arch of the aorta from anterior to posterior (**FIG 9**). When mobilizing the hilum or removing the aortopulmonary window LNs, care must be made to avoid injury to the nerve. During the initial assessment, it should be noted if there is invasion of the nerve by the tumor. The mediastinal pleura is divided lateral to the phrenic nerve and the inferior pulmonary ligament is divided. The hilum is exposed and the tumor should be assessed for resectability by palpating the hilar structures.

Division of Pulmonary Veins

- With the mediastinal pleura divided, the lung is retracted laterally. The pulmonary veins are identified and, after careful blunt dissection, are divided using a vascular stapler.

Division of Pulmonary Artery

- The pulmonary artery is visualized cephalad to the superior pulmonary vein. It is divided using a vascular stapler after careful blunt dissection.

Division of Bronchus

- The left main bronchus is longer than the right bronchus, and exposure of the carina is often challenging due to the presence of the heart on the left side. However, the same principles are applied to dividing the left bronchus as to the right. Proximal dissection is minimized to preserve blood flow to the bronchial stump. The bronchus is divided as close as possible to the carina using a thick tissue stapler. The stump should be covered with well-vascularized tissue to facilitate healing. The pleural cavity should be filled with warm saline and the stump tested for a leak under water at pressures of 20 to 25 cm H_2O.

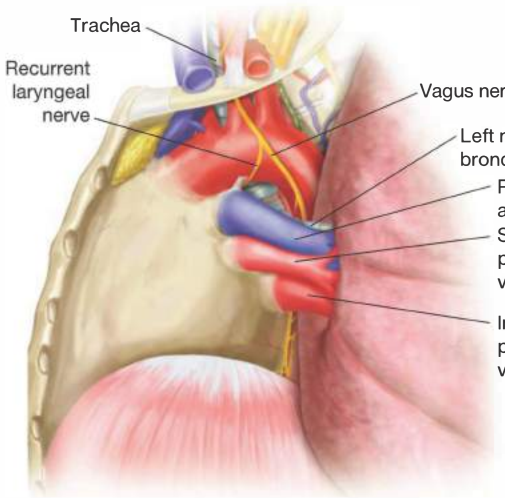

FIG 9 ● Left pneumonectomy. Division of the mediastinal pleura exposes the left hilum. Care should be exercised to avoid injuring the left RLN during dissection of the hilum.

PEARLS AND PITFALLS

Patient selection	▪ Pneumonectomy is associated with a high rate of postoperative morbidity. ▪ Consideration should be given to a lesser pulmonary resection if oncologically feasible. ▪ There is no one test to determine if a patient is able to tolerate a pneumonectomy but is a clinical decision based on a patient's performance status and PFTs.
Intraoperative management	▪ IV fluid should be restricted intraoperatively. ▪ Test clamp the pulmonary artery prior to division. ▪ Low tidal volume ventilation should be used when the patient is intubated. ▪ Early extubation should be the goal for all patients.
Bronchial stump closure	▪ Bronchial stump should be flush with the carina. ▪ All bronchial stumps should be reinforced with pedicled soft tissue coverage. ▪ The bronchial stump should be tested under water for leaks after it is divided at a pressure of 20 to 25 cm H_2O. ▪ The right bronchial stump is at increased risk for breakdown compared to the left side.

Avoidance of RLN damage	■ During dissection of the left hilum need to be alert to the presence of the RLN at the arch of the aorta.
Management of the postpneumonectomy space	■ If a chest tube is inserted into the postpneumonectomy space, it should be placed on water seal and removed within the first 48 hours.
Postoperative management	■ Patients should be fluid restricted for the first 48 hours with IV fluids titrated to urine output. ■ Aggressive pulmonary toilet should be performed and a low threshold for bronchoscopy should be maintained for clearance of respiratory secretions.

POSTOPERATIVE CARE

- Patients should be extubated, if possible, in the operating room and transferred to an intensive care unit immediately postoperative.
- If a chest tube is inserted into the pneumonectomy space, it should be placed on water seal and removed within 48 hours. Suction applied to a chest tube may induce a mediastinal shift into the postpneumonectomy space causing significant hemodynamic changes.
- Daily chest x-rays should be obtained with attention paid to the level of pleural fluid on the pneumonectomy side and the position of the mediastinum. By 2 weeks, the postpneumonectomy space should be 80% to 90% filled with pleural fluid and complete opacification should occur by 4 weeks postoperatively.
- Patients should be fluid restricted over the first 24 to 48 hours postoperative, and IV fluids should be judiciously adjusted to maintain adequate renal function as acute lung injury is associated with patients who receive more than 3 L of crystalloid in the first 24 hours.[4] Diuretics should be administered to patients demonstrating signs of fluid overload or respiratory distress.
- Pneumonectomy patients need aggressive pulmonary toilet and should ambulate within 48 hours of surgery. Physical therapy should be involved early in the postoperative course of debilitated patients.
- A low threshold to perform bronchoscopy for pulmonary toilet should be maintained for those patients who are unable to generate a cough, clear their respiratory secretions, or have a change in respiratory status.

OUTCOMES

- In general, a pneumonectomy is well tolerated among carefully selected patients. However, pneumonectomy is a procedure associated with significant postoperative morbidity and mortality. Rates of major postoperative adverse events vary depending on the series but ranges from 30% to 59%.[5] Pneumonectomy is generally associated with a mortality of 4% to 8%.
- Right-sided pneumonectomies are associated with higher rates of postoperative morbidity and mortality. This is thought to be due to an increased incidence of bronchopleural fistulas in this patient population.[6]
- Increasing age has a negative effect on outcome, with patients older than 65 years having a significantly higher risk of having an adverse event than younger patients.

COMPLICATIONS

- Respiratory failure
- Pulmonary edema/acute respiratory distress syndrome (ARDS)
- Pneumonia
- Atelectasis
- Chylothorax
- Postpneumonectomy syndrome
- Bronchopleural fistula
- Empyema
- Arrhythmias: most commonly supraventricular arrhythmias
- Myocardial infarction
- Wound infection
- Deep vein thrombosis/pulmonary embolism
- Vocal cord paralysis

Chapter 9

Thymectomy

Jason Leonard Muesse Shanda Haley Blackmon

DEFINITION

- Thymectomy is defined as resection of the thymus gland.
- The most common indications for thymectomy are myasthenia gravis and thymoma. Less common indications for thymectomy include thymic carcinoma, neuroendocrine tumors of the thymus, ectopic parathyroid glands, and thymic cysts.
- Thymectomy has been most commonly performed through a median sternotomy, as described by Alfred Blalock. Alternate approaches include video-assisted thoracoscopic surgery (VATS), robotic-assisted thoracoscopic surgery (RATS), and transcervical approach.[1]

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of anterior mediastinal mass includes thymoma, thymic carcinoma, lymphoma, and germ cell tumor.
- Thymomas have cytologic features of malignancy in less than 10% of cases. However, thymomas lacking malignant features cytologically can express malignant behavior by recurring locally and metastasizing even after resection; thus, the term "benign" thymoma should not be used.[2]
- The most widely accepted and clinically applicable staging system for thymoma is the Masaoka staging system, which is based on microscopic or macroscopic invasion into mediastinal structures.[3]

PATIENT HISTORY AND PHYSICAL FINDINGS

- One-third of patients with thymoma are asymptomatic.
- Among patients symptomatic from thymoma, about 40% present with local symptoms directly related to the mass itself, including chest pain, cough, and dyspnea, but can include superior vena cava syndrome.[2]
- The parathymic syndrome most commonly associated with thymoma is myasthenia gravis, which occurs in approximately 45% of patients with thymoma (reported ranges from 10% to 67%). Other associated autoimmune conditions include pure red cell aplasia and hypogammaglobulinemia, which can occur in up to 5% of people with thymoma.[2]
- Approximately 10% to 15% of patients with myasthenia gravis have a thymoma.
- Fevers, night sweats, and other constitutional symptoms may indicate lymphoma rather than thymoma.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Computerized tomography is the most useful imaging modality for thymoma. Thin-slice cuts will improve preoperative planning.
- Thymomas can have variable uptake on positron emission tomography, so it is not routinely recommended. Magnetic resonance imaging can also provide helpful information about invasion into vessels or adjacent structures (**FIG 1**).[4]
- Masses larger than 5 cm (not including thymus gland itself) in maximal diameter or those invading mediastinal structures either warrant specialized surgical planning or possibly enrollment into a neoadjuvant treatment protocol.[5]
- Fine needle aspiration or core biopsy of the anterior mediastinal mass is recommended preoperatively in most cases to rule out lymphoma or germ cell tumor. If the biopsy is consistent with thymoma, resection of the entire thymic gland is indicated.[4]
- Myasthenia gravis can be diagnosed with serum testing for the acetylcholine receptor antibody or through clinical improvement in symptoms with administration of edrophonium chloride.

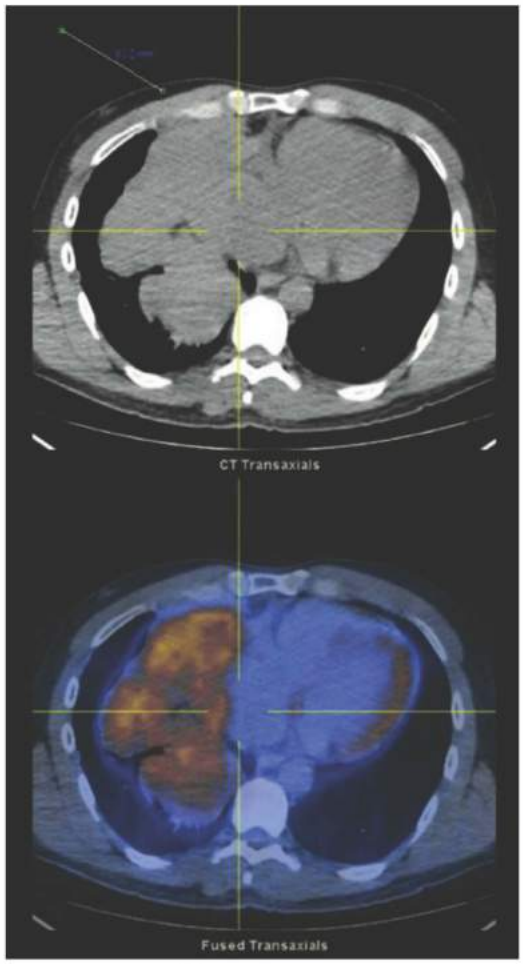

FIG 1 • Positron emission tomography (PET) scan. Standard uptake value (SUV) of 6.5 in biopsy-proven thymoma measuring 14 cm × 8.3 cm in 38-year-old male.

SURGICAL MANAGEMENT

Preoperative Planning

- The decision to perform thymectomy for treatment of myasthenia gravis must involve the patient, the treating neurologist, the anesthesiologist, and the thoracic surgeon. Preoperative optimization of the patient's myasthenia gravis symptoms with pyridostigmine, steroids, and in some cases, plasmapheresis is critical.
- Special anesthetic requirements may be necessary for patients with myasthenia gravis, taking care to avoid anticholinergics. The anesthetic team should be notified preoperatively of the patient's medical condition and the severity of their symptoms in appropriate time to make accommodations.[6]
- All patients who will undergo single-lung ventilation (VATS or RATS) should have preoperative pulmonary function testing to ensure they will be able to tolerate single-lung ventilation during resection. If the patient is deemed unable to tolerate single-lung ventilation, resection via sternotomy or transcervical approach is indicated. All patients with myasthenia gravis need pulmonary function testing preoperatively.
- Central venous access should be obtained prior to beginning procedure.
- A sternal saw should always be present in the operating suite and readily available in the event emergent conversion to sternotomy for bleeding is necessary.

Positioning

- For median sternotomy or transcervical approach, a single lumen endotracheal tube is adequate.
- For VATS or robotic-assisted thoracoscopic approach, we strongly prefer the use of double lumen endotracheal tube placement to single lumen endotracheal tube with bronchial blockers. If the patient needs to be repositioned intraoperatively, we feel that the double lumen endotracheal tube is much less likely to be dislodged than a bronchial blocker and provides more reliable lung isolation.
- We confirm the placement of the double lumen endotracheal tube with bronchoscopy before positioning the patient.
- Each time the patient is repositioned, proper placement of the double lumen endotracheal tube is confirmed with bronchoscopy.

TECHNIQUES

THYMECTOMY BY STERNOTOMY

Positioning

- Place patient in supine position.
- We prefer arms tucked at the patient's side and use an axillary roll placed laterally under the scapulae.
- Use clippers to remove hair from sternal notch to below xiphoid process. Prep and drape skin in sterile fashion from the sternal notch to below xiphoid process.

Boundaries of Dissection

- The boundaries of dissection for radical thymectomy are the innominate veins superiorly, the phrenic nerves bilaterally, and the diaphragm inferiorly (**FIG 2**).
- Preservation of the phrenic nerve is of the upmost importance and it should never be sacrificed unless the diagnosis of thymic carcinoma is confirmed and tumor grossly invades the nerve. Even in these cases, the surgeon must consider the implications of diaphragmatic paralysis on a patient who may need adjuvant chemotherapy and radiation. Both phrenic nerves should never be divided.[1]
- With invasive thymoma, involved structures should be resected en bloc with the thymic mass at the time of initial operation, always sparing at least one phrenic nerve.[7]
- Mark areas of dissection for invasive thymoma with surgical clips to help direct future radiation therapy.[7]

Median Sternotomy Incision

- Partial or "mini-sternotomy" can be used as long as entirety of thymus tissue can accessed and phrenic nerves visualized bilaterally. Visualization must not be sacrificed for cosmesis (**FIG 3**).[7]
- Incise skin from 1.5 cm below the sternal notch to level of 4th or 5th intercostal space for partial sternotomy or to xiphoid process for full sternotomy.
- Use a sternal saw to separate the sternum down the midline.
- Mind adhesions that could be present from the underlying thymoma itself or from previous sternotomy.

Right Inferior Pole Dissection

- The order of dissection with regard to thymectomy by sternotomy is surgeon preference, with regard to starting on the right or left or from the superior or inferior. We choose to start at the right inferior pole for both open and minimally invasive approaches.
- The right phrenic nerve is identified.
- The right inferior pole is identified and dissected from the pericardial fat pad, dividing attachments to non-thymic tissue.
- Arterial blood supply to the inferior pole is from the pericardiophrenic branches. These small vessels are well suited for ligation with a bipolar energy source such as LigaSure (Covidien, Mansfield, Massachusets) or an ultrasonic vessel-sealing device such as the Harmonic Ace (Ethicon Endo-Surgery, Blue Ash, Ohio). These devices are also useful for dividing the mediastinal pleura and connecting tissue.
- The mediastinal pleura is incised 1 cm medial to the right phrenic nerve and division is carried cranially along the lateral aspect of the thymus toward the superior pole. Be mindful of lateral energy transfer from electrocautery or bipolar energy source that could damage the phrenic nerve.
- The major arterial blood supply to the thymus is lateral, from branches of the internal mammary artery. These vessels can be tied, clipped, or divided with advanced vessel-sealing devices as mentioned earlier.

Right Superior Pole Dissection

- Continue dissection of the mediastinal pleura cranially toward the right superior pole.

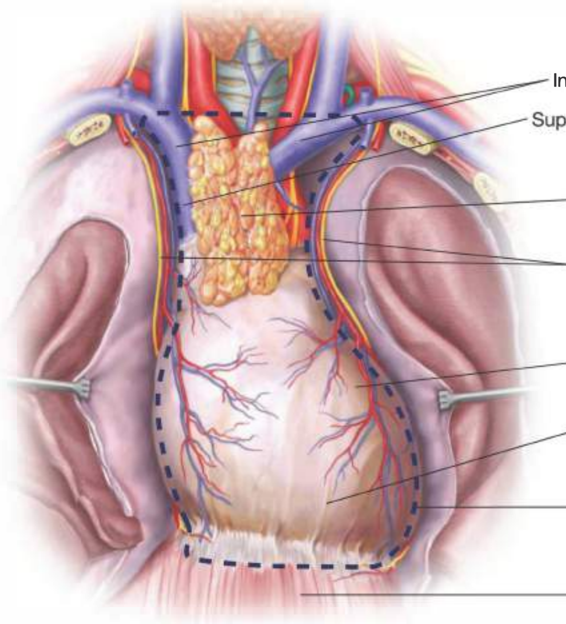

FIG 2 ● Boundaries of dissection for radical thymectomy. Innominate veins superiorly, phrenic nerves laterally, and diaphragm inferiorly. Sternum is anterior to the thymus and the pericardium is posterior to the thymus.

- Gently use the divided thymic tissue as a handle for downward retraction to expose the right superior pole.
- The arterial blood supply to the superior pole branches off the inferior thyroid artery. These vessels can be divided between ties or clips or using advanced vessel-sealing devices.
- Divide the right thyrothymic ligament between clamps or using an advanced vessel-sealing device. Once vessels or tissue attached to the superior pole are divided, they can retract cranially, making gaining control of bleeding difficult.
- Occasionally, a vein draining into the right innominate vein may be encountered. Divide it if present.

Left Inferior Pole Dissection

- Redirect attention to the right inferior pole. Divide the mediastinal pleura from the right lateral pole to the left lateral pole just above the level of the diaphragm, taking care to include all inferior thymic tissue with the thymus.
- Identify the left phrenic nerve and avoid damage to it when dividing laterally across the inferior aspect of the thymic tissue.
- Dissect the left inferior pole away from the pericardial fat pad and divide the left inferior pole from its attachments.
- Incise the mediastinal pleura 1 cm medially from the left phrenic nerve and continue division cranially.
- Divide the left lateral branches of the internal mammary artery.

Left Superior Pole Dissection

- Gently use divided thymic tissue for downward retraction.
- Proceed with division of lateral attachments of thymic tissue toward the left superior pole. Divide remaining attachments of the left superior pole, including branches of the left inferior thyroid artery supplying it.
- There are usually one or two veins that drain the thymus. These are most often encountered at the left superior pole, emptying from the thymus into the left innominate vein. Uncontrolled division of these veins will result in significant hemorrhage, with the superior end of the vein retracting cranially, often out of view. We use a surgical clip or tie proximally and distally when dividing these veins. This vein can also be torn inadvertently with excessive downward retraction on the thymus.
- Small lymphatic branches entering the thoracic duct may be encountered and should be clipped if inadvertently divided. The appearance of chyle may signify division of lymphatic vessels.
- Divide any attachments, if present between left superior and right superior poles.
- Divide the posterior attachments of the thymus to the pericardium.

Specimen Removal

- Remove specimen.
- If thymoma is present, avoid disruption of the capsule.

Sternal Closure

- Place mediastinal drain. If the pleural spaces have not been violated, chest tubes are not necessary.
- Close sternum with sternal wires. Larger patients may benefit from contemporary sternal closure devices to prevent dehiscence, such as sternal plating or use of the Synthes ZipFix System (Synthes Incorporated, West Chester, Pennsylvania). Close overlying skin in preferred manner. We use skin adhesive over all incisions.

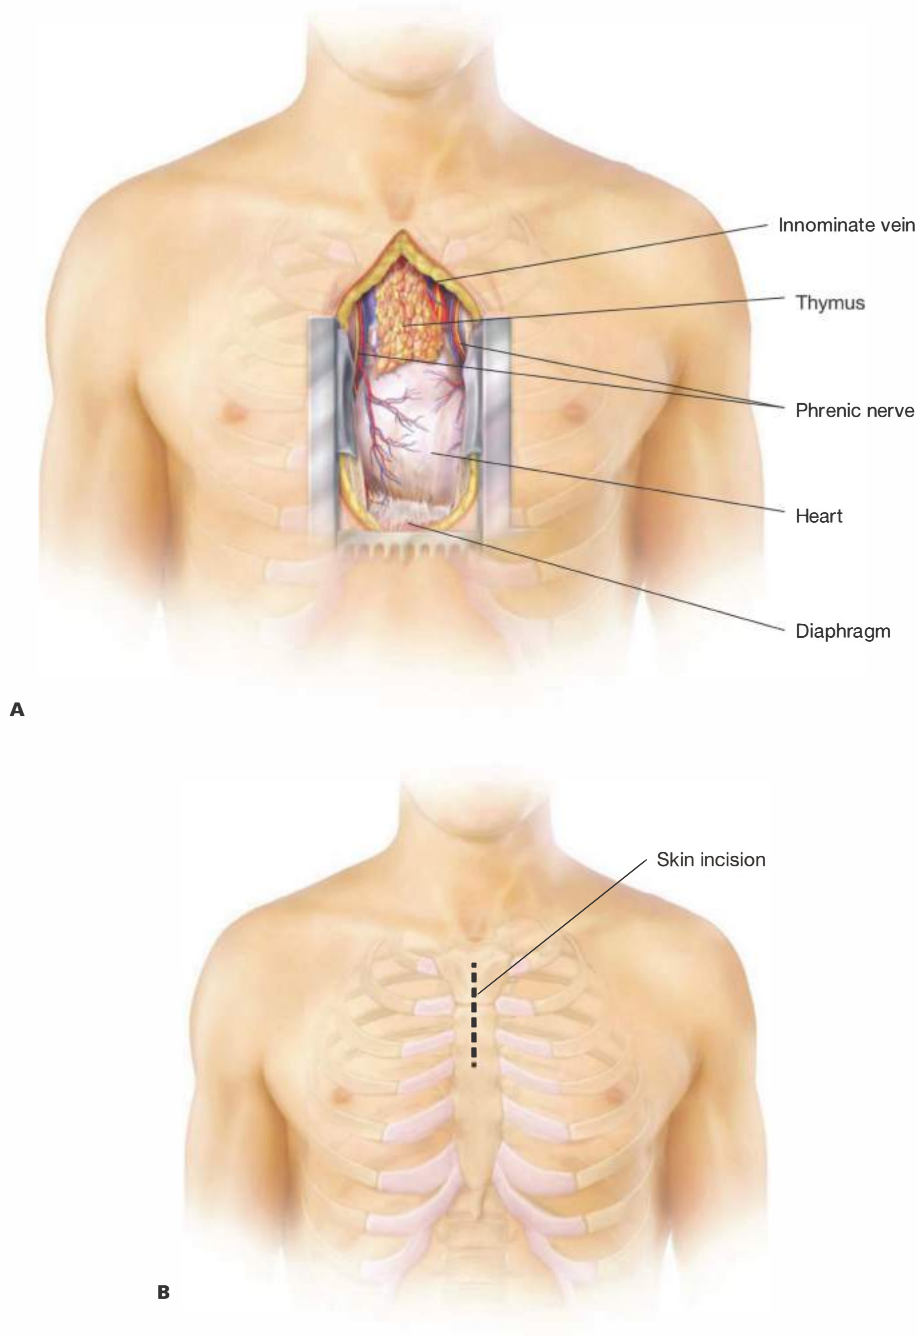

FIG 3 ● **A.** Traditional median sternotomy. **B.** Partial or "mini" sternotomy with incision extending to the level 4 or 5 intercostal space.

VIDEO-ASSISTED THORACOSCOPIC SURGERY THYMECTOMY

Positioning

- Because thymic tissue left behind at time of resection for thymoma or myasthenia gravis can be devastating, we advocate a bilateral approach to thymectomy for VATS and some selected robotic-assisted thymectomy to ensure that all thymic tissue is visualized and removed. When working from one side alone, we feel that the contralateral phrenic nerve cannot always be adequately visualized and is therefore risk of injury when trying to divide the lateral-most attachments. In those cases, a contra lateral VATS check is appropriate.
- For VATS or robotic-assisted approach, the right side should be approached first because of physical constraints from the heart on the left.
- For VATS thymectomy, position the patient in left lateral decubitus, on a beanbag and with an axillary roll in place.
- The patient's anterior superior iliac spine should be at a break in the bed, and the bed should be broken at the hips to at least 30 degrees. This opens the interspaces of the ribs to facilitate port insertion and allows the lung to fall away posteriorly.
- Place the right arm on a support brace over the left arm.
- Pad all pressure points.
- The monitors are placed on each side of the patient near the head. The surgeon and assistant stand on the posterior side of the patient.

Port Insertion

- For VATS approach, 5-mm thoracoscopic instruments can be used for throughout the case but one port site will need to be enlarged for specimen removal at the end of the case (**FIG 4A**).
- If needed, a 12-mm working port can be added on either side to insert a ring clamp for retracting the thymus downward.

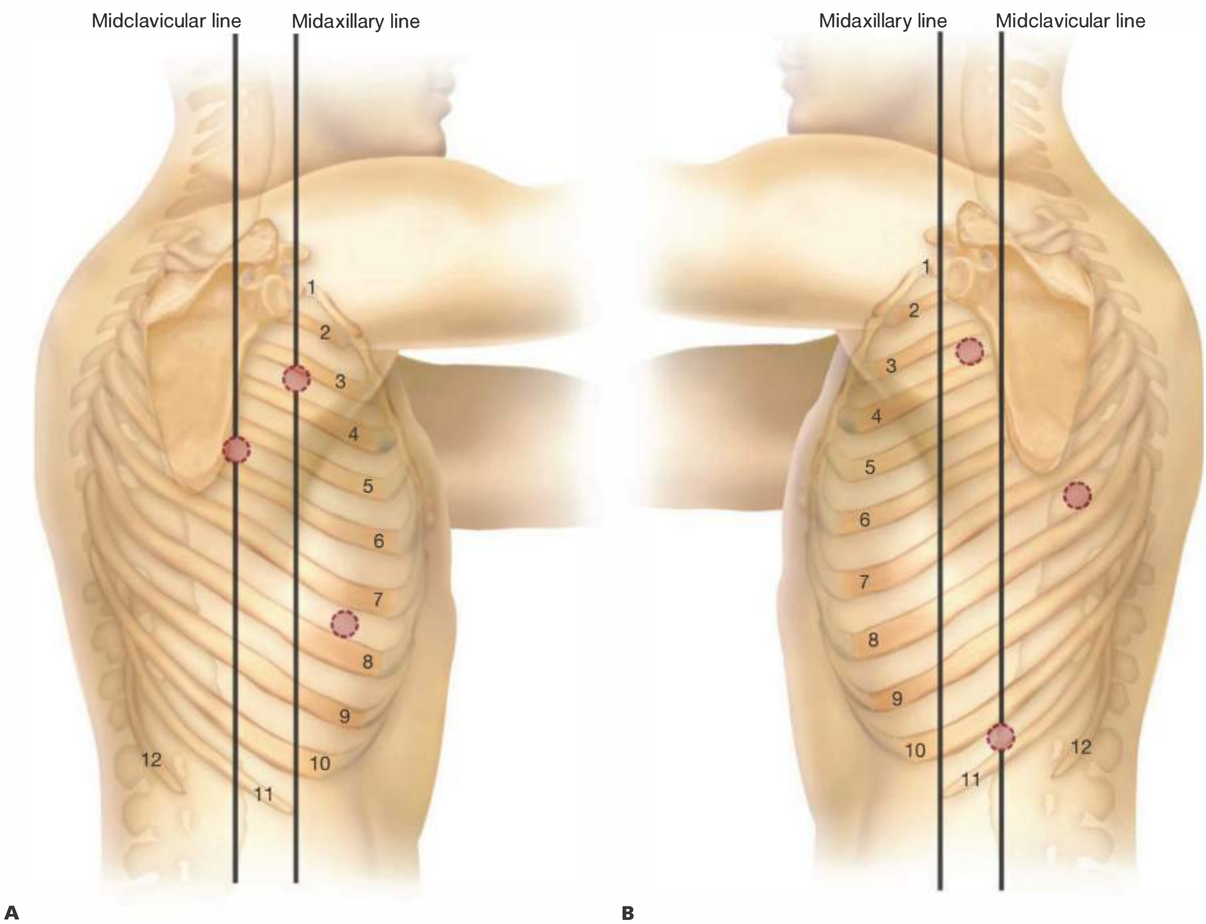

FIG 4 ● **A.** Port placement for right-sided dissection during VATS thymectomy. **B.** Port placement for left-sided dissection during VATS thymectomy.

- Always use protected ports during thymectomy for thymoma, as seeding of the thoracic wall from malignancy has been reported.
- Before inserting the first port, ask the anesthesiologist to stop ventilation to the lung on the side that you will be working on. Confirm adequate single-lung ventilation.
- If starting on the right side, insert the first port between at the 5th or 6th intercostal space along the posterior axillary line. Insert the thoracoscope and inspect the thoracic cavity for suspicious lesions or effusions signaling malignant disease. Biopsy any suspicious lesions and send any suspicious fluid to pathology (**FIG 4A**).
- Under direct intrathoracic visualization from the first thoracoscopic port, taking care to avoid any adhesions or adherent lung parenchyma, insert the second port at the 3rd or 4th intercostal space along the midaxillary or anterior axillary line. This will serve as the camera port for most of the dissection (**FIG 4A**).
- Similarly, insert the third thoracoscopic port at the 5th or 6th intercostal interspace along the anterior axillary line (**FIG 4A**).
- Port location can be varied according to surgeon preference, and additional ports should be used if visualization is not optimal.
- The left-sided ports will need to be placed slightly more posterior in comparison to the right-sided ports to account for the pericardium and heart (**FIG 4B**).
- Insufflation with 8 to 10 mmHg of carbon dioxide gas can facilitate dissection of the thymus away from the sternum anteriorly and pericardium posteriorly, but we do not routinely use insufflation in the thoracic cavity for thymectomy.
- We place bupivacaine or exparel (liposomal bupivacaine) intercostal nerve blocks to the port sites under direct visualization at the time of thoracoscopy, being especially generous around port site where the thoracostomy tube will exit.

Division of Right Inferior Pole

- Identify the right phrenic nerve.
- Proceed with division of right inferior pole from the pericardial fat pad using an advanced vessel-sealing device.
- Using electrocautery at low settings in cutting mode, the mediastinal pleura can be scored 1 cm medially from the right phrenic nerve. This can facilitate lateral dissection.

Division of Right Superior Pole

- Proceed cranially to the right superior pole as described previously using advanced vessel-sealing device to divide attachments.
- Divide right superior pole and right thyrothymic ligament.

Medial Dissection

- From the right side, proceed with dissection toward the patient's left side, dividing superior and inferior attachments of the thymus past midline.
- You will be able to accomplish most of the thymectomy from the right side. However, once it becomes difficult to see the leftmost aspect of the thymus and you cannot safely divide tissue without ensuring that left phrenic nerve is protected, stop dissection from the right side.
- Confirm hemostasis of previously divided tissue. An absorbable hemostatic agent such as Surgicel (Ethicon, Bridgewater, New Jersey) can be used at the superior pole for minor oozing.
- Place a small-bore chest tube on the right under direct visualization and ensure the right lung inflates adequately as positive pressure is administered by the anesthesiologist.
- Remove the other ports and confirm hemostasis from port sites. Close intercostal muscles in one layer with interrupted absorbable sutures and close overlying skin in preferred manner.

Repositioning

- Reposition the patient in right lateral decubitus position with the bed flexed to 30 degrees at hips, using a beanbag and axillary roll as mentioned previously.
- For the left-sided approach, the ports are rotated slight posterior to account for the heart and pericardium. The surgeon and assistant again stand on the patient's posterior side.
- Insert thoracoscopic ports on the left in the same manner as on right.
- Inspect the left thoracic cavity.

Division of Left Inferior Pole

- Identify the left phrenic nerve.
- Dissect and divide left inferior pole and any remaining attachments medially.
- Divide right superior pole and right thyrothymic ligament.
- Score the mediastinal pleura 1 cm medially to the left phrenic nerve and proceed cranially with dissection and division.

Division of Left Superior Pole

- Dissect and divide the left superior pole and any remaining attachments medially.
- Use a laparoscopic clip applier to apply clips to the proximal and distal aspects of the vein or veins that drain from the thymus into the left innominate vein. Divide the vein between the clips using an energy source.

Specimen Removal and Closure

- Place the specimen in a specimen bag and remove through a protected port. For larger thymomas, a port site that will not be used as the chest tube site will need to be enlarged for specimen removal.
- Place a small-bore chest tube on left side and confirm inflation of left lung.
- Close intercostal muscles and overlying skin.

ROBOTIC-ASSISTED THYMECTOMY

Positioning

- Position the patient in the supine position with an axillary roll, or bump and to the right side of the bed.
- Arm maybe placed hanging within a padded towel off the right side of the bed. Tuck the arms at the patient's side.
- Prep skin from above sternal notch to below xiphoid process and to as far laterally as possible on both sides.
- Patients with large, pendulous breasts may require retraction of breast tissue medially using 4-in silk tape. Expose the entire inframammary crease bilaterally.
- The spine of the robot will be on the patient's left and the assistant on the patient's right.
- Place thoracoscopic/VATS tower above the patient's left shoulder.

Port Placement

- Discontinue ventilation to right lung.
- The first incision will be for a 5-mm port, and this will be 2 cm lateral to the midclavicular line at the 6th intercostal space. Through this port, insert a 5-mm thoracoscope. Inspect the thoracic cavity. The VATS thoracoscope will be used to confirm safe placement of subsequent ports.
- Place the next port 2 cm lateral to the midclavicular line at the 2nd intercostal space. This will accommodate one of the working arms of the robot. At this time, we use 8-mm metal trocars designed for the robot.
- Place the robotic camera port 4 cm lateral to the midclavicular line at the 4th intercostal space. This port should be 10 or 12 mm and will accommodate the 10-mm robotic camera head.
- Exchange the 5-mm thoracoscope to one of the other two port sites, and under visualization, replace the 5-mm port at the 6th intercostal space with an 8-mm trocar designed for the robotic arm. This trocar will accommodate the other working arm of the robot.

Docking the Robot

- Dock the robot at the table, with the robotic spine on the patient's left and the robotic arms on the patient's right.
- Using the 5-mm thoracoscope inserted through one of the 8-mm ports, insert the robotic camera into the 12-mm port site at the 4th intercostal space. The 30-degree robotic camera will start in the "up" configuration. This will be placed on arm number "2" of the robot.
- Insert the working arms of the port into the chest under direct visualization. We usually start with a robotic Cadiere dissector at the 2nd intercostal port site, which will be robot arm number "1." The Cadiere can be connected to bipolar energy if needed. A robotic LigaSure arm is inserted at the 6th intercostal port site, at robotic arm number "3." This arm configuration can be varied per surgeon preference.
- An assistant's port can be added wherever necessary for additional downward retraction. The assistant may insert a grasper or a ring clamp into the thoracic cavity to assist as needed.

Dissect the Right Inferior and Superior Poles

- Dissect the right inferior and superior poles in the same manner as described during the VATS approach.
- Divide lateral and medial attachments of the thymus.
- When complete, place a right-sided chest tube, confirm inflation of the lung, and remove the ports under direct visualization.
- Close overlying intercostal muscles and skin as desired.
- If the left phrenic nerve can be visualized from the right, or if right phrenic nerve can be visualized from the left if starting on the right, then the surgeon may be able to complete the thymectomy from one side. If both phrenic nerves cannot be adequately visualized from the same side, then a bilateral approach is warranted. The contralateral side can be approached with VATS or RATS approach.

Reposition the Robot

- Reposition the robotic spine to the patient's right side with the robotic arms on the patient's left side.
- Insert ports on left side in same manner as inserted on the right using a thoracoscope connected to a VATS tower initially for assistance with port placement.
- Avoid damage to the heart when inserting the ports at the 4th and 6th intercostal space.

Dissect the Left Inferior and Left Superior Poles

- Dissect the left inferior and left superior poles in the same manner as described during the VATS approach.
- Clip the vein or veins draining the thymus to the left innominate vein. This will require the assistant to load a clip applier onto one of the robotic arms.
- Place the specimen in a specimen bag and remove from the 12-mm port site.
- Place a right-sided chest tube, confirm inflation of the lung, and remove the ports under direct visualization.
- Close overlying intercostal muscles and skin as desired.

TRANSCERVICAL THYMECTOMY

Positioning

- Place the patient in the supine position, with the head maximally hyperextended using an inflatable bag and a rolled sheet behind the patient's shoulders. Inability to hyperextend the patient's neck must be considered preoperatively.
- Place the back of the head in a doughnut at the very edge of the operating table.
- Tuck the arms at the patient's side. Avoid having any cords or sheets covering the attachment rails of the table, as a retractor will be mounted there later in the case.
- Prep the skin of the anterior neck and chest to the sternal notch in preparation for sternotomy if needed.

- The anesthesiologist will be positioned on the patient's side, and the tubing should be allowed to drop down and not be suspended with a "Christmas tree."[8]

Incision and Isolation

- Make transverse incision just over the sternal notch, below the level where an incision would be made for a mediastinoscopy.
- Elevate superior and inferior subplatysmal flaps. Carry the superior flap to the level of the thyroid cartilage, and the inferior flap is carried to just below the suprasternal notch. Insert two handheld self-retaining retractors to separate the skin flaps.
- Dissect down to and separate the median raphe between the sternohyoid and sternothyroid muscles.
- Incise the ligamentous attachment within the sternal notch and develop the substernal plane using a finger to dissect. The cervical portion of the thymus appears salmon-pink and this color distinguishes it from the surrounding cervical fat.[8]
- The right lobe of the gland often comes up higher than the left and will be identified first. The thymus is anterior to the inferior thyroid vein. Once the inferior thyroid vein is identified, separate it posteriorly.

Division of Superior Poles

- Sit at the head of the bed and use a headlight. The assistant will be positioned on the opposite side of the anesthesiologist at the patient's head.
- Place another self-retaining retractor between the strap muscle.
- Dissect and divide attachments to the right superior and left superior poles. Place a silk traction suture around each pole to use as a handle. Do not cut these sutures; leave a hemostat clamped to their ends (**FIG 5A**).
- Dissect downward toward the innominate vein, which the thymus usually lies anterior to. Small venous branches can be divided between clips or with an advanced vessel-sealing device.
- When the dominant vein emptying into the innominate vein is identified, place ligatures proximally and distally and divide it.
- Use a peanut for dissection initially. Once the dominant vein is divided, further dissection can be carried out with a tonsil sponge.
- Divide lateral attachments to the right and left lobes of the thymus.

Placement of Retractor

- The Cooper thymectomy retractor (Pilling Surgical Instruments, Teleflex Medical, Research Triangle Park, North Carolina) is designed for transcervical thymectomy. Alternatively, the Rultract retractor (Rultract Inc, Cleveland, Ohio), designed for taking down the internal mammary arteries, can be used if a blade of appropriate size for the sternal notch is used. A Thompson retractor (Thompson Surgical Instruments, Inc, Traverse City, Michigan) with an appropriately sized blade can be used if both arms of the retractor are joined together arching over the patient (**FIG 5B**).
- Clamps are applied to the over drapes on each side of the table. Place the sidebars of the Polytract retractor (Pilling Surgical Instruments, Teleflex Medical, Research Triangle Park, NC) into the clamps and place the crossbar of the retractor between the clamps.
- The positioning of the table clamps and crossbar must be adjusted so that patient's entire body can be lifted and suspended off of the table using the Cooper thymectomy retractor (**FIG 5B**).
- Insert the blade of the Cooper thymectomy retractor behind the sternum and lift toward the ceiling. Connect the Cooper thymectomy retractor to the crossbar (**FIG 5B**).
- Insert an Army-Navy retractor on each side of the wound and attach each laterally to the sidebars using Penrose drains or sterile rubber bands.
- Deflate the beanbag behind the shoulder. Now, the patient's entire body weight is being suspended by thymectomy retractor.
- Drape the silk ligatures affixed to the left superior and right superior poles over the top of the crossbar, weighed by hemostats.

Division of the Inferior Poles

- Sweep the right lobe away from right pleural reflection with a tonsil sponge first, then sweep the left lobe away from the left pleural reflection.
- The left lobe is more difficult to dissect than the right because of extension of the thymus into the aortopulmonary window. Avoid traction injury to the phrenic nerves, whose location cannot be seen.[8]
- Proceed caudally with dissection on each side; divide any pericardial attachments sharply.

Removal of Specimen and Closure

- Sweep away the inferior attachments and retract the thymus cranially. After inferior and lateral tissues are swept away and the thymus is freed, it is often attached to small pedicle at the superior aspect of the gland posteriorly. This is likely a previously unidentified vein draining the thymus into the innominate vein. It should be divided between clips.
- Remove the specimen and confirm hemostasis in the mediastinum. Topical hemostatic agents can be used here for minor oozing.
- If any pleural violation occurred, insert a red rubber catheter into the violated pleural place and perform a Valsalva maneuver to evacuate the hemithorax of air just before the wound is closed.
- Close the platysma with absorbable suture and close the skin with absorbable subcuticular suture.
- Obtain a chest radiograph postoperatively. Pneumothoraces that are not large or symptomatic do not need to be addressed because there is no ongoing air leak and thus will resolve spontaneously.[8]

Division of superior poles

- Step-by-step description, with at least one surgical photo or sample drawing for artist to illustrate surgical technique. Photos and illustrations may be used side-by-side.

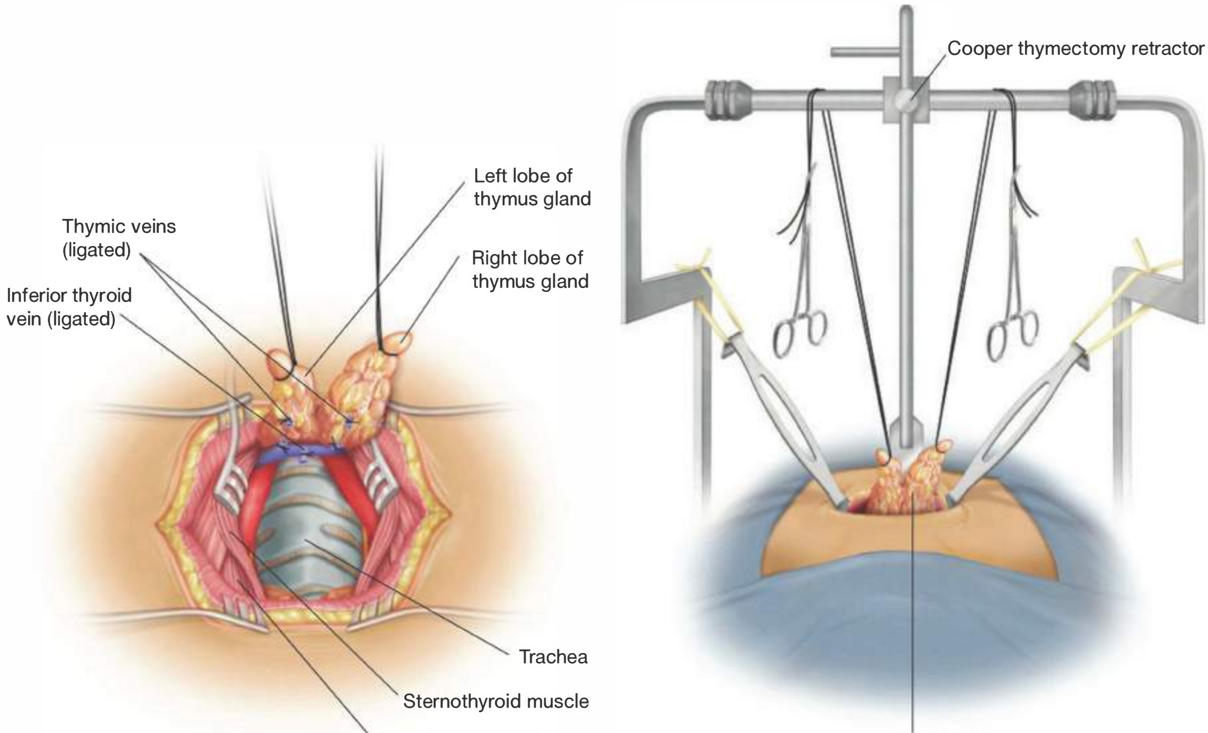

FIG 5 ● **A.** Identify and ligate right and left poles of thymus gland, using them as a handle for superior retraction. **B.** Cooper thymectomy retractor or other fixed blade retractor placed substernally and used to lift the entire patient off of operating table.

PEARLS AND PITFALLS

Imaging and workup	■ Thin-slice computed tomography (CT) of chest with intravenous (IV) contrast is most often used. ■ In almost all cases, biopsy of lesions in anterior mediastinum is warranted preoperatively.
Anesthesia	■ Special anesthetic requirements may be necessary for myasthenia gravis patients, and the anesthesia team should be notified well in advance to make accommodations, if needed. ■ Plasmapheresis may be indicated preoperatively in patients with myasthenia gravis. ■ Double lumen endotracheal tubes are strongly recommended in patients undergoing VATS or RATS thymectomy. ■ Central venous access should be established preoperatively.
Technique	■ The ipsilateral phrenic nerve must be visualized and preserved before initiating resection of thymic tissue on that side. ■ The phrenic nerve must be identified and preserved on at least one side. A phrenic nerve should only be sacrificed if grossly invaded by tumor. ■ Troublesome bleeding can occur if a thymic vein near the left superior or right superior pole tears and retracts cephalad. ■ Doubly ligate thymic veins. ■ Bipolar devices such as LigaSure or Harmonic scalpel can be of assistance with dissection around poles of thymus. ■ Protected ports and EndoCatch bags should be used.
Pitfalls	■ If performing robotic thymectomy and the contralateral phrenic nerve cannot be visualized from the same side the case was started on, the surgeon must operate on the contralateral side as well. ■ Complete resection of all thymic tissue is necessary to obtain cure in myasthenia gravis.

POSTOPERATIVE CARE

- Obtain chest radiograph postoperatively.
- Inpatient observation and patient-controlled anesthetics are recommended for patients undergoing thymectomy by sternotomy, VATS, or robotic-assisted approaches. Patients undergoing transcervical thymectomy can often be discharged home on the day of operation.
- For patients undergoing thymectomy by sternotomy, VATS, or robotic-assisted approaches, obtain a hemogram and electrolyte panel including magnesium and phosphorus levels the first morning postoperatively. Correct any electrolyte imbalances.
- Plasmapheresis or medical may be necessary initially postoperatively, with the guidance of the referring neurologist, when there is difficulty weaning from ventilation or if myasthenic crisis occurs.

OUTCOMES

- Complete stable remission, pharmacologic remission, or improvement of manifestation status of myasthenia gravis occurs in 97.9% of patients undergoing thymectomy by sternotomy and 95.8% in patients undergoing thymectomy by VATS approach.[9]
- Complete remission of myasthenia gravis is between 15% and 35%, depending on literature reviewed.

COMPLICATIONS

- Bleeding from the innominate vein
- Damage to the phrenic nerve, especially devastating in patients with myasthenia gravis
- Pneumothorax with persistent air leak from damage to lung parenchyma
- Chylothorax if thoracic duct or branch of thoracic duct is damaged during takedown of the poles of the thymus
- Inability to wean from mechanical ventilation in patients with more extreme symptoms from myasthenia gravis
- Failure of thymectomy to resolve symptoms of myasthenia gravis (percentage)
- Local recurrence of thymoma if incomplete resection performed
- Metastasis to surgical site
- Death

Chapter 10 Thoracoscopic Sympathectomy

Brett Broussard Douglas Minnich Benjamin Wei

DEFINITION

- Hyperhidrosis is a medical condition that involves the overproduction of sweat/perspiration in the palms, axillae, face, or feet.
- Diagnostic criteria include focal sweating of greater than 6 months and two of the following characteristics: bilateral and symmetric nature, impairs daily activities, occurs weekly at a minimum, onset at younger than 25 years of age, significant family history, and no evidence of focal sweating during sleep.
- Eccrine glands innervated by the sympathetic nervous system are responsible for hyperhidrosis. Acetylcholine is the primary neurotransmitter carried by cholinergic autonomic neurons.
- Hyperhidrosis can be related to an abnormal central response to emotional stress but also occurs spontaneously and intermittently. Eccrine glands appear histologically and functionally normal under microscopic examination.[1] The pathophysiologic basis of hyperhidrosis remains unclear.

DIFFERENTIAL DIAGNOSIS

- Generalized, or secondary, hyperhidrosis can be caused by a wide variety of systemic and metabolic reasons. Excessive heat exposure and obesity are the most common causes of generalized hyperhidrosis. Other causes include endocrine disorders, neuroendocrine tumors, infection, malignancy, and toxins. Hodgkin's disease and tuberculosis are common causes of nocturnal hyperhidrosis.
- Localized unilateral, or segmental, hyperhidrosis is rare and can be attributed to gustatory stimuli; eccrine nevus; eccrine angiomatous hamartoma; glomus tumor; polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes (POEMS) syndrome; and pachydermoperiostosis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present with history of palmar and plantar sweating since childhood. The onset of sweating may be associated with stress or occur during a time of calmness. The timing of palmar and plantar sweating is synchronous.
- The presentation of sweating is intense in nature. Patients may complain of puddles of sweat around bare feet, saturation of paper while writing, or the need to change clothes multiple times a day.[2]
- Hyperhidrosis may have a significant impact on the patient's self-image, occupation, and social interactions.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The diagnosis of primary hyperhidrosis is obtained through a thorough history and physical examination.
- If secondary or unilateral hyperhidrosis is suspected, further evaluation is warranted including laboratory studies and imaging.

SURGICAL MANAGEMENT

- Various nonoperative treatments such as application of aluminum chloride alcohol solutions (Drysol), iontophoresis (placing of hands and feet in water through which electric current flows), botulinum toxin injections, and oral anticholinergics such as glycopyrrolate and oxybutynin are usually tried prior to consideration of sympathectomy.
- The Society of Thoracic Surgeons (STS) expert consensus committee has adopted a nomenclature when describing sympathectomy. For example, R3 refers to a sympathectomy above the 3rd rib space.[1]
- In preparation for sympathectomy, it is important to consider the anatomic presentation of the patient's symptoms for operative planning.
- *Palmar hyperhidrosis*: Disruption of the sympathetic chain above both the 3rd and 4th ribs (R3 and R4) results in the driest hands but carries an increased risk of compensatory hyperhidrosis (CH). R4 disruption alone decreases the risk for CH but may lead to suboptimal dryness of the hands. The consensus committee therefore recommends R3 disruption alone for palmar hyperhidrosis.
- *Palmar and plantar hyperhidrosis* is best treated with R4 and R5 sympathectomy. R4 disruption alone may decrease the probability of CH, but dividing both R4 and R5 results in an excellent reduction in sweating symptoms.
- *Axillary hyperhidrosis* (including palmar-axillary and palmar-axillary-plantar) is best treated with R4 and R5 sympathetic chain disruption. Simultaneous R3 and R4 disruption was found to increase the incidence and severity of CH.
- *Craniofacial hyperhidrosis* needs to be distinguished from blushing. These patients benefit from R3 chain disruption alone. Studies have shown that R2 chain disruption is associated with an increased incidence of Horner's syndrome and CH.[1]
- There are different methods in which the sympathetic chain can be disrupted. Options include the following:
  - Sympathectomy: removal of sympathetic ganglion by transection of chain above and below ganglion
  - Sympathicotomy: simple transection of sympathetic chain
  - Clipping: clip placed at indicated level of sympathetic chain
  - Blocking: Clips are placed above and below ganglion.[2]
- There is no clear advantage to any particular method used to disrupt the chain.
- Proponents of clip application believe that sympathectomy can be reversed in the case of intolerable hyperhidrosis by removal of the clip; however, one study has shown that only about 50% of patients experience a significant decrease in CH after clip removal.[3] Experimental studies suggest that the damage inflicted on the nerve with clip application leads to degeneration of the nerve within 10 days of clip application.[4] It is more important that the correct level is identified and that enough of a gap is created when the nerve bundle is transected to prevent regrowth of the nerve.[1]

Preoperative Planning

- Patients can be intubated with either a double lumen or single lumen endotracheal tube. We prefer a double lumen endotracheal tube, which allows for single-lung ventilation.
- If a single lumen endotracheal tube is used, carbon dioxide (CO_2) insufflation or intermittent apnea is necessary to displace the lung and gain access to the sympathetic chain.

Positioning

- The patient is placed in a supine position on the operating room table with both arms abducted and placed at a 90-degree angle or greater if tolerated (**FIG 1**).
  - The arms should be padded for the full length of the arm board and safely secured with a strap proximal and distal to the elbow.
- The table is then maneuvered into a semi-Fowler's position.
- The chest is then prepped from the base of the neck to the upper abdomen and includes bilateral axillae in the field.

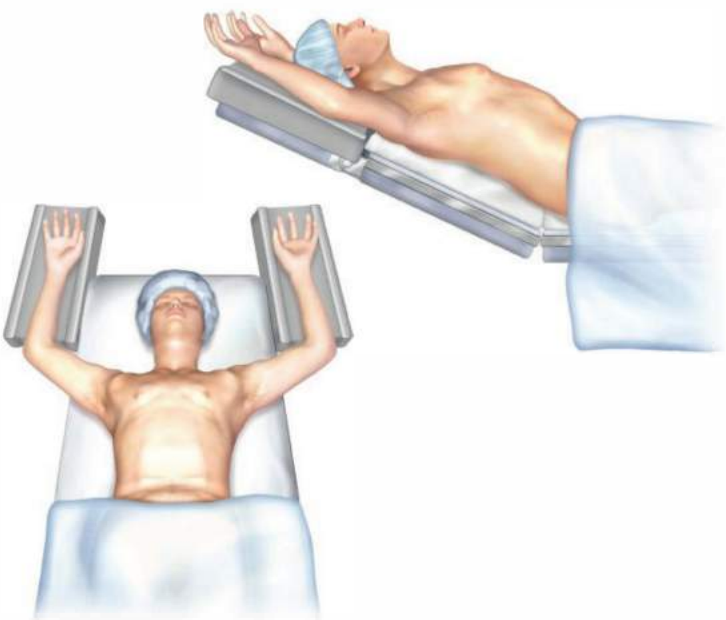

FIG 1 ● The patient is positioned in a semi-Fowler's position, elevated to 30 to 45 degrees. Arms are abducted to 90 degrees or greater to ensure both axillae are exposed.

TECHNIQUES

THORACOSCOPIC SYMPATHECTOMY

Incision and Trocar Placement (Two-Incision Technique)

- A 5-mm incision is made just lateral to the pectoralis major muscle in the anterior axillary line in the 3rd intercostal rib space (**FIG 2**).
- The subcutaneous tissue is then spread bluntly with a hemostat.
- Single-lung ventilation is then performed in the contralateral lung.
- A 5-mm trocar is then placed through the incision with special care to stay just superior to the 3rd rib. Insufflation of CO_2 into the chest may help with deflation of the lung and visualization of the upper sympathetic chain.
- A second 5-mm incision is made approximately 5 cm lateral to first incision.
- The subcutaneous tissues are again bluntly spread and a second 5-mm trocar is placed.

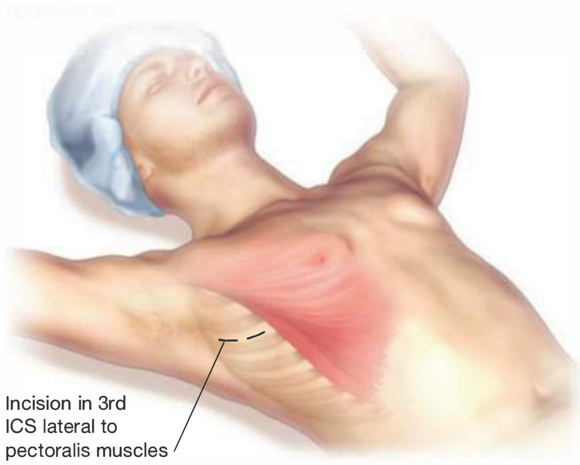

FIG 2 ● An incision is made lateral to the pectoralis major in the anterior axillary line. A second incision is made in the same interspace in the midaxillary line.

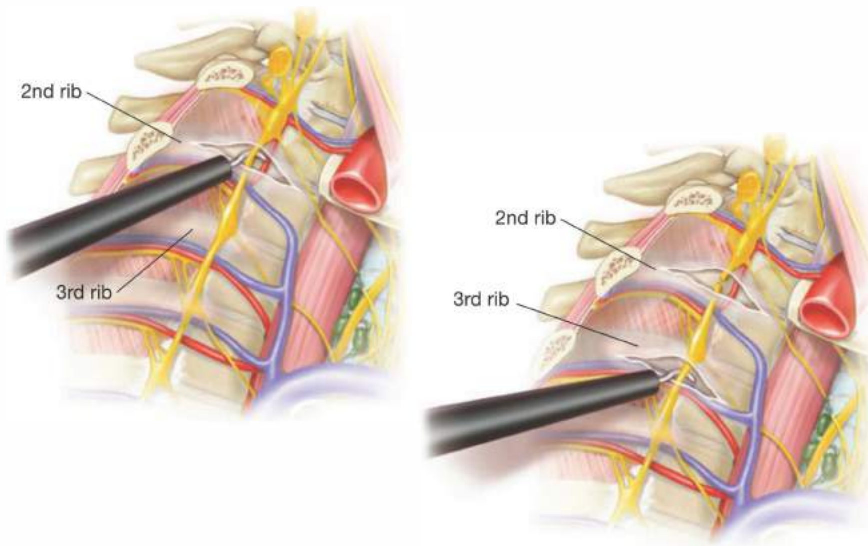

FIG 3 ● The sympathetic chain is identified lateral to the vertebral column. The desired intercostal space for sympathectomy is identified. The parietal pleura is opened medial and lateral to the chain and the hook cautery is passed behind the chain. The nerve is then cauterized and transected.

Rib Identification

- A 30-degree 5-mm scope is then placed in the lateral trocar site.
- The ribs are then correctly identified. The 2nd rib is typically the most proximal rib visualized in the chest. The 2nd rib can also be identified by a descending arterial branch from the subclavian artery that typically crosses the rib 1 cm lateral to the sympathetic chain.

Sympathetic Chain Disruption

- The sympathetic chain is then identified near the rib heads at the desired interspace(s) (e.g., above the 3rd rib for a so-called R3 sympathectomy) (**FIG 3**).
- Using a hook cautery, the parietal pleura is then cauterized on the medial and lateral side of the sympathetic chain.
- The hook is then bluntly placed around the sympathetic chain and transected by electrocautery. The distance between the transected ends of the nerve should be one rib space. Special care is made to avoid adjacent blood vessels.

Hemostasis and Pneumothorax Evacuation

- Once the appropriate chain levels have been transected, the chest should be thoroughly inspected to ensure hemostasis. This includes port sites.
- The lung is then reinflated under direct visualization to ensure proper expansion.
- A 16-Fr chest tube is then placed through a trocar while positive pressure ventilation is performed. Assuming that the surgeon is confident that the lung was not injured during the procedure, the chest tube is placed on suction and the trocar and chest tube are removed together during positive pressure ventilation.
- The incision is then closed with a continuous 3-0 Vicryl running suture and biologic glue.
- The procedure is repeated on the contralateral side.

SINGLE-INCISION THORACOSCOPIC SYMPATHECTOMY

Incision and Instrument Placement

- A 1-cm incision is made in the anterior axillary line in the 3rd intercostal space just lateral to the pectoralis major. The subcutaneous tissue is bluntly spread with a hemostat.
- A 5-mm trocar is inserted. The operative site is visualized either by single-lung ventilation or by CO_2 insufflation.
- A thoracoscope is inserted and the desired level of sympathetic chain is identified.
- The trocar is withdrawn and the hook cautery is placed adjacent to the thoracoscope into the thoracic cavity.
- The same steps as outlined above for sympathectomy via two incisions are followed.
- Alternatively, an operating thoracoscope (**FIG 4**) can be used to perform single-incison thoracoscopic sympathectomy.
- If significant adhesions are encountered, conversion to a two-port technique will allow greater maneuverability of the hook cautery for pneumolysis.

FIG 4 ● Operative thoracoscope.

PEARLS AND PITFALLS

History of breast augmentation	■ Special consideration must be made during the placement of trocars to avoid damage to implants.
Nerve of Kuntz	■ A nerve that can join the 2nd intercostal nerve to the 1st intercostal nerve and has been associated with persistent hyperhidrosis after sympathectomy.[5] Fibers that travel slightly lateral to the main sympathetic nerve below the 2nd rib should not be technically referred to as the nerve of Kuntz; however, they should be divided if encountered at the level of the sympathectomy.

POSTOPERATIVE CARE

- In the postoperative care unit, a chest radiograph is performed to ensure proper lung inflation and no residual pneumothorax. A small pneumothorax may be observed with chest radiograph repeated a few hours later. A large pneumothorax may be better treated with aspiration or small-bore catheter placement.
- Narcotic oral pain medication is typically sufficient for pain control.
- If adequate pain control is achieved and chest radiograph is satisfactory, the patient may be discharged home from the postoperative care unit. Alternatively, patients may feel more comfortable with a single-night stay in the hospital.

OUTCOMES

- Evaluating outcomes after thoracoscopic sympathectomy has been difficult due to variable reporting methods and inconsistent reporting of success rates.
- Immediate success rates following thoracoscopic sympathectomy have been reported at 90% to 100% in the literature.
- Multiple randomized clinical trials comparing R3 disruption versus R2 to R4 or R4 alone show that R3 disruption gives a superior result with less severe CH for palmar hyperhidrosis alone.[6–8]
- For axillary hyperhidrosis, randomized clinical trials show R4 chain disruption and R3 to R4 disruption to have a 100% immediate success rate but R4 disruption to have a superior CH rate, 42% versus 100%.[9,10]

COMPLICATIONS

- Complications after thoracoscopic sympathectomy can be divided into immediate and chronic.
- Immediate complications include the following:
  - *Postoperative pain* can include incisional pain related to port placement and pleuritic retrosternal pain. This can typically be controlled with oral narcotic pain medications.
  - *Bleeding* is a rare complication and can be the result of intra- or extrathoracic sources. The risk for bleeding can be greatly reduced by careful port placement to avoid intercostal vessels and avoiding crossing vessels near the sympathetic chain during transection of the nerve.
  - *Horner's syndrome* can occur due to improper identification of the 2nd rib or proximal transmission of heat from cautery causing injury to the stellate ganglion. Risk of injury is greatly reduced for sympathectomy below the 2nd rib.
  - *Pneumothorax* can be avoided by close attention to avoid parenchymal injury during port placement and proper technique when reinflating the lung and evacuating the chest.
- Chronic complications include the following:
  - CH is cited as occurring from 3% to 75% in the literature and is classified as mild, moderate, and severe. Mild CH is triggered by ambient heat, psychological stress, and exercise where sweat is tolerable and does not flow. Moderate CH is described as sweat that accumulates into droplets but does not require a change of clothes. Severe CH includes sweat that flows profusely and requires multiple changes of clothes in 1 day. It is physically and emotionally debilitating. CH has a higher incidence with interruption of the T2 ganglion.[1]
  - *Bradycardia* can result from transection of sympathetic fibers that innervate the heart. Careful consideration of the desirability of the procedure should be made for those patients who have a resting heart rate of less than 55 beats per minute.
  - *Recurrent hyperhidrosis* can mainly be attributed to inadequate surgery. This may be due to anatomic variants, including increased adipose tissue around sympathetic chain, increased vascularity, or possible reinnervation. The results of reoperative sympathectomy are comparable to initial sympathectomy in terms of symptom control; however, reoperative sympathectomy is associated with increased likelihood of requiring postoperative pleural drainage, longer hospital stay, greater difficulty of operation (e.g., adhesions), and a higher risk of CH.[11]

Chapter 11

Mediastinoscopy

James Wiseman Shanda Haley Blackmon

DEFINITION

- Mediastinoscopy is the evaluation of the anterior mediastinum through endoscopic means.
- Video mediastinoscopy is the current technique discussed in this chapter.
- It remains the gold standard for mediastinal exploration in lung cancer staging and can be applied to the sampling of any tissue of the anterior mediastinum for diagnostic purposes.
- Through traditional video mediastinoscopy, levels 2, 4, 7, and 10 lymph nodes can be reached (**FIG 1**). Through an extended cervical mediastinoscopy (ECM), the paraaortic and aortopulmonary lymph nodes can be reached.
- Additionally, but less frequently, mediastinoscopy can be used in the setting of mediastinal disease for therapeutic purposes.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients being considered for mediastinoscopy frequently present following identification of either mediastinal or pulmonary pathology on plain film radiography. A minimum of two views is required to differentiate between abnormalities of the anterior, middle, and posterior mediastinum, including either a posteroanterior view or an anteroposterior projection and a lateral projection. Lymphadenopathy is rarely visible on plain films, typically necessitating the use of alternative imaging modalities in assessing for lymph node enlargement.
- Computed tomography (CT) of the chest is a critical tool in the early evaluation of patients with known or suspected lung cancer or other diseases involving mediastinal structures. The primary use of CT is the radiographic visualization of abnormalities of the mediastinum (i.e., neoplasm, abscess, lymphadenopathy). In the setting of lung cancer, CT is most useful in identification of mediastinal adenopathy. Lymph nodes are considered to be positive if they demonstrate a short-axis diameter larger than 1 cm. Using this threshold, however, the negative predictive value (NPV) of CT scan ranges from 77% to 90%, with a positive predictive value (PPV) of 41% to 74%.[1–3] Despite these limitations, the use of CT has allowed some centers to implement a selective approach to mediastinoscopy.
- Considerable attention has been given to the use of positron emission tomography (PET) in the evaluation of primary mediastinal pathology and, in particular, assessment of the mediastinum for lymphadenopathy in the evaluation of the lung cancer patient. Several studies have reported NPV in excess of 95% with the use of PET to evaluate for metastatic disease to mediastinal lymph nodes.[4–6] False-positive findings are frequent with PET, however, and the identification of PET-avid nodes demands confirmation.

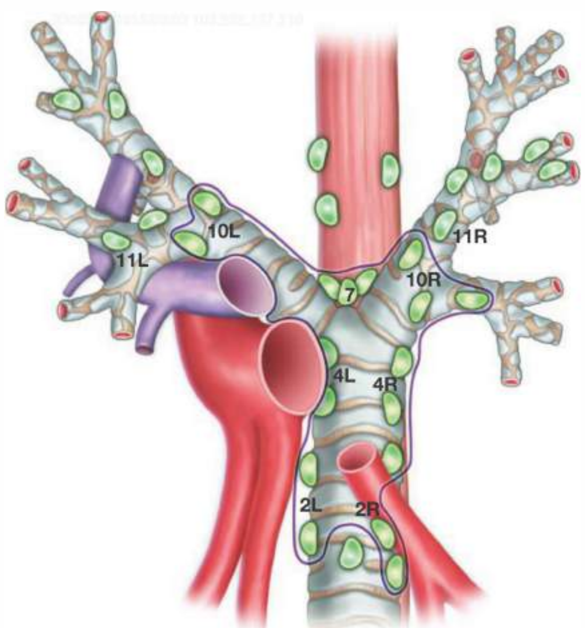

FIG 1 ● Mediastinal lymph node anatomy, as seen from the perspective of the surgeon.

SURGICAL MANAGEMENT

- The most common indication for mediastinoscopy is for staging in the setting of lung cancer. Some institutions employ mediastinoscopy routinely in the evaluation of these patients. Others advocate for a selective approach, informed by the findings of other imaging modalities. In this setting, centrally located tumors, known as adenocarcinoma, nodes larger than 1 cm on CT scan, and PET-avid nodes should prompt the use of invasive means of obtaining tissue for diagnosis.
- Mediastinoscopy is also a valuable diagnostic tool in the evaluation of nonneoplastic causes of mediastinal lymphadenopathy as well as other masses found in the mediastinum for which identification cannot be accomplished through noninvasive means.
- Absolute contraindications to mediastinoscopy include innominate artery aneurysms and the presence of a tracheostomy.[7]
- The presence of a thyroid goiter, depending on size, may present technical difficulties for the surgeon, and very large goiters may preclude performance of the procedure altogether.
- Repeat mediastinoscopy, although challenging, is usually possible and safe.

Preoperative Planning

- A complete history and physical, focusing specifically on previous mediastinal operations, should be obtained. Although prior mediastinal surgery (coronary artery bypass graft [CABG] surgery, esophagectomy, etc.) does not preclude mediastinoscopy, it is essential to be aware of such history during the planning phase.
- All patients with planned mediastinoscopy should have coagulation studies done preoperatively. In general, a target international normalized ratio (INR) of 1.2 should be achieved to minimize risk of intraoperative and postoperative bleeding. Antiplatelet therapy should be stopped prior to an elective procedure such as mediastinoscopy.

Positioning

- Following induction of general anesthesia, the patient is placed supine with the head close to the top edge of the operating table. The procedure can be facilitated through extension of the neck by placement of a rolled towel or beanbag device horizontally from shoulder to shoulder. Some patients may not tolerate complete neck extension due to prior cervical spine surgery or degenerative disease.
- The entire neck and chest should be sterilely prepped and draped in the event that an emergent sternotomy is required to address intraoperative complications.

INCISION

- The typical location of the incision is centered along the midline, approximately 1 cm superior to the sternal notch. We favor a horizontal incision, with a length of approximately 1.5 to 2.5 cm (**FIG 2**).
- The incision is carried through the platysma and subcutaneous tissue until the vertically oriented sternohyoid muscles are identified. The avascular plane separating these muscles can then be opened, revealing the underlying sternothyroid muscles.
- The surgeon will occasionally encounter engorged anterior jugular veins or their tributaries at this level of the dissection. These represent a significant bleeding risk and can be ligated if hemorrhage is encountered or anticipated. Clips should be avoided as they are prone to dislodgement with advancement of the mediastinoscope.
- The neck muscles are similarly spread vertically at the midline, at which point the pretracheal fascia and anterior wall of the trachea can be identified.
- A well-placed incision will usually access the pretracheal fascia inferior to the thyroid gland (**FIG 3**). However, the thyroid gland may occasionally require gentle cephalad retraction for adequate exposure of the trachea. The use of a tracheal hook can often be used to gain exposure in this area without interfering with the operative field.
- The pretracheal fascia is then incised and the pretracheal space bluntly developed digitally. A useful cue indicating complete development of the plane is the palpation of the innominate artery anteriorly at the fingertip following this maneuver.

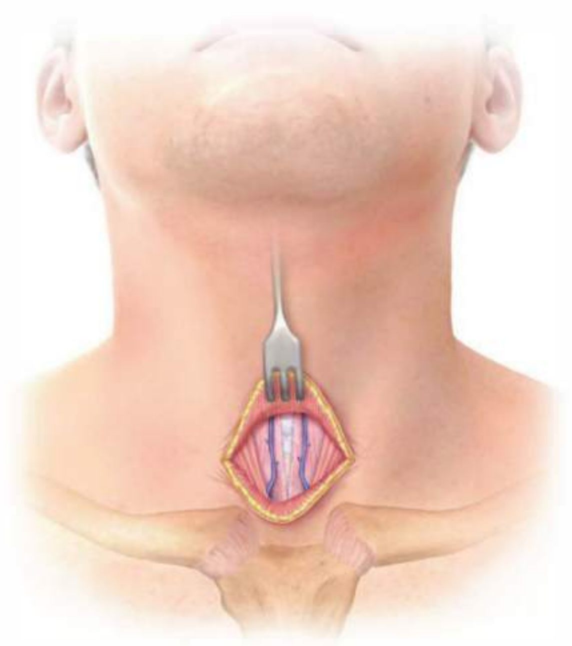

FIG 2 ● Mediastinoscopy is conducted via a horizontal incision one fingerbreadth above the sternal notch.

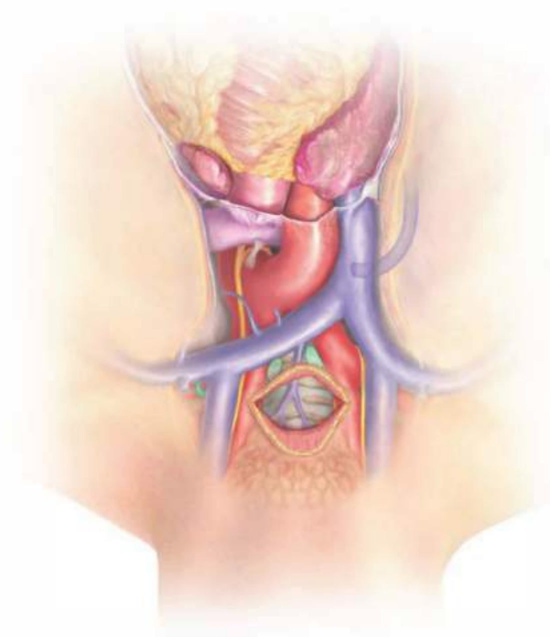

FIG 3 ● Mediastinal anatomy.

INTRODUCTION OF THE MEDIASTINOSCOPE

- The mediastinoscope is then placed into the created tunnel and advanced. Full advancement to the level of the carina can be accomplished using blunt dissection with a suction catheter.

SAMPLING OF TISSUE

- In the setting of a mediastinal mass where only tissue diagnosis is required, blunt biopsy forceps are adequate to obtain tissue. Hemostasis can be established following biopsy using pressure by packing the mediastinum with gauze, careful application of low-energy cautery connected to a suction device, or the use of commercial hemostatic factors such as Surgicel® or Arista®.
- Lymph nodes can be identified by their color and consistency. Any nodes targeted for removal should be dissected away from surrounding tissues. Dissection should be done primarily bluntly, using the suction catheter, Kittner dissector, or blunt biopsy forceps.
- Once mobilized, target nodes should be easily removable with gentle traction and twisting while grasping the tissue with biopsy forceps. Difficulty in removing a node may suggest the need for further dissection.
- For completeness of lung cancer staging, every effort should be made to obtain nodes from levels 2 and 4 bilaterally and level 7. Level 2 nodes will be encountered almost immediately upon entering the pretracheal space superior to the innominate artery, with level 4 nodes found more caudally. Level 7 nodes are found inferior to the carina. If grossly positive tissue is seen at higher stations, further sampling is unnecessary.[8]

WITHDRAWAL OF THE MEDIASTINOSCOPE

- The mediastinoscope is withdrawn slowly to assess hemostasis. Minor bleeding can be controlled by packing the tunnel with gauze. Bioabsorbable hemostatic agents can also be introduced into the space and left in place. Occasionally, bleeding vessels may require clip application at the end of the case for adequate hemostasis.
- It is advisable to use electrocautery sparingly, but it can be safely used at low energy. Cautery should be avoided at all times in the area of station 4 on the left side of the surgical field, as this poses unnecessary risk of injury to the recurrent laryngeal nerve.
- Violation of the pleural space can be identified by filling the tunnel with saline. Loss of the saline suggests disruption of the pleura. Bubbling of the fluid may imply pleural or pulmonary injury, occasionally requiring the placement of a chest tube.
- Standard mediastinoscopic techniques are limited in their ability to access many nodal stations. ECM was initially described by Specht and colleagues[9] in 1967 and was subsequently popularized for accessing nodes of the aortopulmonary (AP, stations 5 and 6) and subaortic lymph nodes (**FIGS 4** and **5**).
- The same incision as for standard mediastinoscopy is used for ECM. Using digital dissection, the plane between the left carotid artery and innominate artery is developed. This allows passage of the mediastinoscope over the aortic arch, with access then gained to the subaortic nodal basins. If the scope is then rotated slightly in a medial fashion, paraaortic lymph nodes can be accessed.

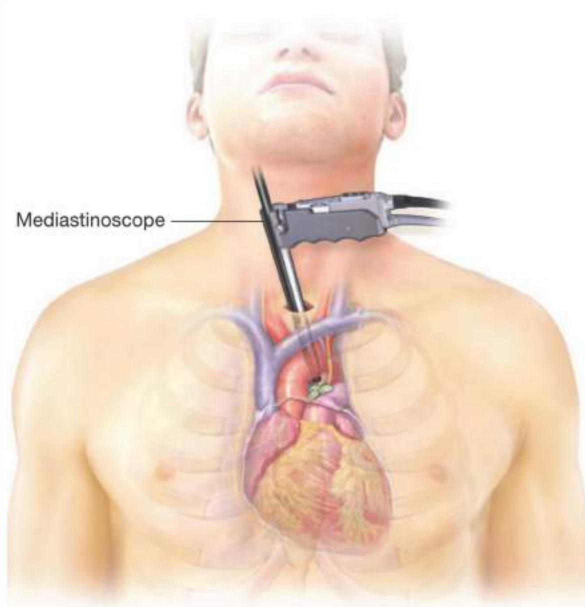

FIG 4 ● Technique of passing the mediastinoscope obliquely over the aortic arch in the performance of ECM.

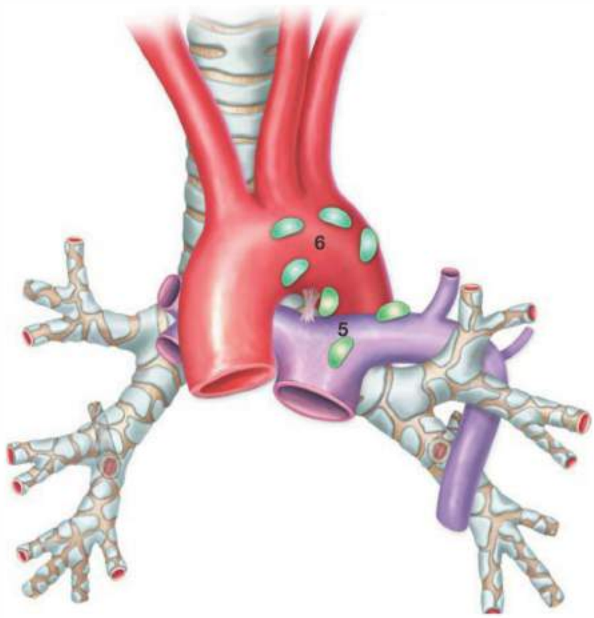

FIG 5 ● Additional lymph node basins accessible through ECM.

CLOSURE

- The sternohyoid muscles are reapproximated in the midline using absorbable sutures.
- Subcuticular closure of the skin using 4-0 Monocryl sutures in an interrupted fashion is generally preferred.

PEARLS AND PITFALLS

Anatomy	■ Always identify the innominate artery and azygous vein prior to nodal sampling. ■ Beware of crossing branch of the bronchial artery at level 7, as this represents a significant bleeding risk.
Node sampling	■ The appearance of venous structures approximates that of anthracotic lymph nodes. Care should be taken to appropriately and definitively identify structures before attempts are made to remove them.
Node presentation	■ Always label the station from which a node was sampled immediately upon retrieval. ■ If tuberculosis is suspected, touch preparation of the specimen is required. ■ If lymphoma is suspected, the specimen must be immediately treated with RPMI-1640 media and submitted for flow cytometry. ■ If a staged operation is planned, sampled lymph nodes can be submitted for permanent analysis. It is advisable, however, to submit a sample for frozen analysis to confirm the presence of nodal tissue. When resection and staging are planned for the same day, all mediastinal samples should be submitted for frozen evaluation. ■ If a mediastinal mass is encountered, at least one biopsy should be submitted for frozen analysis to confirm the presence of adequate tissue for diagnosis. ■ Our practice is for the surgeon to deliver all specimens to the pathology lab for the purposes of providing history and clarifying orientation.

POSTOPERATIVE CARE

- A postoperative chest radiography should be obtained to ensure that no pneumothorax is present.
- Mediastinoscopy, unless done as a precursor to immediate lobectomy, can be safely done on an outpatient basis. Patients may be discharged once standard discharge criteria are satisfied.

OUTCOMES

- Mediastinoscopy has a reported sensitivity of 87% to 95% and a specificity of 100% (Table 1).
- Although mediastinoscopy remains the gold standard for mediastinal staging in the setting of newly diagnosed lung cancer, endobronchial ultrasound (EBUS) or endoscopic

Table 1: Benchmark Figures for Mediastinoscopy

Sensitivity	87%–95%
Specificity	100%
Negative predictive value	96%–99%

From Anraku M, Miyata R, Compeau C, et al. Video-assisted mediastinoscopy compared with conventional mediastinoscopy: are we doing better? Ann Thorac Surg. *2010;89(5):1577–1581, with permission.*

ultrasound (EUS) via an esophageal approach with fine needle aspiration is gaining in popularity.
- In certain populations (multiple comorbidities, previous mediastinal operations), ultrasound-guided approaches to mediastinal sampling are preferred.

COMPLICATIONS

- Complication rates associated with mediastinoscopy are as high as 3%.[9] These include pneumothorax (0.5%), bleeding requiring reoperation (0.1%), and recurrent laryngeal nerve paralysis (0.4%).[10] Video mediastinoscopy appears to be safer than the traditional approach of merely using a tunneled visualization device.
- Major hemorrhage from injury to vascular structures should occur in less than 0.1% of procedures. This can result from damage to the aortic arch or its branches, superior vena cava, azygous vein, or pulmonary artery. Less commonly, hemorrhage is caused by injury to the innominate or jugular veins. In the event of a major bleeding event, clear communication with the anesthesiologist is critical to ensuring timely response to changing physiologic demands and preventing adverse outcomes.
- Hemorrhage from the innominate artery can be temporarily halted by insertion of a digit into the cervical incision and gently pressing the vessel against the posterior aspect of the sternum (**FIG 6**).
- If major bleeding cannot be controlled through the existing cervical incision, sternotomy is often the quickest and most effective approach for gaining exposure to vulnerable vascular structures. The mediastinum should be packed with gauze and resuscitation initiated, although preparations are made for conversion. If the bleeding can easily be controlled with pressure, anesthesia should be given time to prepare for the sternotomy prior to beginning the repair.
- Tracheal or bronchial injuries are infrequent and can usually be managed with packing if small. Larger injuries may require primary closure after appropriate surgical exposure.
- Esophageal perforation can occur, usually in the subcarinal area. If recognized immediately, this can be repaired primarily. A right thoracotomy provides the best exposure and allows for the surgeon to buttress the repair with an intercostal muscle flap when appropriate. Adequate treatment may require esophagectomy with diversion and staged reconstruction if diagnosis of a perforation is delayed by more than 48 to 72 hours.

FIG 6 ● Schematic drawing demonstrating emergent maneuver for hemorrhage control. A finger is inserted through the incision and advanced to the level of the innominate artery. The artery is then compressed to the underside of the sternum while the patient is being prepped for sternotomy. Packing is eventually placed to control hemorrhage when possible.

Chapter 12

Cricopharyngeal Diverticulum: Open Repair

William R. Carroll Kirk P. Withrow

DEFINITION

- Diverticula of the hypopharynx have been recognized for over 200 years. Zenker's diverticulum is by far the most common, with an annual incidence rate of 2/100,000 individuals.[1] The disorder is acquired rather than congenital and typically occurs in older adults. Men are more commonly affected than women. There are two types of pharyngoesophageal diverticula. *Traction diverticula*, resulting from a pulling force on the outside of the alimentary tract, are more commonly seen in the mid- to distal esophagus and often result from inflammatory or neoplastic processes adjacent to the muscularis. *Pulsion diverticula*, such as Zenker's, result from an internal pushing force causing the mucosa and submucosa to herniate through the muscular wall. Zenker's diverticula occur where increased intraluminal pressure causes herniation through a deficiency in the muscular layer at Killian's dehiscence. Killian's dehiscence is located at the junction of the inferior constrictor and the cricopharyngeus muscles (**FIGS 1** and **2**).
- The history of Zenker's diverticulum is rich. The anatomy of the pharyngoesophageal junction was first detailed by Antonio Valsalva in 1704. The diverticulum was first described by Abraham Ludlow[2] (mentor of Edward Jenner of smallpox fame) in 1764. Sir Charles Bell (Bell's palsy, Bell's nerve) described the pathophysiology of uncoordinated hypopharyngeal contraction against a closed cricopharyngeus muscle. The disorder is named for Friedrich von Zenker, a German physician and pathologist, who catalogued 27 cases in 1877.[3,4]

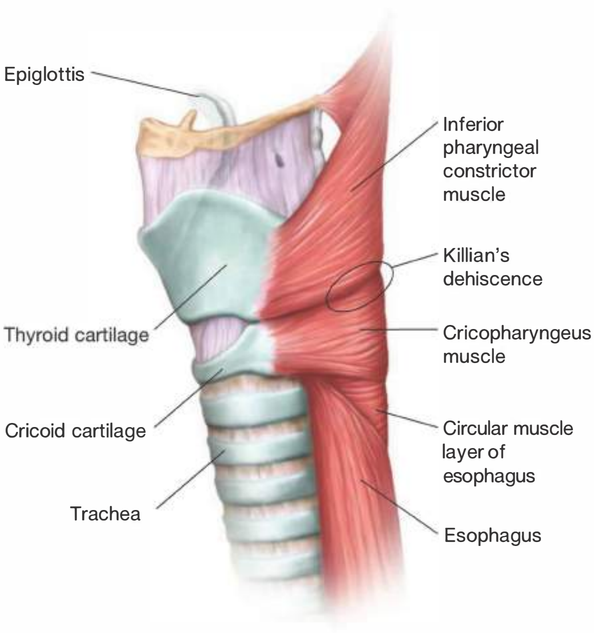

FIG 1 • Anatomy of the junction of the hypopharynx and esophagus. Killian's dehiscence is located between the inferior pharyngeal constrictor and the cricopharyngeus muscles.

DIFFERENTIAL DIAGNOSIS

- Zenker's diverticulum typically presents with dysphagia, regurgitation of undigested food, and occasionally, aspiration pneumonia. Causes for cervical dysphagia in adults may be grouped into three categories: *internal*, *external*, and *motility*. Internal disorders include inflammation and edema, stenosis, and neoplasm. External disorders produce extrinsic compression of the pharyngoesophageal segment and may include thyroid disease, adenopathy, abscess, and congenital cysts. Motility disorders include achalasia, stroke, esophageal spasm, myasthenia, and bulbar palsy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Cervical dysphagia is the most common presenting symptom of Zenker's diverticulum. Symptoms may be quite subtle and include chronic cough and unexplained weight loss. As the patient swallows, food and liquids preferentially enter the wide mouth of the diverticular pouch rather than passing through the inappropriately closed upper esophageal sphincter. As food and liquid accumulate, the patient develops a sense of neck fullness and may hear gurgling sounds in the lower neck. A pathognomonic type of regurgitation is common in which the patient regurgitates food minutes or even hours after eating that is completely undigested and not mixed with gastric contents. The pouch may fill and empty spontaneously during deglutition. When the pouch empties, the contents may spill into the airway, causing aspiration with coughing or pneumonia. The aspiration may be subtle and lead to recurrent respiratory infections and eventually chronic respiratory insufficiency. Death due to untreated Zenker's diverticulum typically results from pulmonary complications.
- Physical findings of Zenker's diverticulum include neck fullness or a mass in the tracheoesophageal groove that may gurgle or decompress with palpation (Boyce's sign). Audible gurgling may be detected over the same region with swallowing. Inspection of the hypopharynx may reveal pooling of secretions.[1] The pouch is typically not visible unless the patient undergoes esophagoscopy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Barium swallow is usually needed to definitively diagnose Zenker's diverticulum. The study characteristically reveals a diverticular sac originating just superior to the prominent and poorly relaxing cricopharyngeus muscle. Radiologists describe this prominent muscle as a cricopharyngeal "bar."
- Computed tomography (CT) or magnetic resonance (MR) imaging of the neck is unnecessary if barium swallow

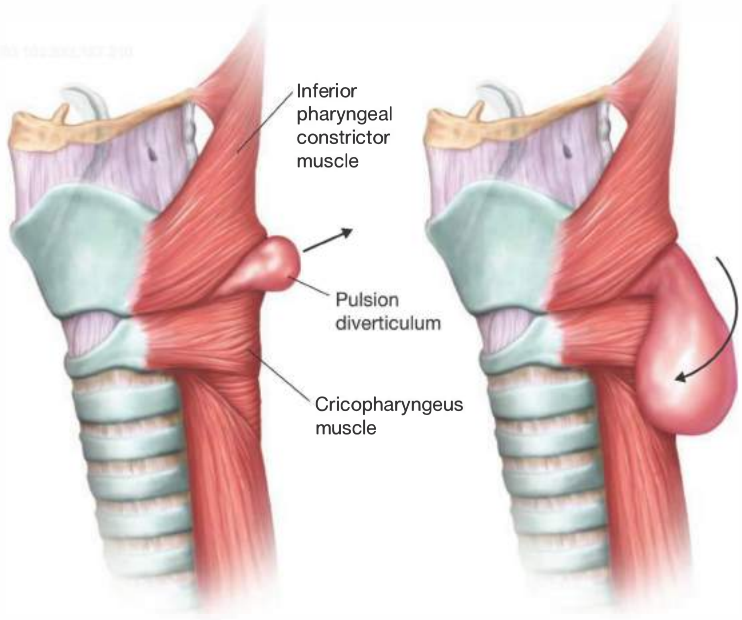

FIG 2 ● As intraluminal pressure increases due to spasticity of the cricopharyngeus muscle, the pulsion diverticulum forms.

confirms a Zenker's diverticulum. These studies would typically reveal a fluid-filled, cyst-like density adjacent to the level of the cricopharyngeus muscle.

- Chest imaging may reveal evidence of chronic aspiration pneumonitis.

SURGICAL MANAGEMENT

- Surgery is the mainstay of treatment for Zenker's diverticulum. Initially, surgeons sought to control the lesions by creating a controlled pharyngocutaneous fistula. In 1884, Niehans performed the first resection of a Zenker's diverticulum in Bern, Switzerland, but the patient died within 2 weeks of hemorrhage.[4] Wheeler[5] in Ireland completed the first successful resection in 1886. Until the mid-1900s, most operations were performed in two stages. In 1945, Harrington[6] at the Mayo Clinic reported a series of 107 cases repaired by a single-stage procedure that soon became the standard of care.
- Medical therapy with Botox injection of the cricopharyngeus muscle may provide *temporary* improvement of symptoms.
- Contemporary surgeons typically choose between an open and an endoscopic approach. When feasible, most prefer an endoscopic approach initially, citing faster recovery, lower complications, and success rates that are comparable, if not superior, to the open approach.
- The most common indication for the open approach is poor endoscopic exposure due to trismus, macroglossia, or spine disorders including osteophytes, kyphosis, or ankylosing spondylitis. Another indication for an open approach is failure of a prior endoscopic approach. Ironically, the most fragile patients are occasionally better candidates for an open approach. When the pulmonary status is particularly poor, the authors and others have used an open approach with local anesthesia successfully.[7]
- Whether open or endoscopic, a complete cricopharyngeal myotomy is the most important component of the operation.
- A diagnosis of Zenker's diverticulum does not always mandate intervention. These lesions are commonly found during routine esophagoscopy for other indications. The lesions may be observed if the patient is asymptomatic (no dysphagia, weight loss, chronic aspiration) and the lesion is relatively small (<2 cm) on barium swallow.

- The open approach includes two components: a cricopharyngeal myotomy and management of the diverticular sac. The myotomy is performed as described in the following discussion. The sac may either be resected or mobilized and suspended. The authors prefer resection, but the suspension option will be briefly illustrated as well.

TECHNIQUES

ENDOSCOPY AND DILATOR PLACEMENT

- Endoscopic evaluation of the diverticulum precedes the open approach if feasible. The diverticulum is visualized and the pouch is packed lightly with strip gauze to allow easier identification transcervically. A Maloney dilator (36 to 40 Fr) is placed into the cervical esophagus to simplify the myotomy.

POSITIONING

- The patient is placed in a supine position with the neck extended and head turned toward the nonoperative side. A shoulder roll may be helpful with a low-lying larynx or short neck.

SKIN INCISION

- A transverse incision is made in a natural skin crease at approximately the level of the cricoid cartilage (**FIG 3**).

FIG 3 ● Surgical approach is typically via a transverse incision in the left neck at the level of the cricoid cartilage.

APPROACH

- Subplatysmal flaps are developed. The investing fascia is opened along the anterior border of the sternocleidomastoid muscle and the muscle is rotated posteriorly. The plane of approach lies between the carotid sheath and the central compartment fascia. The central compartment contains the strap muscles, thyroid gland, larynx, trachea, and pharyngoesophageal segment. The plane is relatively avascular but is crossed at this level of the neck by branches of the thyroid vein and the omohyoid muscle.
- The omohyoid muscle can usually be mobilized superiorly or inferiorly without dividing but causes little morbidity if divided. The carotid artery is typically located more medial and deep to the jugular vein. The vagus nerve travels within the sheath but is often located posterior to the carotid artery and may not be seen.
- The recurrent laryngeal nerve, however, will commonly be at risk. The nerve lies in the tracheoesophageal groove within the central compartment at this level of the neck. To avoid damaging the nerve, the surgeon can either directly identify the nerve or approach the retropharyngeal space from a position well lateral to the central compartment. The authors prefer *not* uncovering the nerve but dissecting adjacent to the anterior edge of the carotid artery as the retropharyngeal space is approached (**FIG 4**). Once this space is reached, dissection can safely proceed medially while placing the nerve at very little risk. The authors do not typically employ laryngeal nerve monitoring during this procedure.

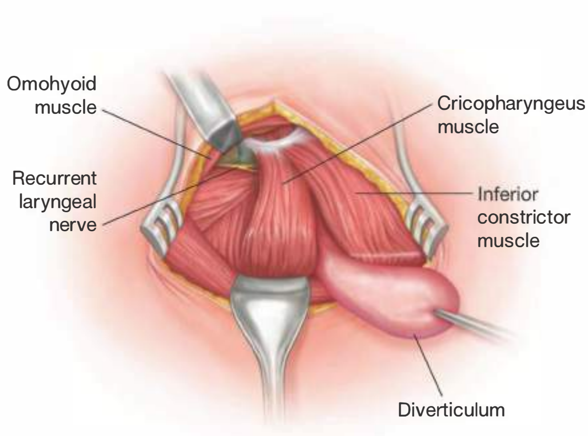

FIG 4 ● The diverticulum presents through Killian's dehiscence, with the inferior constrictor muscle cephalad and the muscle caudal.

MOBILIZING THE DIVERTICULAR SAC

- The most challenging portion of the procedure may be identifying and safely mobilizing the diverticular sac. Killian's dehiscence is located near the inferior border of the cricoid cartilage.
- The mouth of the sac exits the hypopharynx posteriorly. Depending on the size of the sac and the degree of associated fibrosis, the remainder of the sac is typically positioned to the left of midline.
- The wall of the diverticular sac should be carefully separated from the adjacent fibrofatty tissue. If there has been acute inflammation or previous surgery, this dissection may be tedious.
- Gauze packing previously placed within the sac may help delineate the wall of the sac from surrounding inflammatory tissue. The entire sac should be mobilized up to the junction with the back wall of the hypopharynx.

CRICOPHARYNGEAL MYOTOMY

- A myotomy is performed prior to transecting the diverticulum. The back wall of the pharyngoesophageal segment is identified, and the myotomy is positioned 1 to 2 cm to the left of the posterior midline (**FIG 5**).
- A hemostat is used to define the muscle and separate it from the underlying mucosa. The muscle is then divided sharply over the hemostat.
- A typical myotomy will be longer than 2 cm in length and should extend downward onto the cervical esophageal segment.
- The dilator placed in the esophagus will simplify this step. The color of the dilator should be visible through the esophageal wall as the underlying mucosa is approached.

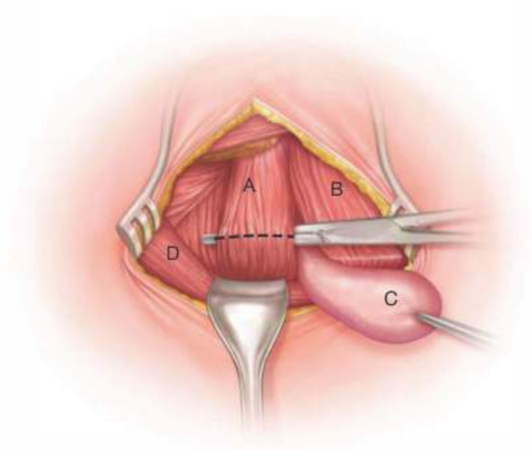

FIG 5 ● A complete cricopharyngeal myotomy is performed to relieve increased intraluminal pressure causing outflow obstruction. *A*, cricopharyngeus muscle; *B*, inferior constrictor muscle; *C*, diverticulum; *D*, omohyoid muscle

DIVISION OF THE DIVERTICULUM SAC AND MUCOSAL REPAIR

- Once fully mobilized, the sac can be resected or simply suspended. If suspension is preferred, the sac should be tacked upward so that the mouth of the diverticulum is dependent (**FIG 6**).
- The distal end of the sac is tacked to central compartment fascia with absorbable suture.
- The authors prefer to resect the diverticulum at this point. The dilator within the esophagus helps distinguish the neck of the diverticulum from the normal pharyngeal segment. Be aware that resection of normal pharynx

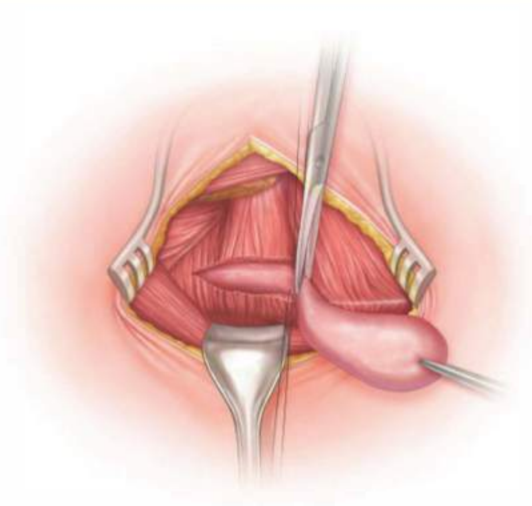

FIG 6 ● The neck of the diverticulum is transected at the junction with the pharyngeal wall, taking care not to resect normal pharyngeal lumen.

TECHNIQUES

and esophagus is surprisingly easy to do if the diverticular opening is wide-mouthed.

- Stay sutures are placed 180 degrees apart at the mouth of the diverticulum to help identify the line of closure.
- The sac is then transected with scissors or a stapling device.
- If cut sharply, a two-layer, imbricating closure is performed to minimize the chance of leak (FIG 7).
- Suction-assisted drains are placed after thorough irrigation, and the wound is closed in two layers.

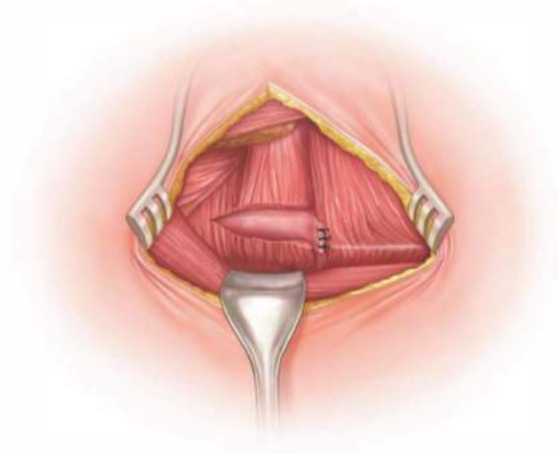

FIG 7 ● Closure of the pharyngotomy.

PEARLS AND PITFALLS

Indications	■ Symptoms may be subtle. Most patients have dysphagia. ■ Pulmonary complications of Zenker's diverticulum are common.
Workup	■ Barium swallow is necessary and sufficient for diagnosis.
Procedure	■ Begin with esophagoscopy. Consider gauze packing in diverticulum and dilator in esophagus to help delineate diverticulum from normal mucosa. ■ Approach retropharyngeal space from a lateral position to minimize risk to the recurrent laryngeal nerve. ■ A complete cricopharyngeal myotomy is essential. ■ The sac may be resected or suspended.

POSTOPERATIVE CARE

- If the diverticulum has been resected, patients are kept NPO for 3 days and an enteral feeding tube is used for nutrition. The authors typically repeat a modified barium swallow on day 3 to detect a potential leak and to determine adequacy of myotomy and efficacy of the swallow. If appropriate, patients are allowed to swallow full liquids and are discharged from the hospital. The diet is advanced to soft foods as tolerated.

OUTCOMES

- A review of the literature finding 1,696 cases of Zenker's diverticulum repaired by an external approach revealed 95% improvement in initial symptoms.[8] Another report compared patients treated by external approach ($n = 101$) with patients treated by an endoscopic approach ($n = 86$) and concluded that significantly more patients have symptomatic relief after external (open) approaches.[9] Open and endoscopic approaches for treatment of Zenker's diverticulum have not been compared in prospective clinical trials. Most surgeons today prefer the less invasive endoscopic approach when feasible.[1] Following an external approach to Zenker's diverticulum, the surgeon can anticipate that approximately 90% of patients will have improved symptoms and radiologic findings.

COMPLICATIONS

- As noted, many patients with Zenker's diverticulum are older and chronically debilitated. The surgeon should carefully weigh operative risk and frankly inform the patient and family accordingly.
- Complications from open repair of Zenker's diverticulum result from damage to adjacent structures during the approach and from infectious complications related to salivary fistula and chronic aspiration. In a literature review, Engel and

Panje[10] reported these complication rates from an external approach to Zenker's diverticulum: fistula (6.3%), recurrent laryngeal nerve injury (3.6%), mediastinitis (3.1%), pneumomediastinum (0.8%), and death (2%). Gutschow et al.[9] reported fistula in 8.6% and mediastinitis in 3.6% (0% in patients with external approach). Chang et al.[8] reported overall complication rates of 11.8% for external approaches and 5.5% for combined endoscopic approaches.

Chapter 13

Cricopharyngeal Diverticulum: Endoscopic Repair

Kirk P. Withrow William R. Carroll

DEFINITION

- Diverticula of the hypopharynx have been recognized for over 200 years. Zenker's diverticulum (ZD) is by far the most common with an annual incidence rate of 2/100,000 individuals.[1] Specifically, ZD is an outpouching of hypopharyngeal mucosa that occurs at the junction of the inferior constrictor and cricopharyngeus (CP) muscle through a weak area known as Killian's dehiscence (**FIG 1**). As it is essentially just a mucosal sac, it is technically considered a "false" diverticulum. This is an acquired disorder that most commonly presents between the sixth and eighth decade of life and affects more men than women. In rare cases, there is a family history of ZD and evidence of genetic predisposition toward its development.[2] Although the exact etiology of ZD remains debatable, most agree that it represents a pulsion diverticulum occurring due to a rise in intraluminal pressure relative to the resistance of the esophageal wall. Although manometry data from available studies provide conflicting information about CP muscle activity in ZD patients, clinical observation as well as less favorable swallowing outcomes in patients who did not have a CP myotomy as part of their treatment strongly implicate abnormal CP function in the formation of ZD.
- Historically, ZD was first recognized by Abraham Ludlow in 1796 and was named after Friedrich Albert Zenker who reported a series of ZD patients in 1877. The first successful open repair of a ZD was reported by Wheeler in 1882.[3] In 1917, Mosher first introduced the concept of endoscopic treatment of ZD that has now seen tremendous advances with respect to both instrumentation and technique.[4] The most common method used for treatment of ZD, the endoscopic staple-assist approach, was first reported by Collard in 1993.[5]

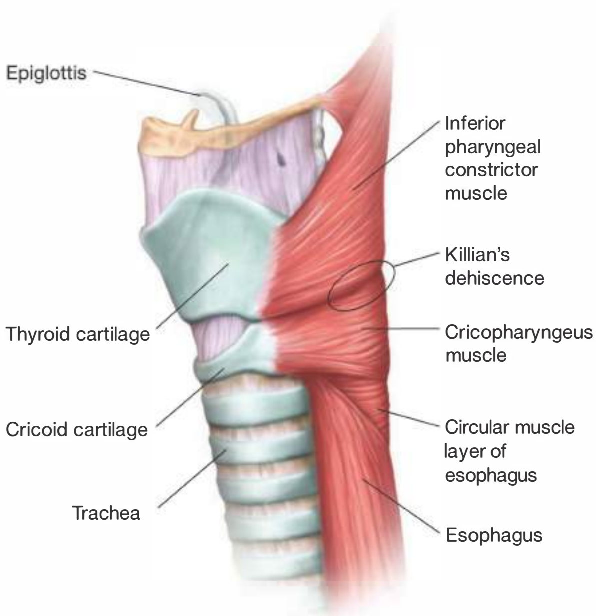

FIG 1 ● Anatomy of the junction of the hypopharynx and esophagus. Killian's dehiscence is located between the inferior pharyngeal constrictor and the CP muscle.

DIFFERENTIAL DIAGNOSIS

- Achalasia
- Esophageal cancer
- Esophageal dysmotility
- Esophageal spasm
- Esophageal stricture
- Gastroesophageal reflux disease (GERD)
- Thyroid goiter
- Myasthenia gravis
- Bulbar palsy

PATIENT HISTORY AND PHYSICAL FINDINGS

- Cervical dysphagia is the most common presenting symptom of ZD. Other symptoms may be quite subtle and include chronic cough, unexplained weight loss, and halitosis. As the patient swallows, the bolus preferentially enters the relatively wider mouth of the diverticular pouch rather than passing through the inappropriately closed upper esophageal sphincter into the esophagus. This in turn may lead to a sense of neck fullness and may be associated with a gurgling sound in the lower neck referred to as cervical borborygmi. Regurgitation of completely undigested food ingested minutes to hours previously is considered near pathognomonic for ZD. The pouch may fill and empty spontaneously during deglutition leading to coughing, choking, and possibly aspiration. Many patients report significant negative psychological and social impact due to a fear of suffering from choking and regurgitation during a meal.
- Most commonly, ZD patients present with a normal physical exam. When an abnormality is present, it is generally a neck mass in the tracheoesophageal groove that may gurgle or decompress with palpation (Boyce's sign). Audible gurgling may be detected over the same region with swallowing. Inspection of the hypopharynx may reveal pooling of secretions. Visualization of the pouch is generally only possible via esophagoscopy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Barium swallow is the primary study used in the diagnosis of ZD. A characteristic sac is noted just posterior to the esophagus (**FIG 2**). It arises just superior to a prominent

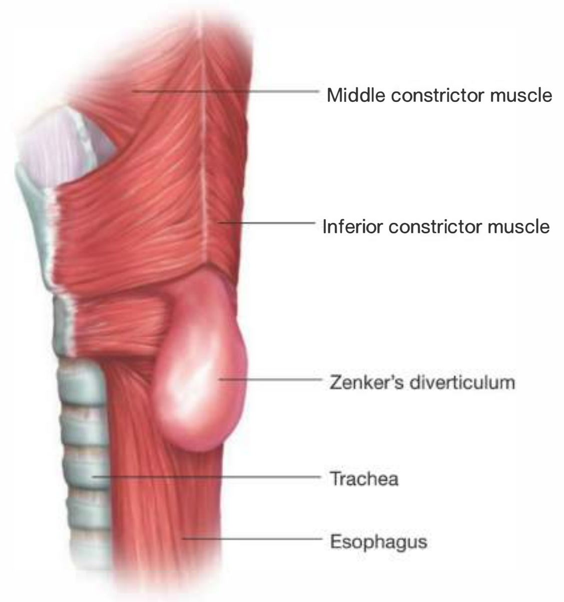

FIG 2 ● Zenker's diverticulum. The increase in intraluminal pressure during deglutition in face of relative cricopharyngeal hypertonia leads to the formation of a mucosal outpouching just superior to CP muscle (pulsion diverticulum).

CP muscle often termed a CP "bar." With this study, the surgeon can accurately size the sac and determine its location. Some authors recommend obtaining manometry testing on all ZD patients; however, that is not the practice of the authors. Computed tomography (CT) and magnetic resonance imaging (MRI) are not generally needed in these patients.

SURGICAL MANAGEMENT

Preoperative Decision Making

- The first decision a ZD surgeon has to make is whether to offer the patient surgery at all. If a patient is minimally symptomatic and of advanced age, then continued observation may be the best course of action. Medical therapy with botulinum toxin aimed at treating CP muscle achalasia is another option, although the benefit of this in ZD is much more limited than that seen in CP dysfunction without diverticulum. On the other hand, if surgery is to be offered to the patient, the surgeon should be capable of performing both open and endoscopic approaches and should clearly delineate the pros and cons of each. With an open approach, there is a cervical scar, longer surgical time, longer recovery, and longer delay to eating but potentially higher rates of symptom improvement and a lower rate of recurrent symptoms. With an endoscopic approach, there is no cervical scar, there is shorter surgical time, and most patients can resume eating the same day. Unfortunately, it is associated with a rate of recurrence as high as 10% in some reports.[6] The increased rate of recurrence is understandable as the act of dividing the common wall between the diverticular sac and the esophagus, and thus the CP muscle contained therein, does not always result in a complete CP myotomy. It is the belief of the authors that the rate of recurrence after an endoscopic repair may, at least in part, be directly related to the amount of CP muscle left intact.
- The primary anatomic considerations for an endoscopic repair include (1) factors related to exposure and (2) size of the diverticulum. Bloom et al.[7] reported unsuccessful exposure in 30% in a series of 30 patients in 2010. Shorter neck, shorter hyomental distance, and increased body mass index (BMI) showed significant correlation with failed exposure, whereas the presence of maxillary teeth trended toward significance. Further diminished cervical mobility and trismus may also hinder successful endoscopic exposure. With respect to the size, it is generally felt that very small (<2 cm) and very large (>4 cm) diverticulum may be best treated via an open approach. In the case of a small diverticulum, this is due to difficulty in engaging and grasping the common wall between the ZD and esophagus. Various modifications to the endoscopic technique address this and include using carbon dioxide (CO_2) laser or Harmonic scalpel, modifying the tip of the stapler to allow the blade and staples to be deployed closer to the tip of the device, and using traction sutures to pull the diverticulum into the jaws of the stapler.[8] The concern with a very large diverticulum is that the large, redundant, hypotonic sac may lead to persistent symptoms of dysphagia, although this is only anecdotal at present. Visosky et al.[9] reported a series 61 ZD patients who underwent endoscopic treatment and noted the main risk factors for recurrence were size larger than 3 cm and the associated amount of redundant mucosa noted after repair.

Operative Management—Endoscopic Approach

- The successful treatment of ZD via an endoscopic approach, much like the open counterpart, includes two components: a cricopharyngeal myotomy and management of the diverticular sac. In contrast to an open repair in which a myotomy is performed followed by management of the diverticulum itself, these occur simultaneously when performing an endoscopic repair. Essentially, the "common wall" or septum between the diverticulum and esophagus is divided, leading to the creation of a "common cavity." Structurally, the common wall is composed of the CP muscle with the herniated mucosa draped over it. In this sense, the two primary goals of ZD surgery can be achieved via an endoscopic approach, but they cannot be separated from one another.

- Patients are placed under general anesthesia and have oral endotracheal intubation. Preoperative antibiotics are given to cover oral flora. If teeth are present, they are protected with a rubber dental guard; if edentulous, a moist gauze is used to protect the alveolus. The eyes are protected with Tegaderm to maintain closure and gauze secured over top. A shoulder roll is used as needed to optimize position.
- A bivalve diverticuloscope is then used to expose the ZD. Either the adjustable Weerda diverticuloscope (Karl Storz, Tuttlingen, Germany) or the slightly longer, fixed blade van Overbeek (Medin, Groningen, Holland) is generally used. It is advanced into the postcricoid space and further into the hypopharynx with care not to cause mucosal injury by forcing the scope. The posterior blade is directed into the ZD and the anterior blade into the esophagus. If using the Weerda, adjustments are made to maximize visualization and the diverticuloscope is attached to a laryngeal suspension arm. At this point, the common wall or septum should be centered in the operative field between the two blades of the scope and probing of both the ZD and esophagus can be readily performed (**FIG 3**). Any food debris within the ZD is cleared with suction. The use of a 0- or 30-degree rigid Hopkins rod telescope facilitates excellent visualization of the surgical field. The authors prefer using a 30-degree telescope as the beveled lens affords varying views simply by rotation of the scope.
- It is at this stage in the endoscopic treatment of ZD that many variations and options exist. As stated, the most frequently performed procedure is a staple-assisted repair. This decreases the concern some surgeons have about the risk of mediastinitis in the setting of a sutureless repair as several staple lines are deployed along each side of the incision. Typically, the 35-mm Endo GIA (U.S. Surgical Corp, Norwalk, CT) is used in this technique (**FIG 4**). If this is not long enough, the surgeon may elect to use multiple 35-mm staple loads, a 45-mm staple load, or occasionally, the combination of endoscopic stapler and Harmonic scalpel. In an effort to minimize the amount of residual septum and thus the amount of residual CP muscle remaining after endoscopic staple-assisted repair, modification of the instrument was introduced. By shortening the anvil, the incising blade and the staple lines are allowed to extend closer to the base of the septum, thus leaving a lower residual septum and presumably minimizing the risk of persistent or recurrent symptoms. On the contrary, this modification does potentially increase the risk of perforation as the incising blade is more readily able to pass beyond the confines of the diverticulum. The authors routinely used a modified form of the Endo GIA stapler with excellent results and no increase in complications. Regardless of whether the stapler is modified, the staple cartridge blade is placed in the esophagus and the anvil blade is placed in the diverticulum (**FIG 5**). Once the blades are in position, they are approximated, thus grasping the septum. Again, the use of a telescopic lens allows rapid confirmation of accurate placement of

FIG 4 ● **A,B.** Endo GIA stapler. The area indicated at the tip of the stapler anvil represents the portion that is removed when a modified stapler is used.

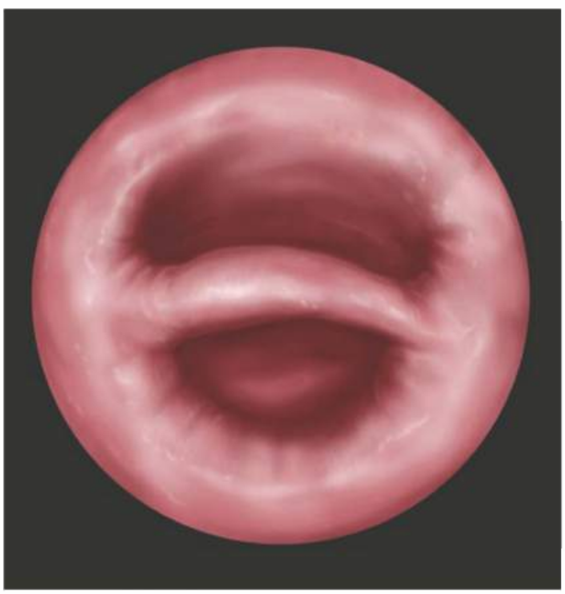

FIG 3 ● Endoscopic view of exposed ZD.

the stapler. Activation of the stapler leads to simultaneous incision of the septum and stapling of both sides. Removal of the stapler allows assessment of the adequacy of the repair (**FIG 6**). If desired, a nasal feeding tube can be placed under direct visualization at this time.

- Additional methods for the endoscopic treatment of ZD include Harmonic scalpel and CO_2 laser. The authors use the Harmonic scalpel for endoscopic treatment of smaller ZD as this instrument is more readily able to grasp the septum (**FIG 7**). Whited et al.[10] reported an increased complication rate when comparing Harmonic to staple-assisted repair (25% vs. 4.88%). On the contrary, Sharp et al.[11] reported a higher complication rate in staple-assisted repair as compared to Harmonic scalpel (17.9% vs. 5%), although this was not significant. It should be noted that both studies reported that all complications occurred in patients with ZD larger than 2 cm. In the study by Sharp et al.,[11] the Harmonic scalpel was preferentially used in cases with smaller diverticulum size, a fact that may account for the lower complication rate in that group. Further, the authors use the CO_2 laser primarily for performing CP myotomy to treat cases such as CP dysfunction without ZD formation. This is primarily due to reports of mediastinitis as well as an increased incidence of subcutaneous emphysema with CO_2 laser division of the common septum,[12,13] indicating a possible increased risk of transmural injury of the pharynx. It is the opinion of the authors that this is most likely due to collateral thermal damage as well as the necessity of incising the mucosa and underlying muscle without grasping the septum, an aspect of both stapler- and Harmonic-assisted repair, which serves in part to limit the incision to tissue present within the lumen.

PEARLS AND PITFALLS

- Diagnosis is generally suspected via history and confirmed by barium esophagram.
- Patients should be counseled regarding all treatment options including observation, open repair, and endoscopic repair. A surgeon who treats ZD should be comfortable with both endoscopic and open treatment as performing the same procedure for every patient is not likely to provide the best care.
- Regardless of approach, a complete CP myotomy is essential and failure to completely divide the muscle likely results in an increased rate of recurrent ZD.

POSTOPERATIVE CARE

- Following endoscopic ZD repair, patients are kept NPO until the absence of a pharyngeal leak is confirmed with a water-soluble contrast (i.e., Gastrografin) esophagram. The authors most often perform this on the morning of the first postoperative day but can be performed as early as 6 to 8 hours after surgery. If no leak is detected and a nasal feeding tube was placed, it is removed at this time and the diet is advanced. The patient is typically discharged at this time on a restricted liquid diet for the first 3 postoperative days and advanced to a soft diet as tolerated until follow-up appointment 2 weeks after discharge. If doing well, they can advance the diet to normal as tolerated at this time. On the contrary, if a leak is identified, the patient is kept NPO and maintained on enteral nutrition via a nasogastric feeding tube. If no nasal feeding tube was placed at the time of surgery, this is best accomplished under fluoroscopy to ensure the tube is not placed in a false passage. Alternatively, provided the leak was noted to be small, the patient can be kept NPO and maintained on intravenous (IV) fluids for a few days until a repeat esophagram shows resolution of the leak.

OUTCOMES

- Narne et al.[14] reported a 30-year experience comparing 297 patients treated via an open approach (n = 116) and an endoscopic staple-assisted approach (n = 181). Successful resolution of symptoms was reported in 92% and 94% in the endoscopic group and the open group, respectively. Of note, follow-up in the endoscopic group was 2 years compared to 4 years for the open group. Chang et al.[6] reported on 159 patients treated with endoscopic staple-assisted repair noting excellent results but a 12% recurrence rate. Other studies cite recurrence rates as high as 19% to 32%.[15,16] Another report compared patients treated by external approach (n = 101) with patients treated by an endoscopic approach (n = 86) and concluded that significantly more patients have symptomatic relief after open repair.[17] Although open and endoscopic approaches for treatment of ZD have not been compared in prospective clinical trials, most surgeons today prefer the less invasive endoscopic approach when feasible. Despite some variability in the data, treatment of ZD is via either approach.

COMPLICATIONS

- As with any transoral procedure, there is a risk of dental injury during the procedure. This risk can be minimized by use of a dental guard and exercising caution during the exposure. Major complications from endoscopic repair of ZD are predominately related to pharyngeal leak and associated infectious sequelae. Although recurrent laryngeal nerve injury has been reported from endoscopic repair of ZD,[18] the fact that the approach is intraluminal makes this complication exceedingly rare. Gutschow et al.[17] reported an increased rate of fistula in open repair compared to endoscopic repair (8.6% vs. 0%). Interestingly, five of the six cases of salivary fistula occurred after open repair that was performed without CP myotomy, further underscoring the importance of complete myotomy in the treatment of ZD. Three cases of mediastinitis occurred in this series, all in patients treated with CO_2 laser–assisted endoscopic repair.[17]

Several other studies comparing endoscopic staple-assisted and laser-assisted repair noted an increased rate of subcutaneous emphysema in those treated with the CO_2 laser.[12,13,19] Chang et al.[6] reported a 2.0% rate of significant complications without any mortality. Wasserzug et al.[20] reported two complications in his series of 60 patients treated with endoscopic staple-assisted repair. Esophageal perforation occurred in one case while severe esophageal edema occurred in another; both resolved with only conservative management.[20] Overall, the complication rate for endoscopic approach to repair of ZD is comparable if not favorable when compared to an open approach.

Chapter 14

Epiphrenic Diverticulum Treatment

Ryan Levy   Catherine Go   Ryan A. Macke   Peter Ferson
James D. Luketich

DEFINITION

- Epiphrenic diverticula are those that occur in the distal 10 cm (lower third) of the esophagus. They constitute approximately 20% of all esophageal diverticula. The underlying pathophysiologic mechanism is a result of increased intraluminal pressure, presumably secondary to an esophageal motility disorder. Most commonly, epiphrenic diverticula occur in the setting of achalasia or diffuse esophageal spasm. A high-pressure environment in the esophageal lumen is potentially created by some form of distal functional or mechanical obstruction, such as a nonrelaxing, hypertensive lower esophageal sphincter (LES); repetitive normal to high amplitude simultaneous contractions; or a distal peptic stricture. A prior fundoplication for the treatment of reflux may also lead to epiphrenic diverticula in the setting of an esophageal motility disorder. Any of these processes may lead to herniation of the mucosa and submucosa through an area of weakness in the muscle layers of the esophagus. Epiphrenic diverticula are thus false, or pulsion, diverticula.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of epiphrenic diverticula includes hiatal hernia, esophageal webs and strictures, esophageal duplication cyst, and esophageal carcinoma. Equally relevant is the differential diagnosis of the underlying cause of the epiphrenic diverticulum, which includes achalasia, diffuse esophageal spasm, nonspecific motility disorder, hypertensive LES, end-stage gastroesophageal (GE) reflux disease with a "burnt out" esophagus, peptic stricture, or failed previous fundoplication.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Epiphrenic diverticula are estimated to be symptomatic in only 15% to 20% of cases. Typical symptoms include dysphagia and regurgitation. Reflux and chest pain may also commonly occur. Pulmonary symptoms may include chronic cough, productive or purulent sputum, or chronic dyspnea. Malodorous breath may also be present.
- On history, it is important to elicit whether the patient experiences symptoms of GE reflux disease, regurgitation, chest pain, or dysphagia. Additional medical history such as recurrent pneumonia, lung abscesses, or repeated aspiration episodes is pertinent. A history of weight loss is not uncommon.
- Prior procedures such as esophageal dilations or botulinum toxin injection are also pertinent.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Epiphrenic diverticula are associated with an underlying esophageal motility disorder in most cases. It is imperative to not only assess the size and location of the diverticulum but also to characterize the motor function of the esophagus.
- A barium esophagram is the initial test performed to define the anatomy of the diverticulum and esophagus. Size, location, and right or left sidedness can be determined from the esophagram. This provides a "road map" for operative planning, as diverticula more than 7 to 10 cm above the diaphragm are not easily accessible through the transhiatal route and may be better approached from the chest. Barium esophagrams may also offer information about motility.
- High-resolution manometry, the current gold standard, is necessary to evaluate for an underlying esophageal motility disorder. In the setting of achalasia, manometry demonstrates aperistalsis with a nonrelaxing LES. Other manometric patterns seen in the setting of epiphrenic diverticula include diffuse esophageal spasm (80% or more simultaneous contractions of normal amplitude), nonspecific motility disorder, nutcracker esophagus, or hypertensive LES. Failure to identify and treat the underlying motility disorder during diverticulum resection has been associated with high rates of recurrence and leak along the suture line in the range of 10% to 20%.[1] Specifically, failure to perform an adequate myotomy in such patients has yielded leak rates exceeding 25% when diverticulectomy alone is performed.
- Preoperative upper endoscopy is necessary to examine the esophagus and stomach for the presence of Barrett's, esophagitis, and to exclude malignancy.[2] In addition, the presence of a pop upon passage of the scope across the LES may further confirm the diagnosis of achalasia. Lastly, it is important to remove debris from the diverticulum on the day of surgery.

SURGICAL MANAGEMENT

- The need for surgical resection of epiphrenic diverticula largely depends on the patient's symptoms. Small, asymptomatic diverticula (less than 3 cm) often do not require intervention. Symptomatic patients with small diverticula may benefit from myotomy (with concomitant partial fundoplication) to correct the underlying motility disorder. Larger diverticula require diverticulectomy in addition to myotomy (with concomitant partial fundoplication).

Preoperative Planning

- A review of the barium esophagram is helpful to confirm the size and location of the diverticulum relative to the diaphragm and GE junction. It also defines the esophageal anatomy in terms of degree of esophageal dilation and presence of megaesophagus or sigmoid appearance in the setting of achalasia.
- The patient's diet should be restricted to clear liquids for 2 days prior to surgery to minimize the accumulation of food debris in the diverticulum prior to operation.
- The anesthesiologist must be informed that rapid sequence induction is needed to minimize risk of aspiration.
- After induction of anesthesia, upper endoscopy should be performed to delineate esophageal anatomy, rule out malignancy, and remove debris from the pouch. Esophagogastroduodenoscopy (EGD) should also evaluate for the presence of a "pop," which is consistent with achalasia.
- Prophylactic antibiotics should be administered prior to skin incision, with consideration given to covering for oral flora, anaerobes, and yeast.
- Standard procedures such as sequential compression devices and Foley catheter are employed.

Positioning

- Positioning of the patient varies with surgical approach. When approaching epiphrenic diverticula from the abdomen, the patient is positioned supine. If a thoracic approach is chosen, the patient is placed in either a right or left lateral decubitus position. The authors prefer a right-sided video-assisted thoracic surgery (VATS) approach, and therefore use the left lateral decubitus position. If a thoracic approach is used, single-lung ventilation is needed with use of a double lumen endotracheal tube or bronchial blocker.

TECHNIQUES

VIDEO-ASSISTED THORACIC SURGERY

- Either a right or left VATS may be used for a minimally invasive thoracic approach to the diverticulum. The location of the diverticulum typically dictates the side of the approach. Classically, distal diverticula have been approached from the left side, whereas more proximal diverticula are more readily approached from the right. However, in the authors' experience, a right-sided VATS approach works equally well for the classic, distally located right- or left-sided epiphrenic diverticula.

Video-Assisted Thoracic Surgery Port Placement

- We commonly employ a five-port approach to VATS resection of epiphrenic diverticula. The port placements are identical to the ports we employ for minimally invasive esophagectomy. Specifically, the surgeon works from the posterior ports, which include an infrascapular tip 5-mm port and a 10-mm port in the 9th interspace along a line parallel to the infrascapular tip port. The remaining three ports are assistant ports and include a 10-mm camera port in the 9th interspace along the posterior axillary line, a 5-mm port for endoscopic suction in the 7th interspace in the midaxillary to posterior axillary line, and a lung retraction 10-mm port in the 5th interspace in the posterior axillary line. See **FIG 1** for ideal placement of ports.[3]

Entering the Chest and Mobilizing the Esophagus

- Upon entering the chest, the inferior pulmonary ligament is divided and the lung is retracted superiorly and anteriorly.
- A diaphragm stitch is placed through the central tendon of the diaphragm with a 48-in 0-Surgidac Endo Stitch. It is brought out the right flank at the level of the inferior diaphragm insertion using an endoscopic Endo Close device. Tension is applied to the retraction stitch to retract the diaphragm caudally, exposing the distal esophagus and esophageal hiatus.
- Using sharp dissection with a heat source such as an ultrasonic scalpel, the mediastinal pleura overlying the esophagus is opened. As much of the pleura as possible is kept intact so that it may be reapproximated over the repair at the end of the procedure. As such, the pleura is gently dissected away from the esophagus. Opening

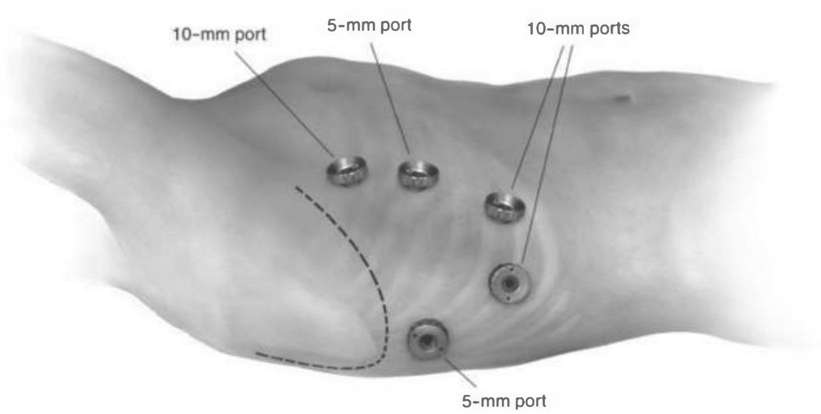

FIG 1 ● Right VATS thoracoscopic port placement.

of the mediastinal pleura from the diaphragm up to the azygous vein is beneficial, as it will be necessary for the performance of a long myotomy. The azygous vein can be divided as needed with an endoscopic stapler.

- Once the pleura has been opened adequately, esophageal mobilization is carried out. If an ipsilateral approach is taken to the diverticulum (right VATS for a right-sided diverticulum), minimal mobilization is needed. However, if the diverticulum protrudes on the contralateral aspect of the esophagus, the esophagus must be mobilized so that it may be rotated to provide adequate exposure for dissection of the diverticulum and its neck.
- A Penrose drain may be used to encircle the esophagus and aid in esophageal mobilization.
- Both vagus nerves should be identified and preserved whenever possible.
- It is necessary to expose the entire diverticulum and its neck. The diverticulum may be grasped with an endoscopic Babcock grasper (Snowden-type endoscopic forceps). Alternatively, a long stitch may be placed in the apex of the diverticulum to aid with retraction during dissection. Subsequently, the diverticulum is circumferentially dissected free from its surrounding attachments. It is not uncommon for there to be significant inflammatory type adhesions from the diverticulum to surrounding structures. It is essential to dissect the surrounding esophageal muscle fibers down to the neck of the diverticulum. This maneuver is critical in order to ensure complete resection of the diverticulum at the time of stapling. A common technical error is failure to expose the true neck of the diverticulum, which subsequently results in improper positioning of the stapling device and therefore leaves a residual diverticulum.

Diverticulectomy

- Once the neck of the diverticulum is clearly visualized, either the endoscope or a 48- to 54-Fr bougie should be inserted into the esophagus beyond the GE junction. This prevents narrowing of the esophageal lumen during stapling of the diverticulum. If difficulty is encountered passing the bougie, intraoperative upper endoscopy should be performed and a wire passed distally through the true lumen of the esophagus into the stomach. The bougie may then be passed over the wire to minimize risk of perforation.
- With minimal tension on the diverticulum, the stapling device is positioned along the base (neck), parallel to the longitudinal axis of the esophagus (**FIG 2**).
- The diverticulum is then transected with a reticulating endoscopic stapler. The authors prefer to use a vascular load for transection of the mucosa and submucosa that comprises the diverticulum.

Esophagomyotomy

- It is preferable to perform the myotomy at least 90 degrees away from the diverticular staple line if possible. The longitudinal esophageal muscle fibers are incised initially with either an ultrasonic scalpel or hook cautery along the direction of the fibers. Alternatively, the myotomy may also be started with a blunt technique by pulling apart the longitudinal muscle fibers. Once the underlying circular muscle fibers are exposed, they are sharply divided. It is critical to lift the circular muscle fibers away from the underlying mucosa to avoid perforation of the mucosa layer (**FIG 3**).

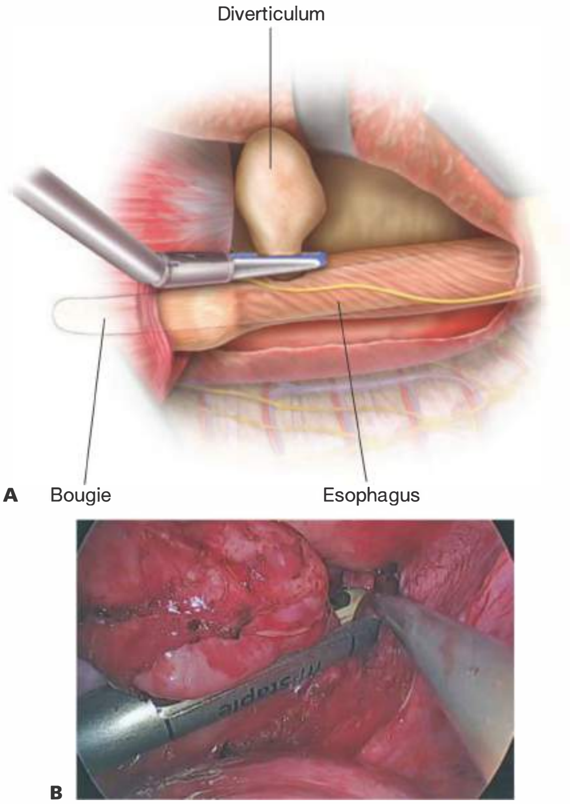

FIG 2 ● **A.** Circumferential dissection of the diverticulum, bougie in the esophagus, and endoscopic stapler excising the diverticulum. **B.** Excision of the diverticulum with the stapler placed at the neck of diverticulum.

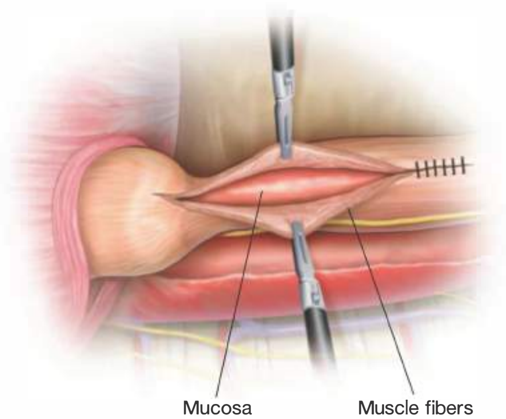

FIG 3 ● Esophageal myotomy with gastric cardia extension.

- Attempt to preserve the main vagal trunks while performing the myotomy.
- The total length of the myotomy should extend several centimeters (3 to 5 cm) above the proximal extent of the diverticulum. Distally, the myotomy should extend to or across the GE junction, depending on the preoperative manometry results and the underlying pathologic diagnosis. For example, an LES that has a normal resting pressure and normal relaxation may not require myotomy across the GE junction, preserving its natural antireflux function. If the patient has achalasia, the myotomy should ideally extend to 3 cm below the GE junction, carrying the myotomy onto the sling muscle fibers of the gastric cardia.
- The muscle layer is dissected laterally off the underlying mucosa for a short distance in the submucosal plane to prevent potential healing of the myotomy site (muscle reconstitution).
- The integrity of the myotomy and diverticulectomy sites are submerged under saline and upper endoscopy with insufflation of air is done to check for leaks. Intraoperative mucosal perforations are repaired with interrupted absorbable suture. The muscle layers are then reapproximated over the diverticulectomy staple line with interrupted 2-0 Surgidac Endo Stitch.
- The mediastinal pleura may also be loosely reapproximated over the esophagus with interrupted 2-0 Surgidac Endo Stitch for additional protection of the staple line.
- The need for an antireflux procedure should also be addressed at this point, depending on the patient's preoperative reflux symptoms and motility studies.[1,4] If the patient carries a diagnosis of achalasia, an antireflux operation should be considered. There are several options at this point. If performing the case from a left VATS, one may attempt a Belsey Mark IV fundoplication. This can be quite challenging and technically demanding from a VATS approach (traditionally performed via left thoracotomy). A second option is to combine VATS with laparoscopy and perform a standard laparoscopic Dor or Toupet (partial) fundoplication. Partial fundoplications are favored in the setting of esophageal motility disorders, as a complete (Nissen) fundoplication may lead to obstruction of the dysmotile esophagus and recurrent diverticula. Lastly, one could forego the antireflux procedure and treat any reflux symptoms with proton pump inhibitors (PPI), opting to perform a fundoplication selectively at a later time depending on patient symptoms and response to medical therapy.

Closure

- Once hemostasis is achieved, a pleural drain (chest tube, Blake drain, or pigtail catheter) is placed.
- A Jackson-Pratt (JP) drain is also placed along the posterior mediastinum near the diverticula staple line to control any leak that can potentially occur postoperatively.
- Intercostal bupivacaine is injected for analgesia.

OPEN THORACIC APPROACH

- The operative steps for an open transthoracic epiphrenic diverticulum resection are similar to those described earlier for the minimally invasive approach. A 7th interspace thoracotomy is used. An open left thoracic approach is ideal when a fundoplication is to be performed from the chest (Belsey Mark IV). Use of a thoracoabdominal (TA) stapler or resection and hand-sewn closure of the mucosa are commonly used techniques for resection of the diverticulum when an open approach is used.

LAPAROSCOPIC TRANSHIATAL APPROACH

Port Placement

- The patient is initially positioned supine, with arms out and a footboard in place (to allow for reverse Trendelenburg positioning, which improves hiatal exposure). The surgeon operates from the right side of the table.
- The abdomen is then mapped. A line is drawn from the xiphoid to the umbilicus and divided into thirds. Five abdominal ports are used (**FIG 4**). The initial port is placed via an open (Hassan) technique in the right paramedian area at the junction of the upper and middle thirds of the previous markings. Pneumoperitoneum is set to 15 mmHg. The left paramedian port serves as the camera port. The assistant then retracts the hepatic flexure to expose the lateral abdominal wall just below the 12th rib. A 5-mm port is placed here and the liver retractor brought in and placed under the left lobe of the liver, retracting it superiorly to expose the esophageal hiatus. Finally, bilateral

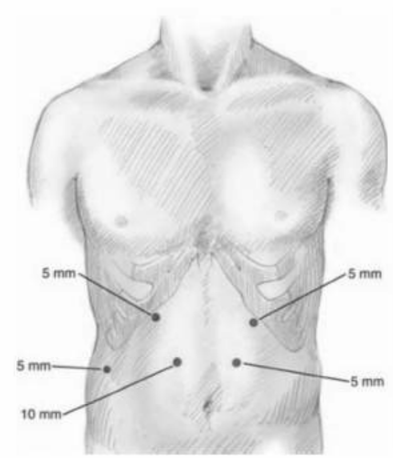

FIG 4 ● Laparoscopic port placement for abdominal approach.

midclavicular subcostal ports are placed. All ports should be a handbreadth apart to avoid unwanted contact between the surgeon's and assistant's instruments. Skin incisions must be made as small as possible to help ports remain in place and minimize accumulation of subcutaneous emphysema. See FIG 4 for ideal placement of ports.[2,5]

Mobilizing the Esophagus

- The gastrohepatic ligament is opened with an ultrasonic scalpel or other energy device to expose the right crus.
- The phrenoesophageal membrane is divided circumferentially around the esophageal hiatus to gain access to the mediastinum and intrathoracic esophagus. The peritoneal lining along the left and right crura should be preserved. Mediastinal mobilization of the esophagus, GE junction, and any associated hiatal hernia is then performed. The anterior and posterior vagal nerves should be identified and preserved during this dissection.
- The short gastric vessels and gastrosplenic attachments are divided so that the upper third of the fundus along the greater curvature is completely mobile for creation of the fundoplication.

Diverticulectomy

- As described earlier, it is necessary to expose the entire diverticulum and its neck. The diverticulum is circumferentially dissected free from its surrounding attachments. Again, it is essential to dissect off the surrounding esophageal muscle fibers down to the neck of the diverticulum. This maneuver is critical in order to ensure complete resection of the diverticulum at the time of stapling.
- Once the neck of the diverticulum is clearly visualized, either the endoscope or a 48- to 54-Fr bougie should be inserted into the esophagus beyond the GE junction as described previously. This prevents narrowing of the esophageal lumen during stapling of the diverticulum.
- With minimal tension on the diverticulum, the stapling device is positioned along the base (neck) parallel to the longitudinal axis of the esophagus.
- Transect the diverticulum with a reticulating endoscopic stapler at its neck.

Esophagomyotomy

- It is preferable to perform the esophagomyotomy 180 degrees from the staple line. However, if this is not possible, then it is preferable to perform the myotomy at least 90 degrees away from the diverticulectomy site.
- The authors prefer to start the myotomy by separating the longitudinal muscle fibers with a blunt technique using Snowden forceps. It is important to pull with equal tension along each side during this maneuver. Once the myotomy is started, we often switch to sharp division of the remaining longitudinal and circular fibers using the ultrasonic scalpel or hook electrocautery. The proximal extent of the myotomy should extend several centimeters above the proximal extent of the diverticulum. If the patient has achalasia, the distal extent of the myotomy should be 3 cm distal to the GE junction so as to include the sling fibers of the proximal most aspect of the gastric cardia.
- Once again, the muscle layer is dissected off the underlying mucosa laterally on each side for a short distance in the submucosal plane to prevent potential healing of the myotomy site (muscle reconstitution).
- Mucosal integrity can be examined by submerging the esophagus in saline and insufflating with the endoscope to look for an air leak. Small leaks can be closed with a simple stitch.
- Along the diverticulectomy site, the muscle layers of the esophagus are reapproximated over the staple line with 2-0 Surgidac Endo Stitch.
- As mentioned previously, at the end of the esophagomyotomy, an antireflux procedure is often performed, which is most commonly a partial fundoplication (Dor, Toupet, or Belsey Mark IV). The authors prefer an anterior 180-degree fundoplication (Dor) for most cases of achalasia and epiphrenic diverticula (FIG 5).

Closure

- A JP drain is placed through the hiatus along the diverticulum staple line to control any potential leak that may occur postoperatively.

FIG 5 ● Laparoscopic Dor anterior fundoplication.

PEARLS AND PITFALLS

Diverticulectomy	■ Staple over a bougie or endoscope to prevent esophageal luminal narrowing. ■ Incomplete dissection of the diverticular neck can lead to stapling too high, leaving a residual diverticulum.
Esophagomyotomy	■ Failure to perform an adequate esophagomyotomy is associated with up to a 20% rate of recurrence and/or leak. Be sure to extend the myotomy beyond the borders of the staple line longitudinally and to address the original motility disorder. ■ Reapproximate the esophageal wall muscle loosely over the diverticulum resection site. This can help minimize the development of pseudodiverticulum at the site. ■ Attempt to preserve the mediastinal pleura that overlies the esophagus. It is helpful to have this layer to close at the end of the case.
Fundoplication	■ Choice of antireflux procedure should be based on patient's reflux symptoms, anatomy, and esophageal motility.

POSTOPERATIVE CARE

- Postoperatively, patients are maintained NPO overnight. Standard use of deep venous thrombosis (DVT) and gastrointestinal (GI) prophylaxis is employed.
- Due to the presence of a fresh myotomy, the authors typically avoid usage of a nasogastric tube. Hang a sign over the patient's bed that states, "Do Not Place a Nasogastric Tube Under Any Circumstance." Blind passage of a nasogastric tube without endoscopic guidance could result in perforation of the mucosa.
- Barium esophagram is performed 24 to 48 hours after surgery to rule out leak or perforation.
- After esophagram, patients can be started on a clear liquid diet (Nissen clear liquid diet).
- The diet is then advanced to Nissen full liquids in the following days, followed by a soft diet. The diet may then be advanced further when the patient is seen in the clinic 2 weeks later.

OUTCOMES

- Interpretation of the literature regarding surgical management of epiphrenic diverticula is difficult owing to the variability in the following:
  - Approach (thoracotomy, VATS, laparoscopic, or combination of approaches)
  - Direction from which the esophagus is approached (right transthoracic, left transthoracic, or transabdominal)
  - Procedures performed (diverticulectomy alone, myotomy alone, diverticulectomy + myotomy, diverticulectomy + myotomy + fundoplication)
  - Choice of fundoplication (Dor, Toupet, Nissen, Belsey Mark IV)
  - Only small case series being reported
- Controversy exists regarding whether or not all epiphrenic diverticula should be treated surgically. Some surgeons have advocated for a more selective approach,[6] whereas others have supported surgical treatment of all patients with epiphrenic diverticula.[1] The current trend is to only operate on patients with severe symptoms (e.g., dysphagia, regurgitation, aspiration) owing to the low rate in progression of symptoms noted in asymptomatic/mildly symptomatic diverticula, which was noted to be 2.8% in a review by Zaninotto and colleagues.[7]
- There are currently no reports in the literature directly comparing open to minimally invasive approaches; however, recent reviews have concluded that better outcomes are obtained with a minimally invasive approach in regard to morbidity, mortality, and length of stay (greater than 1 week in open series and less than 1 week in most minimally invasive series).[8,9]
- Reported morbidity rates in open series range from 5% to 38%[1–3,10–13] with leaks rates ranging from 0%[1,10] to as high as 21%.[2] Thirty-day mortality rates ranging from 0% to 15% demonstrates that surgical treatment of epiphrenic diverticula is not without risk.
- Although minimally invasive approaches (VATS, laparoscopic, or a combination of the two) appear to have similar morbidity rates, ranging from 7% to 45% in series with greater than 10 patients,[4,5,14–18] mortality appears to be significantly lower with only one reported 30-day death[5] and one additional in-hospital death.[4] Leaks rates again are similar in these series, ranging from 0% to 23%.
- There are currently two published small series[19,20] reporting the results of VATS treatment of epiphrenic diverticula. Six of eight patients operated on were completed thoracoscopically in the series reported by Perrachia,[19] whereas one of five patients required laparoscopy to complete the procedure in van der Peet's series.[20] The few other series reporting use of a VATS approach include a mix of other approaches as well,[4,13,15,21,22] making it impossible to make comparisons between minimally invasive approaches (e.g., laparoscopic vs. VATS). The authors favor a right VATS approach for diverticula 7 cm or more above the hiatus, diverticula with anticipated dense adhesions, and redo operations for treatment of recurrent diverticula previously treated with a transabdominal approach.
- The literature reporting use of a laparoscopic approach is more robust,[4,5,15,16,18,22,23] with some authors proposing that the laparoscopic approach be considered the standard initial approach for surgical treatment of epiphrenic diverticula.[22]
- There also remains controversy about what procedures need be performed for adequate surgical treatment of epiphrenic diverticula. Those in favor of both diverticulectomy and myotomy note that recurrence and suture line leaks appear to be more common in patients who have not had a myotomy.[2,3] There are also proponents who favor a more selective approach for myotomy, particularly in patients with

hypotonic esophageal body motor function and/or LES as well as normal esophageal motility.[11,24]

- The length/extent of myotomy required also remains to be clarified. Some authors prefer not to carry the myotomy across the GE junction in case where there is normal LES function. Although others favor a long myotomy that is carried across the GE junction and onto the gastric cardia in all cases.[25,26] The reason for this being that some esophageal motility disorders may occur intermittently and therefore may not be revealed on preoperative manometry testing.[12] The authors favor a long myotomy in all cases, except for those in which there is a distal mechanical obstruction (peptic stricture, stenotic previous fundoplication) with normal esophageal motility. In cases such as this, removal of the distal obstruction (dilation, revision to a partial fundoplication) and diverticulectomy may be all that is needed.
- Inclusion of an antireflux procedure and which type of fundoplication should be employed are additional areas of debate. Some believe that an antireflux procedure should be included in all cases in which the myotomy is carried across the LES and onto the stomach, as these patients are more prone to reflux given the loss of the barrier function of the LES. Most surgeons favor a partial fundoplication (Dor, Toupet, or Belsey Mark IV) due to the high prevalence of ineffective esophageal motility. It should be noted that performing a fundoplication via a VATS approach is technically challenging. The authors favor a laparoscopic Dor fundoplication, either from an initial laparoscopic approach or in combination with a right VATS approach, for patients with significant GE reflux preoperatively, achalasia, hiatal hernia, or when significant dissection in the area of the GE junction performed.

COMPLICATIONS

- Leak
- Perforation
- Pleural effusion
- Pneumothorax
- Empyema
- Bleeding
- Recurrence
- Death

Chapter 15

Long Myotomy for Diffuse Esophageal Spasm

David D. Odell   James D. Luketich

DEFINITION

- Diffuse esophageal spasm (DES) is a nonspecific motility disorder of the esophagus characterized by intermittent and disorganized smooth muscle contractions, often resulting in debilitating dysphagia and/or severe substernal chest pain.

DIFFERENTIAL DIAGNOSIS

- DES is part of a spectrum of motility disorders affecting the esophagus. Consequently, a careful assessment of the clinical presentation and objective diagnostic testing is imperative in order to avoid misdiagnosis and inappropriate treatment. Several conditions may mimic the symptomatic presentation of DES.
  - Achalasia: Characterized by incomplete relaxation of the lower esophageal sphincter coupled with aperistalsis of the esophageal body. Focal distal (Heller) myotomy extending onto the gastric cardia is the treatment of choice for this condition.
  - Nutcracker esophagus: Primary motility disorder of the esophagus characterized by high-amplitude, peristaltic contractions of the distal esophagus. Patients present with pain but do not have dysphagia. Treatment is predominantly medical with the use of calcium channel blockers.
  - Connective tissue disorders: Connective tissue diseases such as scleroderma frequently impact esophageal motility. Patients presenting with primary symptoms of dysphagia should be evaluated for other systemic manifestations of these conditions.
  - Gastroesophageal reflux disease (GERD): Patients with untreated or poorly treated long-standing reflux may develop esophageal dysmotility from chronic inflammation caused by the refluxate. In these patients, control of the reflux (medically or surgically) will typically resolve the motility issues.
  - Pseudoachalasia: Mechanical obstruction of the esophagus from tumor, hiatal hernia, prior antireflux surgery, or foreign body may cause symptoms of dysphagia, esophageal dilation, and dysmotility. Correction of the underlying pathology is the appropriate treatment in these patients and esophageal motility often returns to normal once this is accomplished.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A careful history focused on symptoms of dysphagia is helpful in evaluating patients for DES. Patients should be asked to characterize the frequency (every meal, daily, weekly, etc.) and severity (solids, liquids, salivary secretions, etc.) of their dysphagia.
- Patients should be asked about pain. The quality and duration of symptoms are important details to elicit as well as the relationship of symptoms to swallowing.
- Typical and atypical reflux symptoms should be directly questioned.
  - Typical: heartburn, history of stricture/dysphagia, water brash, globus sensation
  - Atypical: cough, hoarseness of voice, aspiration, recurrent pulmonary infection
- Cardiac history (prior myocardial infarction, history of exertional chest pain, review of any prior cardiac procedures or evaluations [i.e., catheterizations or stress testing])
- Connective tissue disease history: Evaluation of cutaneous lesions, healing difficulty, and concomitant visual problems

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Barium swallow—will show a classic corkscrew appearance of the esophagus characteristic of the disease and corresponding to the simultaneous contractions.
- Esophageal manometry—primary tool for establishing the diagnosis. The disease is typically characterized by simultaneous contractions (30 to 100 mmHg) with intermittent normal peristalsis. DES is typically defined as the presence of symptoms in concert with simultaneous contractions after greater than 10% to 30% of wet swallows. Amplitude of these simultaneous contractions should exceed 30 mmHg to support the diagnosis. The diagnosis of DES is more certain with a higher percentage of simultaneous contractions.
- Esophagogastroduodenoscopy (EGD)—required to assess the anatomy prior to intervention and to rule out alternative pathology. EGD will allow causes of pseudoachalasia (tumor, stricture, obstruction/compression) to be fully assessed with biopsies taken as necessary. This also allows the surgeon the ability to assess for the presence of reflux-related changes, such as Barrett's esophagus, which may require further surveillance. In advanced stages of DES, the endoscopic appearance of the esophagus may be somewhat corrugated as hypertonic muscular bands tend to form in fixed positions.
- Endoscopic ultrasound (EUS)—a useful adjunctive test in surgical planning, as the extent of the spasmodic muscular segment may sometimes be identified by the presence of thickening of the muscular layer on EUS.
- pH studies—may confirm the presence of acid reflux and may help guide the decision to include a fundoplication at the time of surgical correction.

SURGICAL MANAGEMENT

- The bulk of surgical treatment is discussed in the "Techniques" section. Here, consider indications and other more general concerns.

Preoperative Planning

- Patients should be thoroughly counseled regarding the risks of the operation including esophageal perforation, persistent dysphagia, and exacerbation of reflux symptoms. Alternative treatment options including pharmacotherapy with calcium channel blockers should be discussed.

- A liquid diet should be administered for 2 days prior to surgery (longer if significant delay in esophageal clearance is expected).

Patient Positioning

- The patient is turned to the left lateral decubitus position. A beanbag is placed underneath the patient to afford additional support and to fix the patient in position. An axillary roll is positioned at the base of the axilla to minimize nerve compression. Position of the double lumen endotracheal tube, placed prior to turning the patient lateral, is reconfirmed using a pediatric endoscope. The operating surgeon stands on the right side of the table (facing the patient's back) while the assistant stands on the left side of the table.

Airway Management

- The patient is intubated with a double lumen endotracheal tube. This allows for lung isolation on the operative side to provide adequate exposure.

THORACOSCOPIC APPROACH

Port Placement

- A total of five thoracoscopic ports are used (**FIG 1**). A 10-mm camera port is placed in the 8th or 9th intercostal space, just anterior to the midaxillary line. The working port is a 10-mm port placed in the 8th or 9th intercostal space, posterior to the posterior axillary line. Another 10-mm port is placed in the anterior axillary line at the 4th intercostal space, through which a fan-shaped retractor aids in retracting the lung to expose the esophagus. A 5-mm port is placed just inferior to the tip of the scapula for the surgeon's left hand. A final 5-mm port is placed at the 6th rib, at the anterior axillary line for suction by the assistant.

Diaphragm Retraction

- Adequate retraction of the diaphragm is essential to achieve visualization of the lower thoracic esophagus and to aid in the dissection. A retracting suture is used to facilitate this retraction (**FIG 2**). We place a 48-in, 0-Surgidac suture through the central tendon of the diaphragm using the Endo Stitch device. The suture is brought out through the lateral chest wall at the level of the insertion of the diaphragm through a small stab incision, retracting the diaphragm inferiorly in order to expose the distal esophagus.

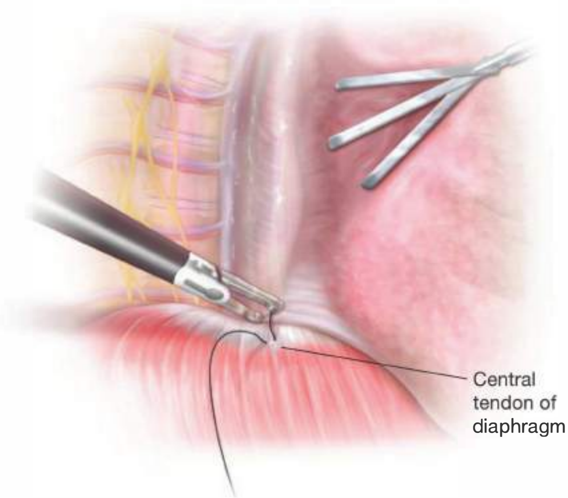

FIG 2 ● Diaphragm retraction suture. Placement of a suture in the central tendon of the diaphragm facilitates retraction and improves visualization of the esophagus.

Pleural Dissection and Esophageal Mobilization

- The inferior pulmonary ligament is divided to the level of the inferior pulmonary vein to allow for maximal anterior lung retraction (**FIG 3A**).

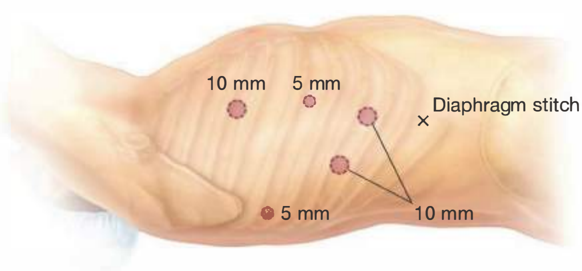

FIG 1 ● Port placement: positioning of the thoracoscopic ports used for esophageal myotomy.

- The dissection is carried onto the avascular pleural plane along the surface of the pericardium, overlying the esophagus (**FIG 3B**). The pleura is incised to expose the esophagus. This dissection is carried superiorly to the level of the subcarinal space. As the goal is to adequately mobilize the esophagus, the nodes may be left in situ rather than mobilizing them with the esophagus, as would be done in a cancer operation.

Airway Dissection

- Care must be taken to identify the membranous wall of the right mainstem bronchus (**FIG 3C**), as it is easily injured during this phase of the dissection. Removing any suction from the right lung during this dissection will prevent the membranous wall from collapsing and can aid in visualization.

Superior Dissection

- The lung is next retracted anteriorly and the pleura incised along the anterior border of the esophagus to the

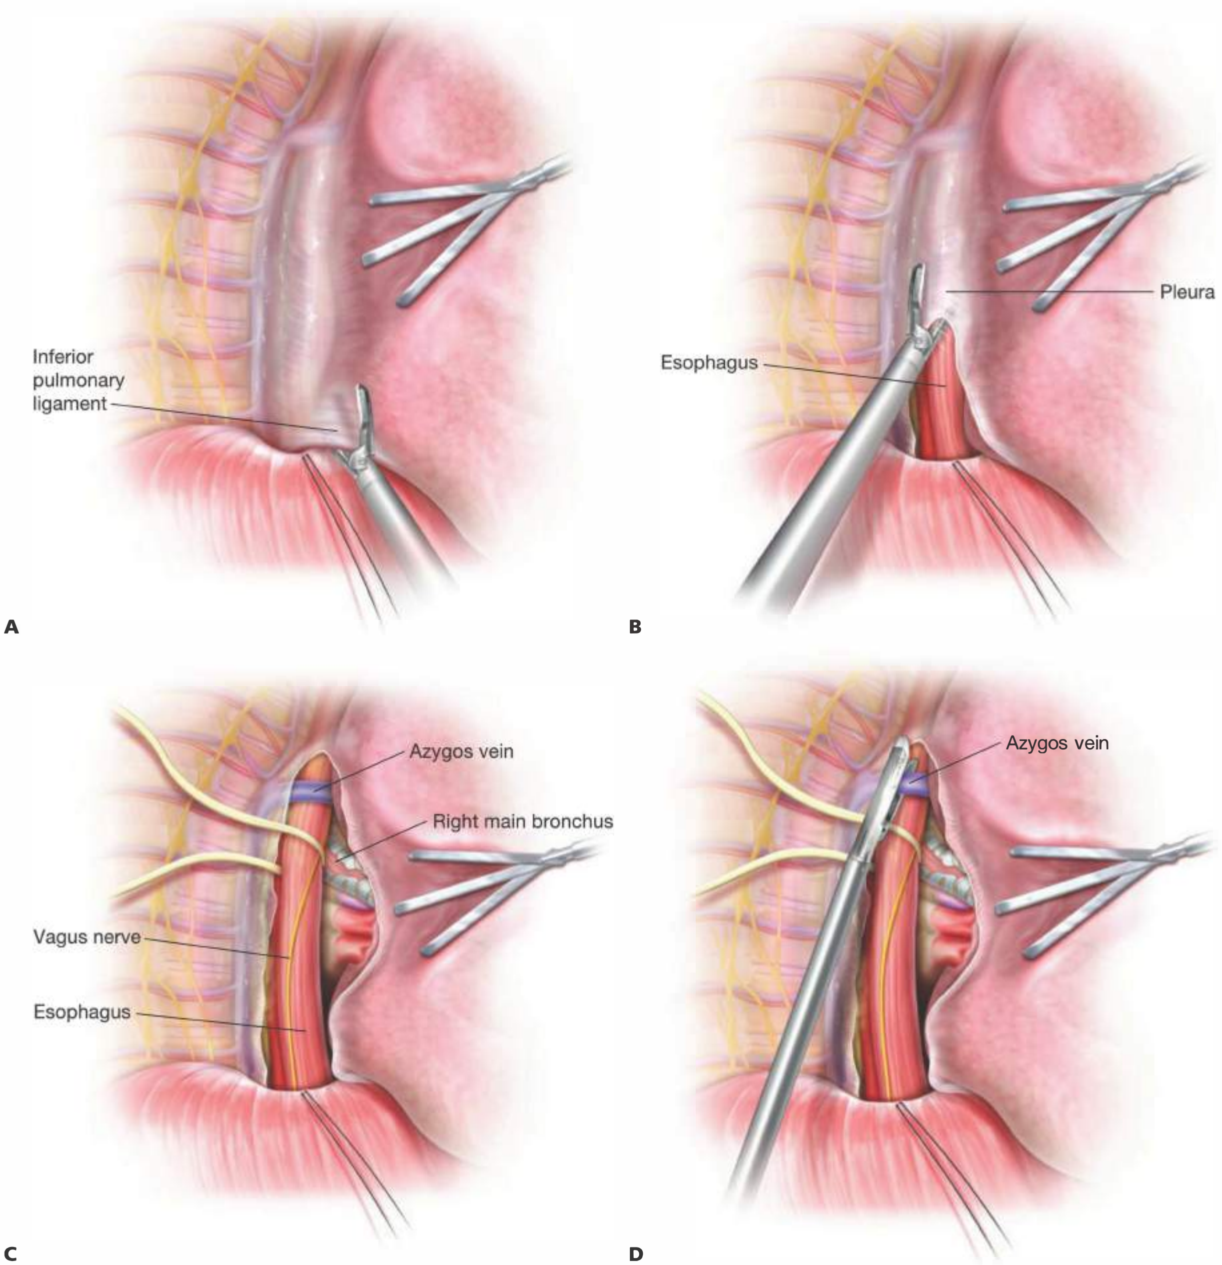

FIG 3 ● Pleural dissection. **A.** Mobilization of the inferior pulmonary ligament. **B.** Beginning of the dissection along the pericardium. **C.** Pleura is incised overlying the esophagus and a Penrose drain used to encircle the esophagus for retraction. E

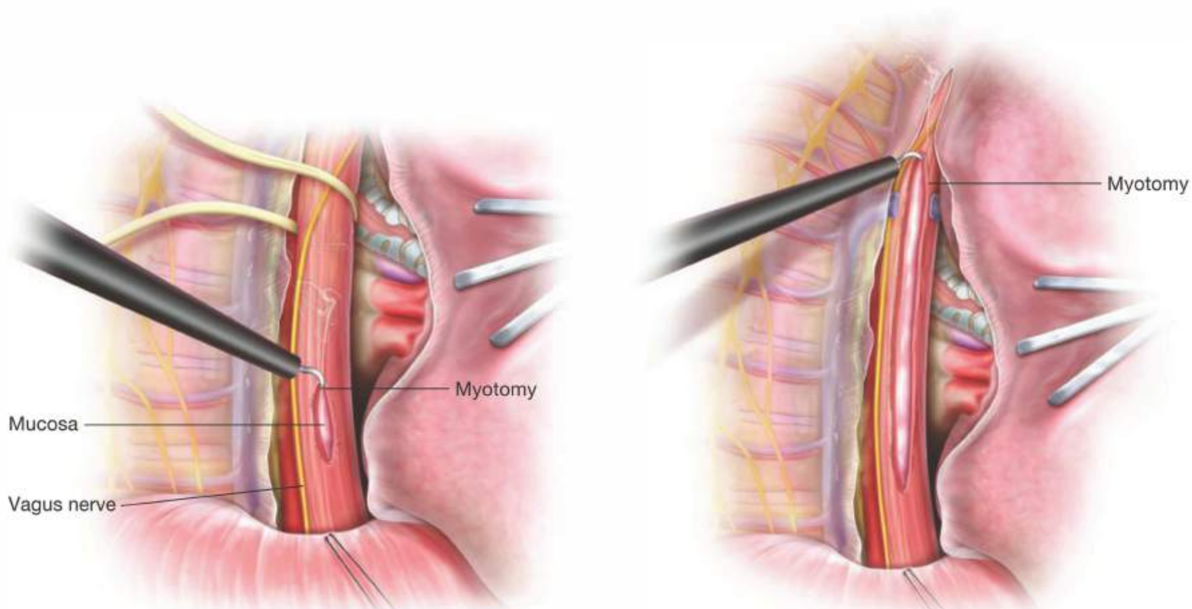
FIG 3 ● *(continued)* **E.** Dissection above the azygous directly on the esophagus to avoid recurrent nerve injury.

level of the azygous vein. The azygous may be divided if the spasmodic segment of esophagus extends above this level (**FIG 3D**). The vagus nerve should be identified and preserved to retain normal gastric emptying and pyloric function.

- Above the level of the azygous vein, dissection is kept close to the esophagus to avoid injury to the recurrent laryngeal nerves (**FIG 3E**). The extent of superior dissection and mobilization depends on the location of the spasmodic portion of the esophagus. Careful review of the preoperative barium swallow examination and manometry studies is necessary to make this determination.

Esophagomyotomy

- The myotomy is begun 6 to 7 cm above the diaphragm. The longitudinal muscle layer of the esophagus is visualized and incised using either hook electrocautery or an energy dissection device (**FIG 4**). The myotomy is carried through the underlying circular muscle layer to expose the esophageal mucosa. The cut ends of the muscle layer should be gently separated from one another to prevent early reapproximation as the myotomy heals. Careful examination of the mucosa should be performed to ensure it is intact.
- The myotomy may be carried onto the stomach if the preoperative manometry indicates dysfunction of the lower esophageal sphincter as a contributing factor in the pathology. The esophagogastric junction and beginning of the gastric cardia may be elevated into the thorax by applying traction to the muscular wall of the esophagus. The esophagogastric junction is marked by the phrenoesophageal ligament through which the left gastric vein travels and is a reasonable landmark for the dissection. Extra care should be taken in the dissection at this level, as the mucosa becomes appreciably thinner at the esophagogastric junction (EGJ).



A B

FIG 4 ● **A,B.** Esophagomyotomy is performed using an energy device.

Evaluation for Leak

- A careful endoscopy is performed to examine the mucosa for any evidence of injury incurred during the creation of the myotomy. Water or saline may be instilled into the chest to submerge the myotomized esophagus in order to elucidate small mucosal tears or full-thickness injury identified with air insufflation via the endoscope.

Closure

- A single chest tube is left in place at the completion of the operation and the lung is aerated under direct vision to ensure complete parenchymal reexpansion. Skin incisions are then closed in layers with absorbable suture.

LEFT THORACOTOMY APPROACH

Thoracotomy Incision

- A left posterolateral thoracotomy incision is made through the 6th or 7th intercostal space (**FIG 5**). A 1-cm section of the 7th rib is resected posteriorly to facilitate wide exposure of the left hemothorax. A nasogastric tube is left in position to facilitate easy identification of the esophagus. The inferior pulmonary ligament is divided so that the lung can be retracted superiorly away from the hiatus (**FIG 6**).

Pleural Incision and Esophageal Exposure

- The mediastinal pleura is incised overlying the esophagus just above the level of the hiatus (**FIG 7**). Dissection is carried circumferentially and a Penrose drain is looped around the esophagus to facilitate retraction without trauma during the course of the dissection. A complete mobilization of the esophagus may not be needed if a fundoplication is not required, although this step will be necessary if a concomitant antireflux procedure (such as a Nissen or Belsey Mark IV fundoplication) is planned.

Esophageal Myotomy

- Using a Metzenbaum scissors or an energy device, the longitudinal layer of muscle is incised to expose the circular muscle fibers (**FIG 8**). These circular fibers are then incised and the cut edges retracted laterally to reapproximation with healing.
- The myotomy length is determined by the extent of abnormal esophagus as assessed on the preoperative imaging evaluation as well as the intraoperative endoscopy (**FIG 9**). In many cases, the spastic segment does not involve the lower esophageal sphincter (LES) and this structure can be spared, preserving the native antireflux mechanism. For those patients in whom the myotomy is carried across the LES, an antireflux procedure may be performed either from the left chest via thoracotomy or by repositioning for a transabdominal approach. Once the myotomy has been performed, attention is given to closure of the crura so as to prevent herniation.
- An air leak test can be performed as described in the video-assisted thoracic surgery (VATS) approach.

Chest Closure

- Standard principles of thoracotomy closure are applied to this case. A single chest tube is left in place in the pleural space to assist with lung expansion.

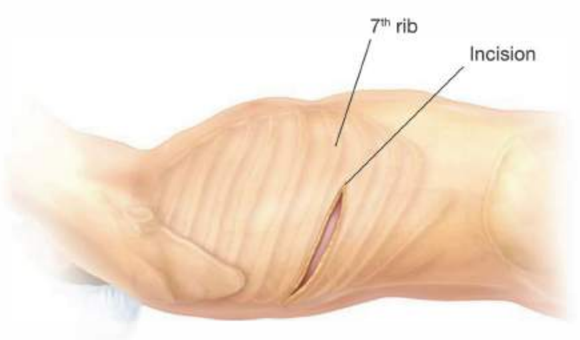


FIG 5 ● Thoracotomy performed through the 7th intercostal space.

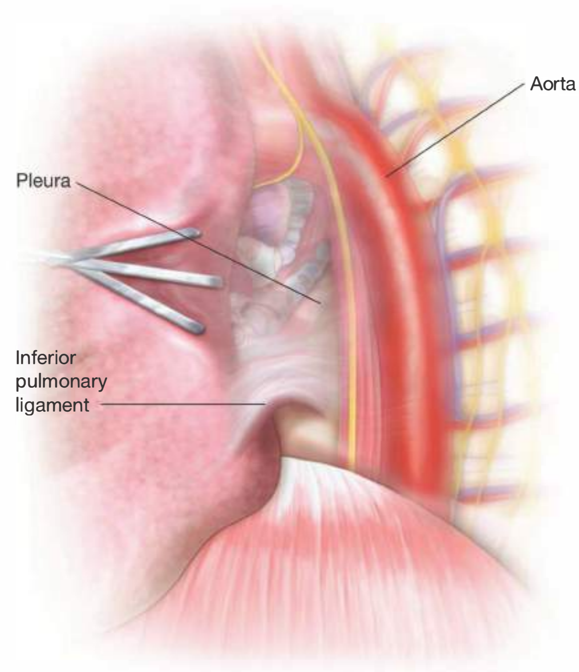

FIG 6 ● Division of the inferior pulmonary ligament and posterior retraction of the lung.

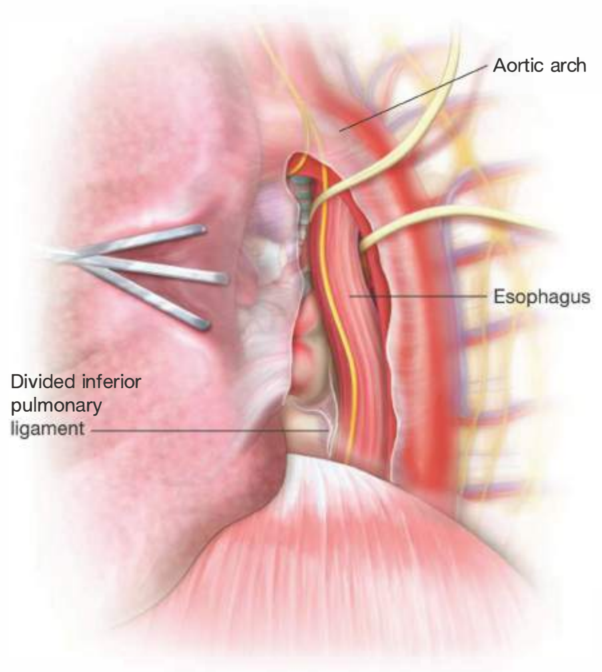

FIG 7 ● Opening of the pleura overlying the esophagus. The esophagus can be encircled with a Penrose drain to facilitate retraction.

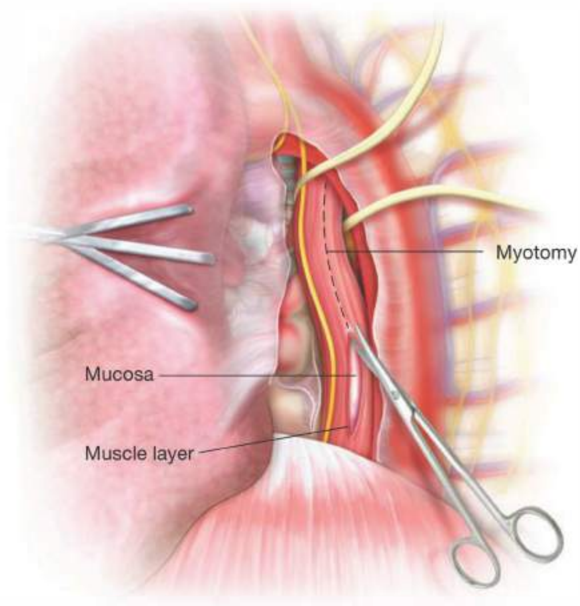

FIG 8 ● The myotomy is begun with a Metzenbaum scissors or an energy device.

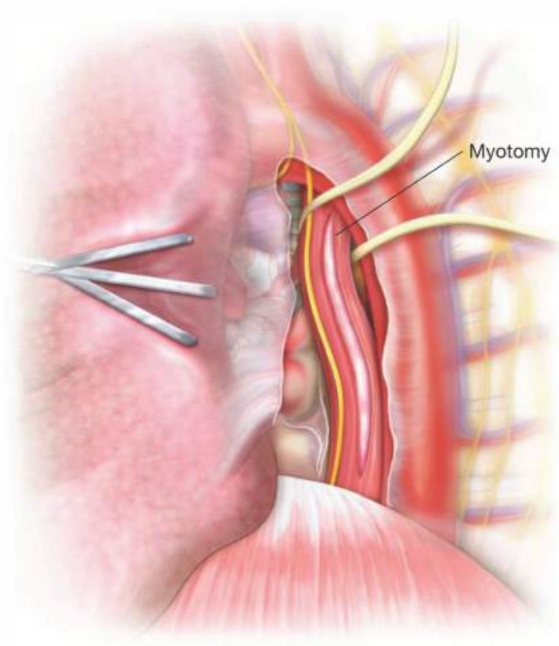

FIG 9 ● Extent of the myotomy should be determined by a combination of intraoperative endoscopy and analysis of the preoperative manometry studies.

PEARLS AND PITFALLS

Reflux	■ An antireflux procedure should be performed in addition to the myotomy if reflux is documented on preoperative pH studies. ■ Many surgeons advocate an antireflux procedure when the myotomy is carried across the EGJ, although this is not uniformly agreed upon. ■ A Belsey fundoplication may be performed from the left chest in the left thoracotomy approach. Otherwise, a laparoscopy may be performed following the thoracic portion of the operation to create the fundoplication. The authors prefer a laparoscopic Dor anterior fundoplication in this setting.
Chylothorax	■ A careful thoracic duct ligation should be considered if there is concern for trauma to the duct.
Extent of myotomy	■ Myotomy should be taken above the level of the aortic arch and ideally, to the thoracic inlet, as smooth muscle fibers may comprise as much as one-third of the upper thoracic esophageal muscle.
Esophageal leak	■ Intraoperative air test can be performed. Unexplained postoperative tachycardia, fever, or chest pain should prompt an urgent water-soluble contrast esophagram.

POSTOPERATIVE CARE

- Postoperative hospital stay is usually limited to 1 to 2 days.
- Barium or Gastrografin swallow may be performed prior to initiation of oral intake to ensure that no mucosal injury or perforation is present as well as to confirm free passage of contrast through the distal esophagus and into the stomach. This may also be useful to establish a postoperative baseline for reference, should delayed issues with reflux or dysphagia arise.
- A liquid diet may be initiated on the first postoperative day following confirmation of esophageal integrity with esophagram. A liquid diet is initially begun, with the patient being advanced to a mechanical soft diet over the course of the first week.

OUTCOMES

- Include functional and prosthetic survivorship data, as applicable.

COMPLICATIONS

- Reflux: Reflux symptoms are common following myotomy and are noted in up to 50% of patients if an antireflux operation is not performed at the time of myotomy. The decision to perform an antireflux operation at the time of the index operation must be individualized to the patient. The extent of demonstrable preoperative acid reflux as well as the degree of esophageal dysmotility must be carefully weighed. Mild to moderate postoperative symptoms may be well controlled with the addition of a proton pump inhibitor to the patient's medications. Lifestyle modifications including the avoidance of late evening meals and head of bed elevation while sleeping can also be quite effective in symptom management. In rare cases, a laparoscopic antireflux operation may be necessary at a later date for patients whose symptoms fail to respond to medical management.
- Dysphagia: Persistent dysphagia following surgical intervention is frequently related to an incomplete myotomy. Additionally, the possibility of an inaccurate diagnosis must also be considered if symptoms persist following myotomy. Edema at the myotomy site, scar formation, and an overly tight antireflux repair should also be considered and may respond to endoscopic dilation.
- Perforation/leak: Unrecognized mucosal injury will often present within 24 to 72 hours with peritonitis, dyspnea and pleuritic pain from pleural effusion, fever, leukocytosis, or overt sepsis. A high index of suspicion is necessary for early diagnosis and aggressive surgical intervention is warranted to facilitate adequate drainage and, when possible, repair of the injury. A feeding jejunostomy should be considered if a prolonged healing time is anticipated. The specific approach is dictated by the location of injury and presentation of the patient. However, a careful endoscopic examination should always play a role in the evaluation of a postmyotomy leak.

Chapter 16

Laparoscopic Heller Myotomy and Anterior Fundoplication for Esophageal Achalasia

Marco E. Allaix Marco G. Patti

DEFINITION

- Esophageal achalasia is a primary motility disorder characterized by lack of esophageal peristalsis and failure of the lower esophageal sphincter (LES) to relax properly in response to swallowing.

DIFFERENTIAL DIAGNOSIS

- Benign strictures secondary to gastroesophageal reflux disease (GERD) and esophageal neoplasms may mimic the clinical presentation of achalasia.
- An infiltrating tumor of the gastroesophageal junction can mimic not only the clinical and radiologic findings of achalasia but also the manometric profile. This condition, defined as "secondary achalasia" or "pseudoachalasia," should be suspected and ruled out in patients older than 60 years of age, with recent onset of dysphagia (less than 6 months), and with excessive weight loss.[1]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Dysphagia is the main complaint, being reported by about 95% of patients. It is often for both solids and liquids. Most patients are able to maintain a stable weight due to changes made in their diet.
- About 60% of patients experience regurgitation of undigested food. It occurs more frequently in the supine position and may lead to aspiration that in turn can cause respiratory symptoms, such as cough, hoarseness, wheezing, and episodes of pneumonia.[2]
- Heartburn is present in about 40% of patients: It is due to stasis and fermentation of undigested food in the distal esophagus rather than due to gastroesophageal reflux (GER).
- Esophageal distention can cause chest pain in up to 40% of patients, and it is usually experienced at the time of a meal.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A thorough evaluation to establish the diagnosis should be performed in all patients with symptoms suggestive for achalasia.[3] It consists of the following studies:
  - *Upper endoscopy* is usually the first test that is performed to rule out the presence of a mechanical obstruction secondary to a peptic stricture or cancer.
  - *Barium swallow* shows a narrowing at the level of the gastroesophageal junction (the so-called *bird's beak*), slow esophageal emptying with an air–fluid level, and either absence of or tertiary contractions of the esophageal wall (**FIG 1**). It also defines the diameter and the axis of the esophagus (dilated and sigmoid in long-standing achalasia) and associated pathologic findings, including an epiphrenic diverticulum. The gastric air bubble is usually absent.

FIG 1 ● Barium swallow: dilatation of the esophageal body, retained barium, and distal esophageal narrowing (bird's beak).

  - *Esophageal manometry* is the gold standard for the diagnosis of achalasia. Lack of peristalsis and absent or incomplete LES relaxation in response to swallowing are the key criteria for the diagnosis. The LES is hypertensive in only about 50% of patients.[3] Recently, a new classification of esophageal achalasia has been proposed based on high-resolution manometry (HRM): type I, classic, with minimal esophageal pressurization; type II, achalasia with panesophageal pressurization; and type III, achalasia with spasm (**FIG 2**).[4]

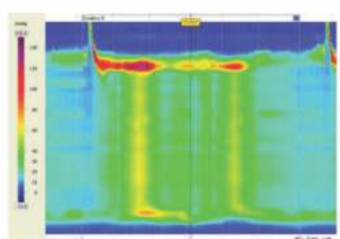

FIG 2 ● High-resolution esophageal manometry: type II achalasia according to the Chicago classification.

- *Ambulatory pH monitoring* is important in untreated patients when the diagnosis is uncertain in order to distinguish between GERD and achalasia. Postoperatively, ambulatory pH monitoring can be performed to rule out GER that is present in about 30% to 40% of cases after Heller myotomy and is often asymptomatic.[5]

SURGICAL MANAGEMENT

Preoperative Planning

- A careful systematic evaluation and the tests described before should be performed in every patient before treatment.

Positioning

- After induction of general endotracheal anesthesia, the patient is positioned supine in low lithotomy position with the lower extremities extended on stirrups, with knees flexed 20 to 30 degrees or straight if using a split-leg table.
- To avoid sliding as a consequence of the steep reverse Trendelenburg position used during the procedure, a beanbag is inflated to create a "saddle" under the perineum.
- Because increased abdominal pressure from pneumoperitoneum and the steep reverse Trendelenburg position decrease venous return, pneumatic compression stockings are always used as prophylaxis against deep venous thrombosis.
- An orogastric tube is placed to keep the stomach decompressed during the procedure and it is removed before starting the myotomy.
- A Foley catheter is inserted at the beginning of the operation and removed at the end.
- The surgeon stands between the patient's legs. The first and second assistants stand on the right and left side of the operating table (**FIG 3**).

FIG 3 ● Position of the patient and surgical team in the operating room.

TECHNIQUES

PLACEMENT OF PORTS

- Five 10-mm trocars are used for the procedure (**FIG 4**).
  - The first incision is made in the midline 14 cm distal to the xiphoid process and a Veress needle is introduced into the peritoneal cavity. The peritoneal cavity is insufflated to a pressure of 15 mmHg. Subsequently, under direct vision, an optical port with a 0-degree scope (**port 1**) is placed. Once this port is placed, the 0-degree scope is replaced with a 30-degree scope and the other trocars are inserted under laparoscopic vision.
- **Port 2** is placed in the left midclavicular line at the same level of port 1. It is used by the assistant for traction on the gastroesophageal junction and as an instrument to take down the short gastric vessels.

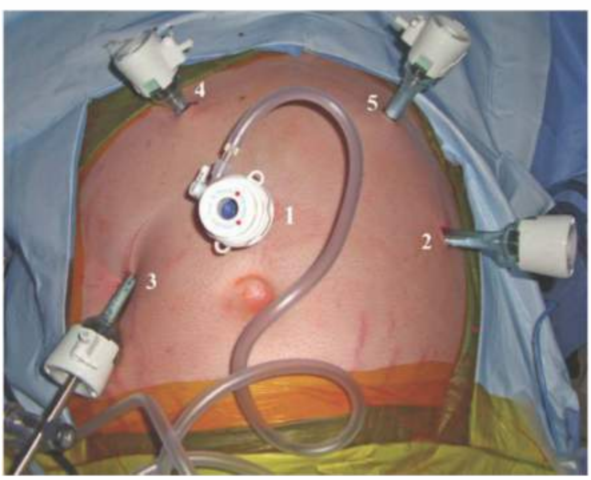

FIG 4 ● Placement of the ports.

- **Port 3** is placed in the right midclavicular line at the same level of the other two ports. A retractor is used through this port to lift the left lateral segment of the liver to expose the gastroesophageal junction. The retractor is held in place by a self-retaining system fixed to the operating table.
- **Ports 4** and **5** are placed under the right and left costal margins so that their axes and the camera form an angle of about 120 degrees. These ports are used by the operating surgeon.
- The instrumentation necessary for the laparoscopic myotomy is reported in Table 1.

Table 1: Instrumentation for Laparoscopic Heller Myotomy and Partial Fundoplication

Five 10-mm ports
0- and 30-degree scope
Graspers and needle holder
Babcock clamp
L-shaped hook cautery with suction–irrigation capacity
Scissors
Laparoscopic clip applier
Electrothermal bipolar vessel-sealing system
Liver retractor
Suturing device
2-0 silk sutures

DISSECTION

- The gastrohepatic ligament is divided, beginning the dissection above the caudate lobe of the liver, where the ligament is thinner, and continuing toward the diaphragm until the right pillar of the crus is identified and separated from the esophagus by blunt dissection.
- Subsequently, the peritoneum and the phrenoesophageal membrane overlying the esophagus are divided and the anterior vagus nerve is identified (**FIG 5A**).
- The left pillar of the crus is then separated from the esophagus (**FIG 5B**).
- Blunt dissection is finally performed in the posterior mediastinum, laterally and anteriorly to the esophagus in order to have about 4 to 5 cm of esophagus without any tension below the diaphragm. Posterior dissection is necessary only if a partial posterior fundoplication is planned.

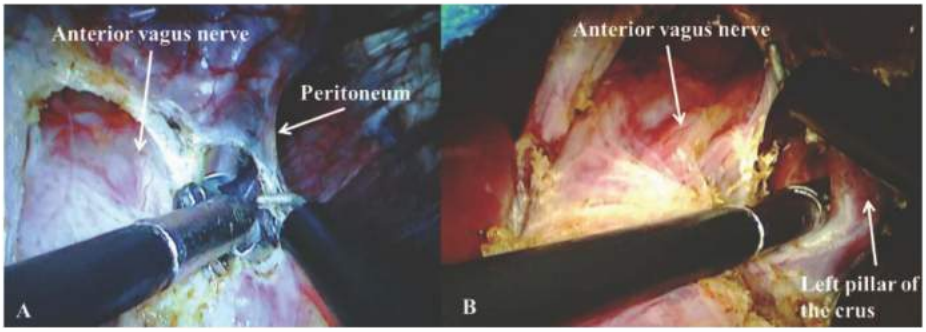

FIG 5 ● **A.** Division of the peritoneum and the phrenoesophageal membrane overlying the esophagus with anterior vagus nerve identification. **B.** Separation of the left pillar of the crus from the esophagus.

DIVISION OF THE SHORT GASTRIC VESSELS

- The short gastric vessels are taken down all the way to the left pillar of the crus, starting from a point midway along the greater curvature of the stomach (**FIG 6**).[6]

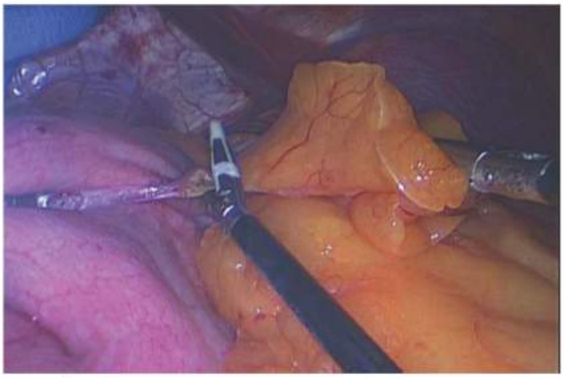

FIG 6 ● Division of the short gastric vessels.

MYOTOMY

- The fat pad should be removed to expose the gastroesophageal junction after identification of the anterior vagus nerve.
- Traction is then applied with a Babcock clamp, grasping below the gastroesophageal junction and pulling downward and to the left in order to expose the right side of the esophagus.
- A myotomy is performed on the right side of the esophagus in the 11 o'clock position using a hook cautery. The proper submucosal plane is found using the cautery, about 3 cm above the gastroesophageal junction.
- Once the mucosa is exposed, the myotomy is extended proximally for about 6 cm above the gastroesophageal junction and distally for 2.5 to 3 cm onto the gastric wall (FIG 7).[7]
- The edges of the muscles are then separated with a dissector in order to have 30% to 40% of the mucosa not covered by muscles.
- Intraoperative endoscopy is rarely necessary, particularly when enough experience is present and a long myotomy onto the gastric wall is performed.

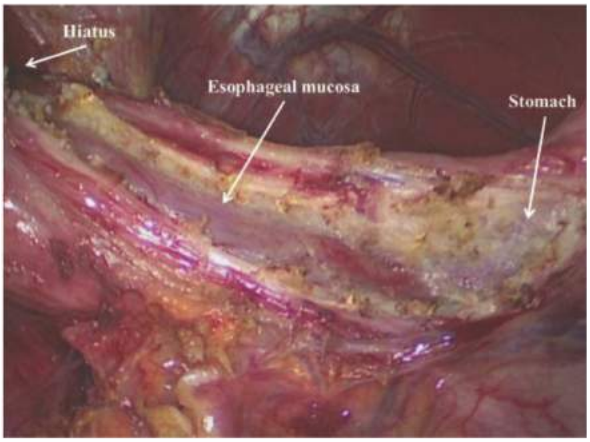

FIG 7 ● Esophageal myotomy.

PARTIAL FUNDOPLICATION

- The main goal of the surgical treatment is relief of dysphagia while preventing GER.[8]
- A laparoscopic Heller myotomy (LHM) alone is associated with postoperative GER in about 50% to 60% of patients.[9]
- Better functional results are achieved with a partial fundoplication added to the myotomy compared to a total fundoplication that is associated with higher rates of postoperative dysphagia.[10]
- Regarding the type of partial fundoplication, no significant differences are evident in terms of control of GER after the partial anterior and partial posterior fundoplication.[5]
- We prefer the partial anterior fundoplication because it is simpler to perform, as posterior dissection is not necessary, and because it covers the exposed esophageal mucosa.

Partial Anterior Fundoplication (Dor)

- The Dor fundoplication is a 180-degree anterior fundoplication.
- Two rows of sutures (2-0 silk) are used. The first row is on the left side of the esophagus and has three stitches. The top stitch incorporates the fundus of the stomach, the muscular layer of the left side of the esophagus, and the left pillar of the crus (FIG 8).

FIG 8 ● Dor fundoplication: top stitch of the left row of sutures.

FIG 9 ● Dor fundoplication: second and third stitches of the left row of sutures.

- The second and third stitches incorporate the gastric fundus and the muscular layer of the left side of the esophagus (**FIG 9**).
- The fundus is then folded over the exposed mucosa so that the greater curvature of the stomach is next to the right pillar of the crus.

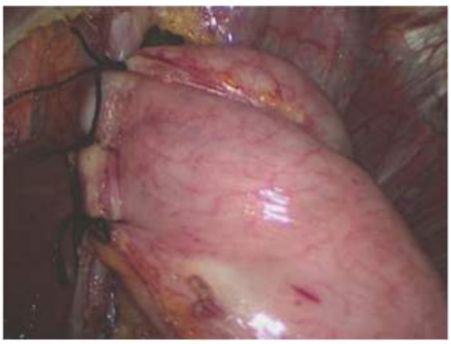

FIG 10 ● Dor fundoplication: right row of sutures.

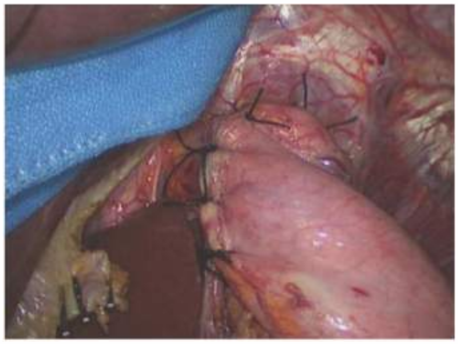

FIG 11 ● Completed Dor fundoplication.

- The second row of sutures on the right side of the esophagus consists of three stitches between the fundus and the right pillar of the crus (**FIG 10**).
- Finally, two additional stitches are placed between the fundus and the rim of the esophageal hiatus to eliminate any tension from the fundoplication (**FIG 11**).

Partial Posterior Fundoplication

- Some authors argue that the posterior partial fundoplication should be used as it might be more effective in preventing GER and because it keeps the distal edges of the myotomy separated.[11]
- The posterior fundoplication requires the creation of a posterior window between the left pillar of the crus, the stomach, and the esophagus followed by the passage of the gastric fundus under the esophagus.
- The hiatus is loosely closed posterior to the esophagus.
- Subsequently, each side of the wrap is attached to the esophageal wall lateral to the myotomy with three stitches. The resulting wrap measures about 220 to 240 degrees.

PEARLS AND PITFALLS

Indications	■ A careful evaluation including manometry, 24-hour pH monitoring, upper endoscopy, and barium swallow must be done.
Placement of ports	■ Extreme care must be taken when positioning port 1, because the site of insertion is just above the aorta. ■ We recommend using an optical trocar with a 0-degree scope to obtain access. ■ If port 3 is too low, the left lateral segment of the liver will not be properly retracted and exposure of the esophagogastric junction may be inadequate. ■ If port 2 is too low, the esophagogastric junction or the upper short gastric vessels may be difficult to access. ■ If ports 4 and 5 are too low, the dissection at the beginning of the procedure and the suturing at the end will be challenging. ■ If port 3 is too medial, the liver retractor may interfere with the instrument used through port 4.
Dissection	■ An accessory left hepatic artery originating from the left gastric artery is frequently present in the gastrohepatic ligament. If this vessel limits the exposure, it may be safely divided. ■ The electrocautery should be used with extreme caution. Because of the lateral spread of the monopolar current, vagus nerves may be damaged even without direct contact. A bipolar instrument represents a safer alternative.

Short gastric vessels division	■ Bleeding, either from the short gastric vessels or from the spleen, and damage to the gastric wall are possible complications. ■ Excessive traction and division of a vessel not completely coagulated are the main causes of bleeding. ■ A burn caused during dissection of the short gastric vessels or traction applied with the graspers or the Babcock clamp are the most common mechanisms of damage to the gastric wall.
Myotomy	■ In patients who have had previous treatment with botulinum toxin injection, the myotomy is technically more challenging due to the fibrosis that alters the normal anatomic planes and may increase the risk of perforation.[12] ■ If a mucosal perforation occurs, it can be repaired with 5-0 absorbable material. ■ In case of bleeding from the cut muscular fibers, gentle compression with a sponge is recommended rather than the electrocautery, which can cause thermal damage to the esophageal wall.

Partial anterior fundoplication	■ To reduce the risk of postoperative dysphagia due to the fundoplication
	  ■ The short gastric vessels should be divided.
	  ■ The wrap should be performed using the fundus rather than the body of the stomach.

POSTOPERATIVE CARE

- Patients spend an average of 1 to 2 days in the hospital and return to work in 2 to 3 weeks.
- Patients are fed the morning of the first postoperative day with clear liquids and then a soft diet.
- They are instructed to avoid meat, bread, and carbonated beverages for the following 2 weeks.
- Most patients resume their regular activity within 2 to 3 weeks.

OUTCOMES

- Long-term follow-up shows that symptoms are improved in 90% to 95% of patients at 5 years and in 80% to 90% at 10 years.
- Most LHM failures present within the first 2 to 3 years of follow-up and may reflect fibrosis of the distal edge of the myotomy that can be successfully treated in most cases with pneumatic dilatation.
- Postoperative GER occurs in about 30% to 40% of patients, and it is usually controlled by acid-reducing medications.

COMPLICATIONS

- Esophageal leak may occur during the first 24 to 36 hours postoperatively, and it is usually the result of a thermal injury of the esophageal mucosa.
  - Typical signs and symptoms include pain, fever, and dyspnea. A chest x-ray may show a pleural effusion.
  - An esophagogram confirms the location and the extension of the leak.
  - Treatment options vary based on the time of diagnosis and on the location and extension of the leak. In case of early diagnosis, small leaks can be repaired directly. If the damage is too extensive or the inflammatory reaction in case of late diagnosis does not allow a direct repair, an esophagectomy may be indicated. In selected cases, wide drainage and placement of a feeding jejunostomy tube with or without the use of an esophageal stent may allow the leak to heal without esophagectomy.
- Pneumothorax occurs in case of intraoperative violation of the parietal pleura. Usually, it resolves spontaneously and does not require tube thoracostomy as the CO_2 is rapidly absorbed.
- Persistent dysphagia is usually due to technical errors, such as a too short of a myotomy or a too constricting fundoplication.
- Recurrent dysphagia after a symptom-free period may be caused by scar tissue in the distal edge of the myotomy, postoperative GER, technical errors cited earlier, or esophageal cancer. In either case, a thorough evaluation is mandatory to rule out malignancies and make a correct diagnosis. Subsequent treatment is tailored to the results of this workup and includes pneumatic dilatation and/or a reoperation.

Chapter 17

Repair of Congenital Defects: Morgagni Diaphragmatic Hernia

Scott A. Anderson Mike K. Chen

DEFINITION

- A Morgagni congenital diaphragmatic hernia (CDH) refers to a defect in the anteromedial diaphragm through the foramen of Morgagni. The most common contents of the hernia include omentum and transverse colon but can also include stomach, liver, spleen, and other segments of bowel. Morgagni hernias more commonly include a hernia sac.
- They account for approximately 3% of surgically repaired diaphragmatic hernias. They are more frequently seen in females and the majority of them are right-sided. Bilateral Morgagni hernias can be seen but are not common.
- Unlike Bochdalek CDHs, Morgagni hernias are generally not associated with pulmonary hypoplasia. They are typically smaller and more frequently an isolated congenital anomaly.

DIFFERENTIAL DIAGNOSIS

- Morgagni CDH can be mistaken for a number of other thoracic anomalies, both congenital and acquired. In infancy, these can include congenital cystic lung disease, esophageal hiatal hernia, and mediastinal mass.
- Later in life, Morgagni hernia can be confused with a mediastinal mass, pericardial fat pad, atelectasis, pneumonia, or a pleural abscess.
- The various imaging and diagnostic studies used to distinguish among these are mentioned in a subsequent section.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The diagnosis of a Morgagni diaphragmatic hernia can sometimes be a long and winding road. Neonates do not frequently arrive with the diagnosis already made by prenatal imaging, as is often the case with Bochdalek CDH. The signs and symptoms of Morgagni hernias are also usually nonspecific. Likewise, routine radiologic imaging can also overlook the more subtle defects. Because of this, Morgagni hernias are sometimes not diagnosed until later in life.
- The most common presentation in neonates and infants is an increased work of breathing or respiratory distress. Many, however, are relatively asymptomatic. Children may present with a history of recurrent chest infections. Teenagers and adults can present with any variety of symptoms including dyspnea, chest pain, abdominal pain, nausea and vomiting, and constipation or they may be completely asymptomatic. Predisposing conditions, such as chronic cough, trauma, pregnancy, and obesity, can contribute to the likelihood of symptomatic presentation.
- The physical examination is most commonly normal. However, distant heart tones and unequal breath sounds may be present. In cases of strangulation or volvulus, the patient may demonstrate significant abdominal tenderness and signs of shock. A detailed physical examination is always indicated in newborns to assess for congenital abnormalities.
- Although most commonly isolated, Morgagni hernias can be associated with congenital heart disease, malrotation, and Down's syndrome.[1] The workup should include an echocardiogram when the diagnosis is made in infancy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Morgagni hernias are not frequently detected on prenatal imaging.
- A posteroanterior (PA) and lateral chest radiograph is the initial diagnostic study of choice. This can have different appearances depending on the contents within the hernia. It may show air-filled loops of bowel projecting over the anterior mediastinum (**FIG 1A,B**) or a well-defined opacity in the right cardiophrenic angle (**FIG 2**). The latter, however, is not very specific.
- The diagnosis can be more readily made on computed tomography or magnetic resonance imaging (MRI) (**FIG 3**).

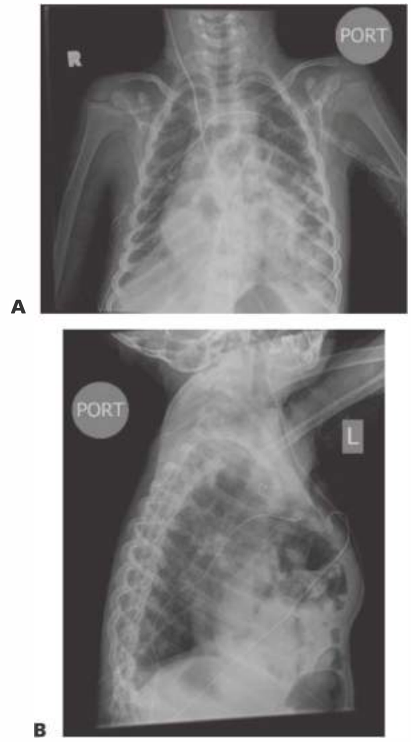

FIG 1 ● PA **(A)** and lateral **(B)** chest x-ray demonstrating air-filled loops of bowel in the anterior mediastinum consistent with a Morgagni diaphragmatic hernia.

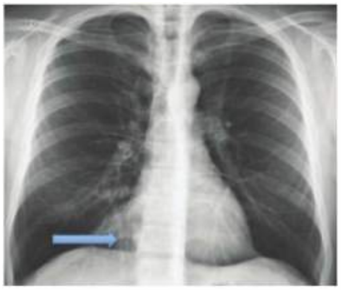

FIG 2 ● PA chest x-ray demonstrates a Morgagni hernia indicated by the opacity *(arrow)* at the right cardiophrenic angle. This hernia most commonly contains omentum.

- Ultrasound, barium enema, and upper gastrointestinal (GI) series also can be a useful part of the diagnostic workup.
- Diagnostic thoracoscopy or laparoscopy is recommended if the diagnosis remains unclear after appropriate imaging studies.

SURGICAL MANAGEMENT

Preoperative Planning

- In general, elective repair of Morgagni hernias is recommended to prevent future complications such as incarceration, strangulation, or volvulus.
- Morgagni diaphragmatic hernias can be successfully repaired through either transabdominal or transthoracic approach using open or minimally invasive techniques. We tend to favor the transabdominal approach when feasible because it allows for better visualization of the central diaphragm and for detection of bilateral hernias that may not be clearly seen on preoperative imaging. Laparoscopy is generally well tolerated in infants, even those with congenital heart disease.[2]

FIG 3 ● Computed tomography of the chest in a patient with a Morgagni hernia. Note the contrast-opacified intestinal contents within the anterior mediastinum, shifting the heart posteriorly and to the right.

- In infants, who can present with respiratory distress, lung protective strategies are initiated. When a ventilator is required, spontaneous respiration and permissive hypercapnia are used. Surgery is then performed on an elective basis, once medically stable, prior to discharge.
- For the patients with Morgagni hernias that present with acute incarceration, strangulation, or volvulus, immediate surgical management is indicated. Appropriate resuscitative measures should be initiated prior to surgery.
- Prior to taking the patient to the operating room, all diagnostic studies should be thoroughly reviewed and the patient appropriately marked on the affected side.
- Ensure that the airway is secure and the endotracheal tube is in a stable position. Pre- and postductal oxygen saturation monitoring is maintained in neonates to assess for signs of right-to-left shunting.

TECHNIQUES

OPEN MORGAGNI HERNIA REPAIR

Positioning

- The patient is placed in the supine position on the operating room table (**FIG 4**).
- Sterile plastic drapes are used as a barrier over the patient outside of the operative field. A warming blanket is also used to maintain temperature stability.

Incision

- A transverse, subcostal incision is made one to two fingerbreadths below the costal margin. An incision made too close to the costal margin can make for a more difficult repair and subsequent fascial closure. An upper midline incision may also be used.
- The abdominal wall muscle and fascia are divided and the peritoneum entered.

Exposure of the Defect and Hernia Reduction

- The falciform ligament of the liver is taken down off the abdominal wall and the left lateral segment mobilized if needed.

FIG 4 ● The patient is positioned in a standard fashion in the operating room.

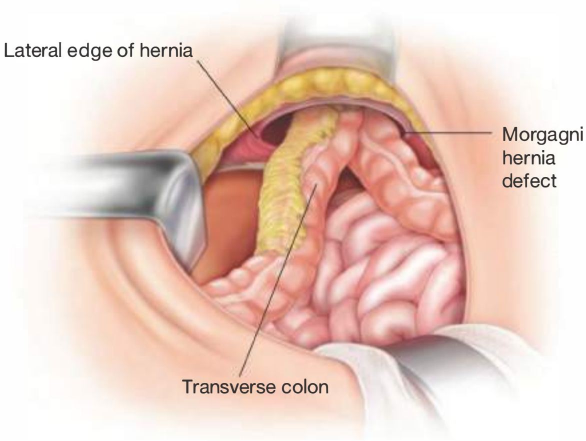

FIG 5 ● The Morgagni hernia defect is exposed and the hernia contents (transverse colon, omentum) are identified and manually reduced.

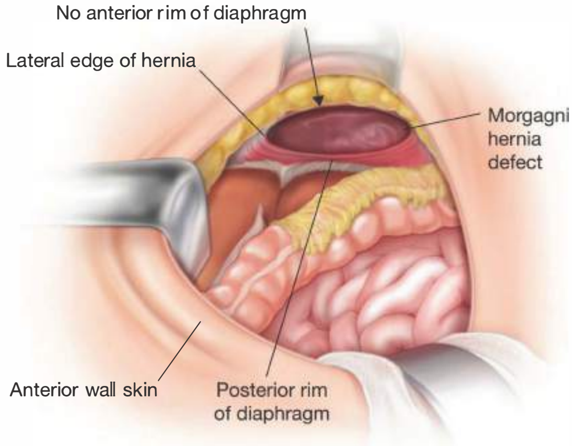

FIG 6 ● The Morgagni hernia contents have been reduced, providing full exposure of the defect. Note that there is essentially no anterior rim of diaphragm present *(arrow)*, and hernia defect is contiguous with the anterior abdominal wall.

- The liver is carefully retracted away from the diaphragm to expose the posterior and lateral boundary of the diaphragmatic hernia defect (**FIG 5**).
- The abdominal contents within the hernia are carefully reduced and returned to the abdomen.
- A hernia sac, when present, is excised with electrocautery.

Repair of the Diaphragm

- An assessment is made to determine the amount of native diaphragm. There is typically no anterior rim of diaphragm and the defect is contiguous with the anterior abdominal wall (**FIG 6**).
- If the Morgagni hernia is small enough for primary closure without significant tension, this is preferred. The defect is repaired with interrupted, simple sutures using nonabsorbable, braided suture material (**FIG 7**). Pledgeted mattress sutures may also be used. However, the diaphragmatic muscle is often attenuated, particularly for those well into adulthood. Therefore, an overlay patch to reinforce the repair may be beneficial.
- For those defects that are too large to close primarily, a prosthetic patch is used. Nonbiologic materials, such as polytetrafluoroethylene (PTFE)/expanded polytetrafluoroethylene (ePTFE), or biologic materials are effective. The patch is carefully fashioned so as to maintain the shape of the diaphragm and to have 2 to 3 cm of overlap. The posterior wall of the diaphragm is sewn first to the patch with interrupted sutures using a braided nonabsorbable material. The sutures are left untied initially. Once the posterior wall sutures are all in place, the patch is then parachuted down and the sutures are individually tied secure. Then, before closure of the anterior diaphragmatic defect is initiated, care is taken to ensure hemostasis on the thoracic side of the patch.
- The anterior portion of the patch is then secured to the anterior abdominal wall and posterior rectus sheath with interrupted suture to complete the repair.

Closure

- Once hemostasis and satisfactory repair is assured, the abdominal wall musculature and skin are then closed in layers. A drain is not needed.

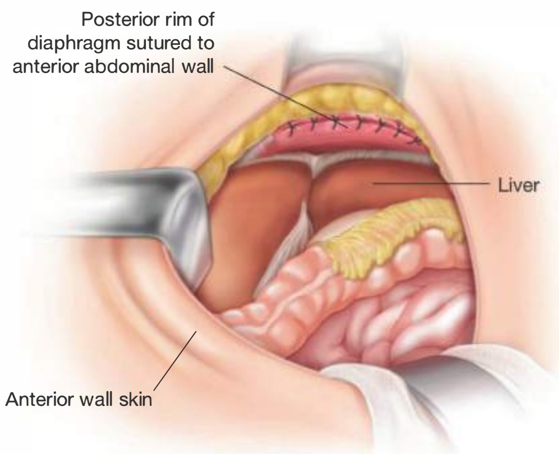

FIG 7 ● The posterior rim of diaphragm is sutured to the anterior abdominal wall with interrupted nonabsorbable suture for a relatively tension-free primary repair.

MINIMALLY INVASIVE MORGAGNI HERNIA REPAIR

- Both thoracoscopic and laparoscopic approaches have been used for Morgagni hernia repair. They each have their benefits and drawbacks, and the technical aspects of the two approaches are not dissimilar.
- We tend to favor the laparoscopic approach in that it provides excellent visualization of both hemidiaphragms. This minimizes the risk of underestimating or missing a more central or bilateral Morgagni hernia defect.

Positioning

- The patient is positioned in a similar manner as a patient undergoing a laparoscopic fundoplication so that the surgeon may stand at his or her feet. Infants and young children are supine and frog-legged at the end of the operating room table (**FIG 8**). Older children and adults are placed in dorsal lithotomy with their lower extremities in stirrups. The operating surgeon stands between the patient's legs.
- Care is taken to properly pad all pressure points.
- The monitors are positioned over the patient's head.

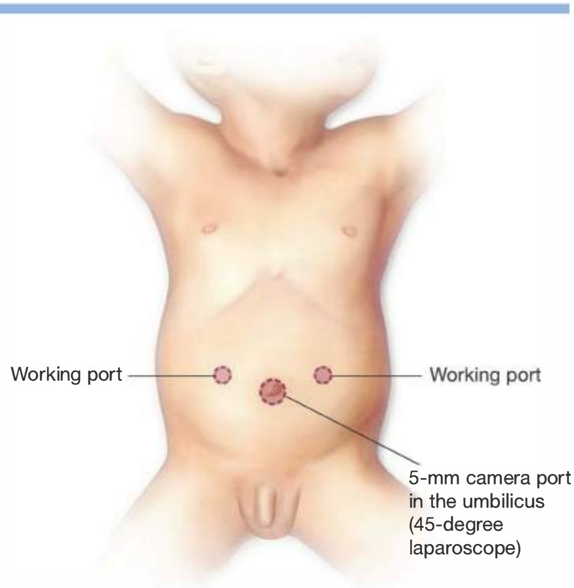

FIG 9 ● A 5-mm port is placed through the umbilicus. Two additional working ports are typically all that is needed and are positioned to appropriately triangulate the hernia defect.

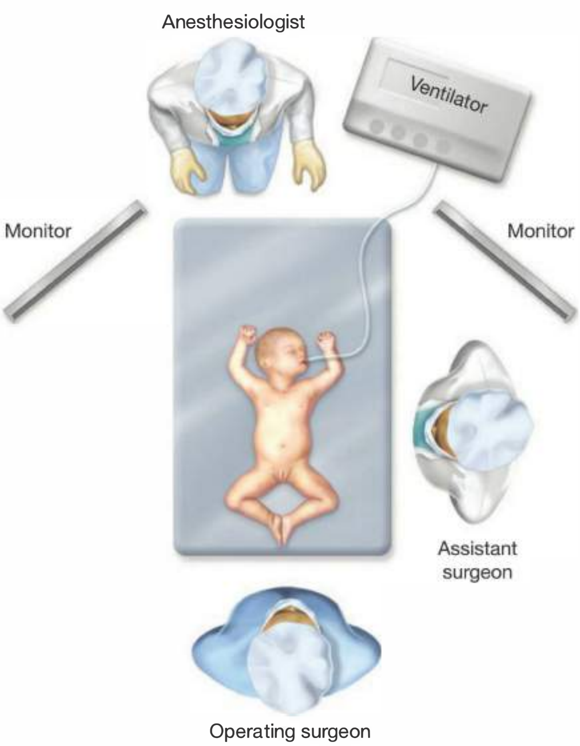

FIG 8 ● The child is positioned at the end of the operating room table in a "frog-leg" position. The operating surgeon stands at the patient's feet with the monitors placed over the patient's head.

Laparoscopic Morgagni Hernia Repair

Trocar placement

- A 5-mm trocar is placed in the umbilicus.
- Pneumoperitoneum is initially set between 8 and 15 mmHg depending on the patient's age and size.
- A 5-mm, 30-degree scope is used for visualization.
- Two additional trocars are placed under direct laparoscopic vision, in the right and left upper quadrants. These will be the primary working ports (**FIG 9**).
- An additional trocar occasionally is needed for retraction.
- A single-incision endosurgical approach is also feasible.

Reduction of the Morgagni hernia

- The hernia contents, typically the omentum and abdominal viscera, are carefully reduced with atraumatic graspers (**FIG 10**). Cotton-tipped Endo Kittners are used to help reduce the liver or spleen when present within the hernia.
- To fully expose the native diaphragm, the falciform ligament may be taken down from the abdominal wall (**FIG 11**). This will often lead the surgeon directly to the lateral extent of the Morgagni hernia and allow for adequate overlap with patch placement.
- The hernia sac, if one is present, is carefully excised circumferentially off the diaphragmatic defect using hook cautery or other endoscopic sealing device. However, this may also be left intact when dissection into the mediastinum proves too arduous to avoid the risk of pneumothorax and pneumopericardium.[3] The peritoneum is then taken off the edge of the hernia defect with cautery.

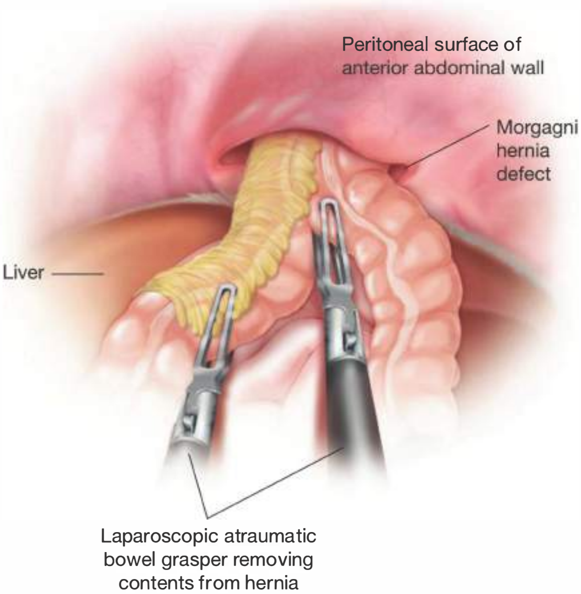

FIG 10 ● The Morgagni hernia is identified and the hernia contents are reduced back into the abdomen with atraumatic graspers.

Repair of the Morgagni hernia

- The hernia defect is measured and an assessment is made as to whether the repair is feasible via a relatively tension-free primary repair or that it will require a patch repair.

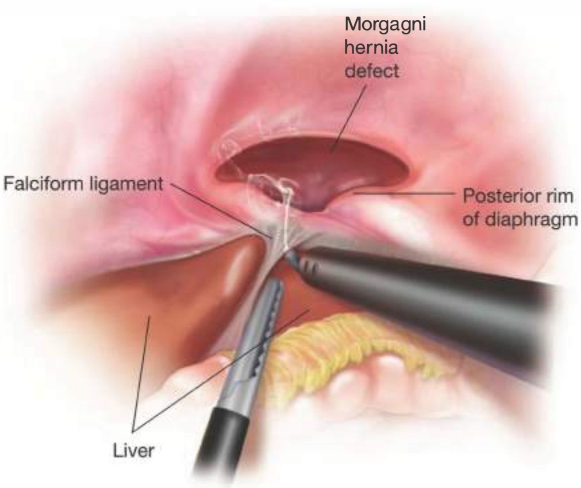

FIG 11 ● The falciform ligament abuts the posterior rim of the Morgagni hernia defect. It is taken down with hook cautery or a bipolar endosurgical device. This provides full exposure of the defect and frees up tension on the hernia repair.

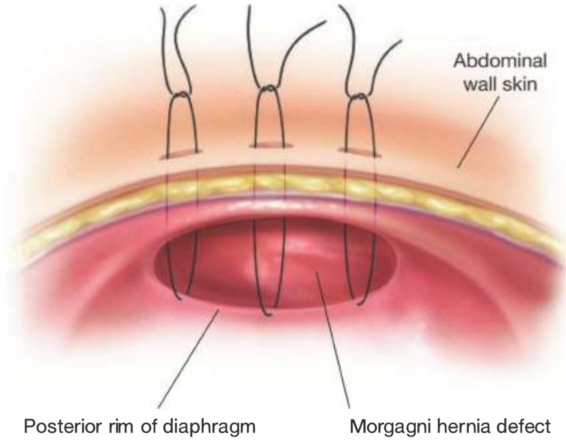

FIG 12 ● A suture is introduced through the anterior abdominal wall and endoscopically passed through the posterior margin of the diaphragmatic hernia defect. The suture is then passed back out through the anterior abdominal wall and the knots may be tied in the subcutaneous tissue.

- For a primary repair, the diaphragm is reapproximated using interrupted nonabsorbable sutures. The closure is begun at the most posterior aspect of the hernia and carried up to the anterior abdominal wall.
- The closure of the defect along the anterior portion of the hernia defect can be challenging but is feasible with intracorporeal suturing techniques. However, we favor a percutaneous technique using an endoscopic suture passer. Small stab incisions are made in the abdominal wall over the central margin of the hernia defect. The suture is percutaneously introduced into the abdomen with an external needle driver through the anterior abdominal wall stab incision. The suture needle is then grasped with the laparoscopic needle driver and passed through the posterior rim of diaphragm intended to be reapproximated. The endoscopic suture passer is then introduced into the abdomen through the same external stab incision but now directed through the anterior abdominal wall fascia about 1 cm away from which the suture was first passed. The suture is retrieved and the knots can be tied extracorporeally within the subcutaneous plane (**FIGS 12** and **13A,B**).
- A prosthetic patch may be needed to achieve a relatively tension-free closure. Similar to open repair, a biologic or nonbiologic prosthetic patch is selected and fashioned to provide 2 to 3 cm of overlap. The patch is rolled tightly and passed through a trocar, or directly through one of the trocar site incisions. It is then unrolled, oriented, and secured to the diaphragm using interrupted nonabsorbable suture or an endoscopic tacking device. Care is taken to avoid injuring the pericardium at the central aspect of the hernia defect. Along the anterior portion, the patch is fixed to the posterior rectus fascia, just below the costal margin (**FIG 14**). This is accomplished using intracorporeal

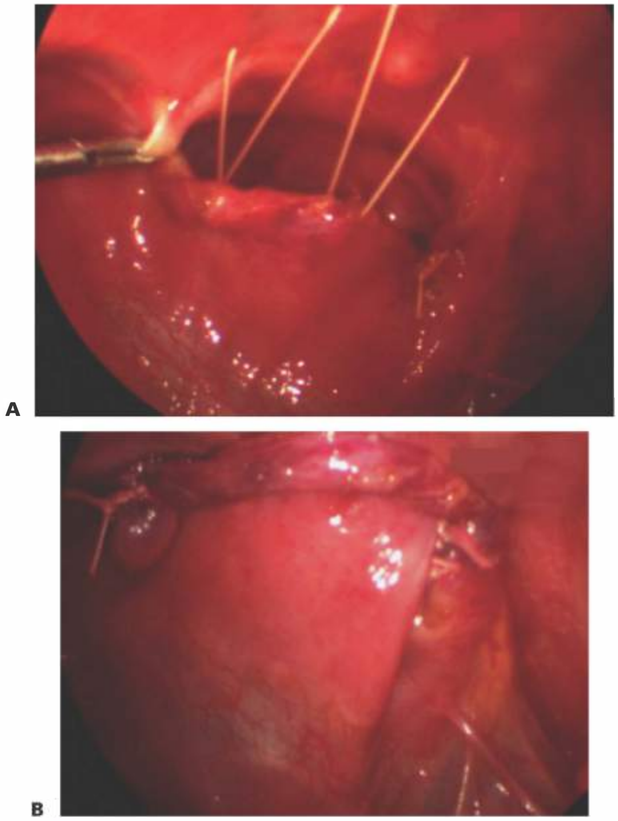

FIG 13 ● **A.** Percutaneous sutures have been passed through the posterior rim of diaphragm and brought back out through the anterior abdominal wall. **B.** The knots have been tied extracorporeally in the subcutaneous tissue, closing the defect.

suturing techniques or an endoscopic tacking device or may be secured externally using a suture passer technique as described earlier.

Closure

- No drains are needed.
- The pneumoperitoneum is released and the liver is allowed to abut the hernia repair.
- The ports are removed in a stepwise fashion.
- The incisions are reapproximated with absorbable suture and skin glue is applied as a dressing.

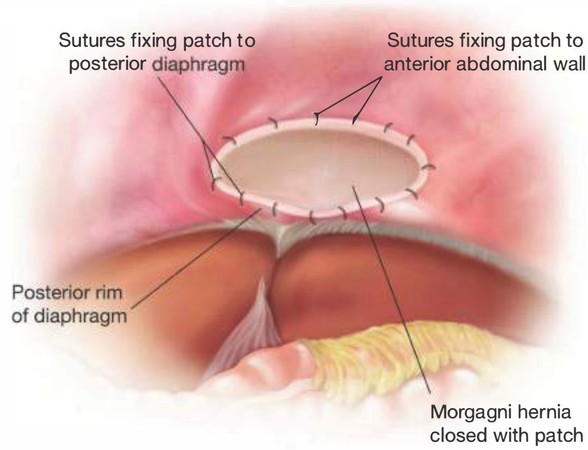

FIG 14 ● A prosthetic or biologic patch is secured to the diaphragm and anterior abdominal wall with 2 to 3 cm of overlap.

PEARLS AND PITFALLS

Preoperative planning	■ A missed bilateral hernia or more extensive central hernia can be avoided with a transabdominal approach.
Incision	■ A transverse subcostal incision should be well away from the costal margin so that there is adequate space to close the anterior portion of the diaphragmatic defect.
Hernia reduction	■ The hernia sac may be left alone to avoid risk of disrupting the pleura or pericardium.
Hernia repair	■ Multiple stitches may be placed through a single abdominal wall stab incision by dissecting a bit subcutaneously. ■ Maintain a low threshold for using a prosthetic patch to achieve a tension-free repair.
Laparoscopy	■ External manual compression of the lower chest and upper abdominal wall can help with suture placement anteriorly.

POSTOPERATIVE CARE

- The majority of patients will be successfully extubated at the completion of the repair.
- They are admitted postoperatively for observation and, barring other issues, are ready for discharge in 24 to 48 hours.
- Follow-up PA and lateral chest radiographs are taken at 1, 6, 12, and 24 months postoperatively to assess for recurrence.

OUTCOMES

- Survival is quite good in all age groups and will primarily depend on other comorbidities.

- Small series in children have demonstrated no difference between laparoscopic and open repair with regard to recurrence rate or intraoperative complications.[4] However, a recent series demonstrated a fairly high recurrence rate—42%—following laparoscopic repair when a patch was not used.[5]
- The complication rate in adults for laparoscopic repair, by comparison, is fairly low at 5%.[6]

COMPLICATIONS

- Recurrent hernia
- Patch infection
- Fluid collection in foramen of Morgagni
- Pneumothorax
- Pericardial effusion or pneumopericardium

Chapter 18

Repair of Congenital Defects: Bochdalek Congenital Diaphragmatic Hernia

Scott A. Anderson   Mike K. Chen

DEFINITION

- A Bochdalek congenital diaphragmatic hernia (CDH) refers to a defect in the posterolateral diaphragm. The abdominal viscera partially translocates through the defect in the thorax in the developing fetus. This affects the growth and maturation of both lungs. The size of the defect can range from fairly small to complete diaphragmatic agenesis. Affected infants are born with pulmonary hypoplasia, lung immaturity, and pulmonary hypertension, to varying degrees. Successful management of these issues is most critical to a favorable outcome.
- The incidence of CDH is 1 in 2,000 to 1 in 5,000 births overall. Approximately 80% will occur on the left side; bilateral defects are rare. It continues to be one of the more challenging congenital anomalies in pediatric surgical patients.

DIFFERENTIAL DIAGNOSIS

- Prenatally and postnatally, Bochdalek CDH can be mistaken for a number of other congenital thoracic anomalies. These can include Morgagni CDH, diaphragmatic eventration, congenital cystic lung disease, esophageal hiatal hernia, and primary lung agenesis.
- The various imaging and diagnostic studies used to distinguish among these are discussed in a subsequent section.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Many, but certainly not all, CDH patients are born with the diagnosis already made on prenatal ultrasound. A team of neonatologists, high-risk obstetricians, and pediatric surgeons are involved in their perinatal care to ensure a safe delivery and expeditious treatment. These patients are immediately resuscitated after delivery with endotracheal intubation and nasogastric decompression. Ventilation with Ambu bag and mask is avoided to minimize gastrointestinal (GI) distention, which can worsen the compression in the thoracic cavity. A strategy of spontaneous respiration and permissive hypercapnia is employed to minimize ventilator-induced lung injury.
- For those without prenatal diagnosis, patients will present shortly after birth with typical signs of respiratory distress, including tachypnea, grunting, and cyanosis. They also will commonly have a scaphoid abdomen, barrel-shaped chest, and diminished or absent breath sounds on the affected side. The heart tones are also shifted toward the contralateral side.
- Ten percent to 50% of CDH patients will have other congenital anomalies, so a thorough physical examination and assessment is indicated. See Table 1.
- Also, a number of syndromes have been associated with CDH including Frey; Beckwith-Wiedemann; Goldenhar; Fryns; and trisomy 21, 18, and 13. A genetics consult is warranted if any of these are suspected.

Outflow tract abnormalities
Musculoskeletal
Tracheobronchial
Genitourinary
Neural tube defects
Chromosomal

VSD, ventricular septal defect.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Prenatal workup includes ultrasound and/or fetal magnetic resonance imaging (MRI). Evaluation of fetal karyotype via amniocentesis or other methods can provide additional information that aids in properly informing and preparing the parents.
- After birth, a chest radiograph is the primary diagnostic study of choice. For a left-sided CDH, this will classically show multiple gas-filled bowel loops within the left hemithorax and contralateral shift of the mediastinum (**FIG 1**). The presence

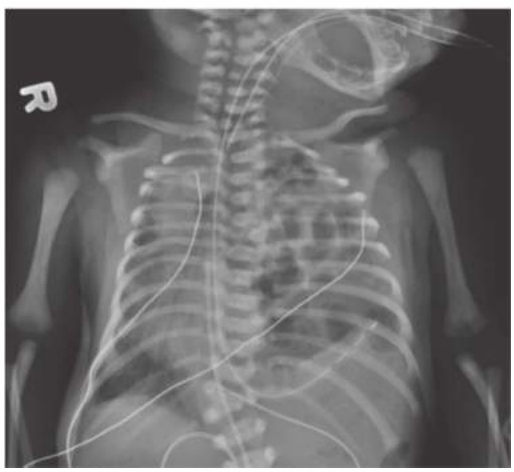

FIG 1 • Chest x-ray in neonate demonstrating a left CDH. Note that the stomach and liver are both transposed into the left chest and the mediastinum is shifted to the right.

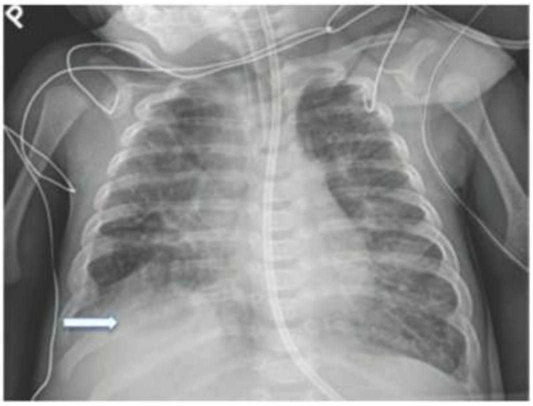

FIG 2 ● Chest x-ray demonstrating a right CDH. The *arrow* denotes the elevated liver at the site of the hernia defect.

of the liver and/or stomach in the chest on plain film can help estimate the size of the hernia defect. A right-sided CDH may demonstrate only an elevated liver shadow if no other visceral contents have traversed the hernia defect (**FIG 2**).

- Computed tomography, MRI, ultrasound, fluoroscopy, and upper GI series with small bowel follow-through may be used as well when the diagnosis is not certain. Diagnostic thoracoscopy or laparoscopy is recommended if the diagnosis remains unclear after appropriate imaging studies.
- An echocardiogram should be obtained as part of the workup for associated congenital anomalies. It can also be useful in quantifying the degree of pulmonary hypertension and then following its treatment. Additionally, intracranial imaging with a head ultrasound is useful, particularly when perioperative extracorporeal membrane oxygenation (ECMO) is considered as part of the infant's management.

SURGICAL MANAGEMENT

Preoperative Planning

- CDH is a physiologic emergency and not usually a surgical emergency. The careful management of the neonate's pulmonary hypoplasia, lung immaturity, and pulmonary hypertension is most critical to his or her successful outcome.
- The optimal timing for surgical repair is unclear, although most current strategies include a period of medical stabilization followed by delayed operative repair.
- Both open and minimally invasive techniques can be used for repair. We favor a thoracoscopic repair for a small defect in the stable patient and an open repair in the less stable patient with a larger hernia defect.
- Prior to taking the patient to the operating room, all diagnostic studies should be thoroughly reviewed and the patient should be appropriately marked on the affected side.
- Ensure that the airway is secure and the endotracheal tube in a stable position. Pre- and postductal oxygen saturation monitoring should be maintained.
- Arterial access is ideal for perioperative and intraoperative blood gas monitoring.
- The infant's own ventilator is preferred over the typical anesthesia circuit.
- If the patient is on ECMO, appropriate perioperative bleeding protocols should be initiated.
- For less stable infants, it may be more appropriate for the surgical repair to take place in their neonatal intensive care unit (NICU) bed space.

TECHNIQUES

OPEN LEFT CONGENITAL DIAPHRAGMATIC HERNIA REPAIR

Positioning

- In the operating room, the infant is placed in the supine position on a shortened bed (**FIG 3**).
- Sterile plastic drapes are used as a barrier over the infant outside of the operative field. A warming blanket is also used to maintain temperature stability.
- For operative repairs in the NICU, the infant is brought to the end of his or her bed at an angle, with his or her feet directed toward one corner (**FIG 4**).
- Both the abdomen and chest are prepared as the operative fields. The umbilical catheters are secured to the patient's lower quadrant, contralateral to the operative side.

FIG 3 ● The infant is positioned in the center of a shortened operating room table. The operating surgeon stands on the side of the CDH with the surgical assistant on the opposite side.

FIG 4 ● The infant is positioned in his or her NICU bed at a 45-degree angle with his or her feet directed toward one corner. The operating surgeon then stands on the side of the CDH and the surgical assistant on the opposite side. The ventilator and other equipment are kept at the head of the bed.

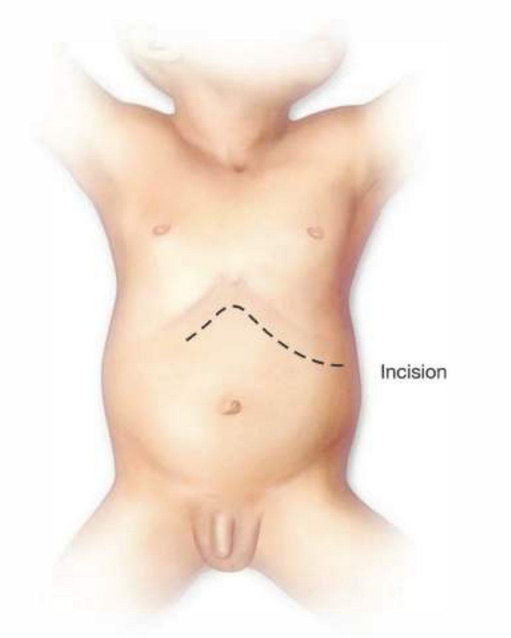

FIG 5 ● A subcostal incision is made one to two fingerbreadths below the costal margin. It may need to be extended across midline to provide adequate exposure for larger diaphragmatic defects.

Incision

- For a left CDH, an ipsilateral subcostal incision is made. Do not make the incision too close to the costal margin as it may leave little room to work with on the lateral chest wall and it may make closure more difficult. The subcostal incision will need to be extended across midline for larger diaphragmatic hernia defects (**FIG 5**).
- The abdominal wall muscle and fascia are divided and the peritoneum entered. The infant's abdominal wall may be gently stretched to help increase domain for the hernia reduction.

Hernia Reduction

- First, the liver needs to be mobilized. The triangular ligament is taken down and the left lateral segment completely freed up. The falciform ligament can usually be left intact.
- The liver is carefully retracted away from the diaphragmatic defect to expose the medial boundary of the diaphragmatic hernia defect (**FIG 6**).
- The reduction of the hernia is typically done in a stepwise fashion.
- The anterior aspect of the incision is retracted cranially. Next, the liver is very carefully reduced from the hernia (if up) and retracted medially with moist lap pads and soft malleable retractors. Then, the small and large bowels are gently reduced from the hernia. Care is taken to keep the mesentery properly oriented and to avoid trauma to the splenic capsule when reducing the colon. Finally, the stomach and spleen are reduced together. This is best done with the index finger. Special attention is paid to avoid traction on the short gastric vessels. All the abdominal viscera can usually be packed within the abdominal cavity using moistened mini-lap pads and malleable retractors. This helps with temperature control and allows some time for the abdominal cavity to begin to accommodate prior to fascial closure. For prolonged procedures, the tightly packed bowel may need to be intermittently unpacked and inspected for ischemia.
- If a hernia sac is present, this is excised.

Repair of the Diaphragm

- An assessment is made to determine the amount of native diaphragm. The posterior aspect of native diaphragm may need to be mobilized and unfolded from the retroperitoneum to fully use it in closure. The anterior diaphragm is then traced medially and the left crus is identified.

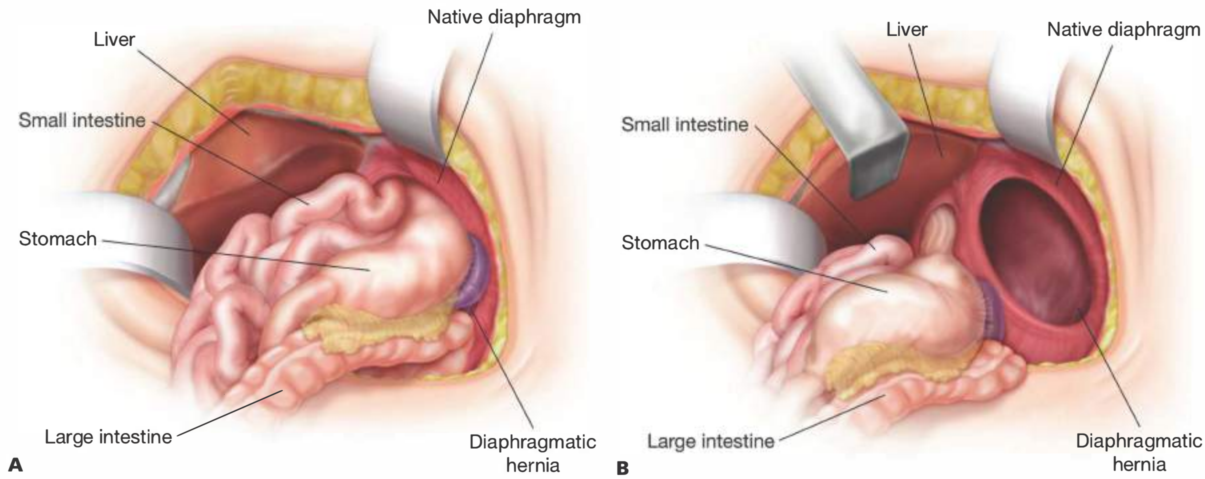

FIG 6 ● **A.** The diaphragmatic hernia defect is exposed. **B.** The abdominal contents have been reduced from the diaphragmatic hernia and the native diaphragm is assessed.

- If the diaphragmatic hernia is small enough for primary closure without significant tension, this is preferred. The defect is repaired with interrupted simple sutures using nonabsorbable braided suture material. For those defects that are too large to close primarily, a 1-mm Gore-Tex soft tissue patch is used. This is carefully fashioned so as to maintain the rounded, dome shape of a normal diaphragm. The posterior wall is sewn first to the patch with interrupted sutures using a braided nonabsorbable material. The sutures are left untied initially (**FIG 7**). Once all in place, the patch is then parachuted down, and the sutures are individually tied secured (**FIG 8**). Then, before closure of the anterior diaphragmatic defect is initiated, care is taken to ensure hemostasis on the thoracic side of the patch.
- For portions of the diaphragmatic defect with no native diaphragm present, the soft tissue patch is sewn directly to rib. A thick taper needle is brought in through the superior aspect of rib and out through the center of the rib to avoid the neurovascular bundle. Once adequate hemostasis is achieved, the anterior wall of the diaphragm is closed (**FIG 9**). A chest tube is not placed unless the patient is anticoagulated on ECMO.

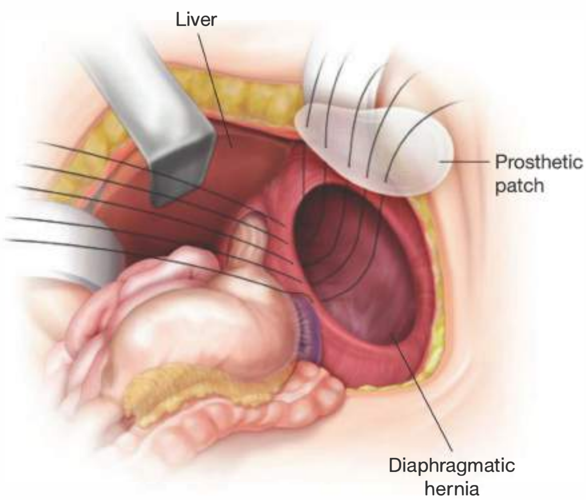

FIG 7 ● The diaphragmatic patch is first sewn to the posterior diaphragmatic defect or chest wall. The sutures are initially left untied to facilitate adequate placement. Once the posterior row is in place, the patch is parachuted down in place and the sutures are tied. Prior to closing the anterior rim of diaphragm, the thorax is inspected for hemostasis.

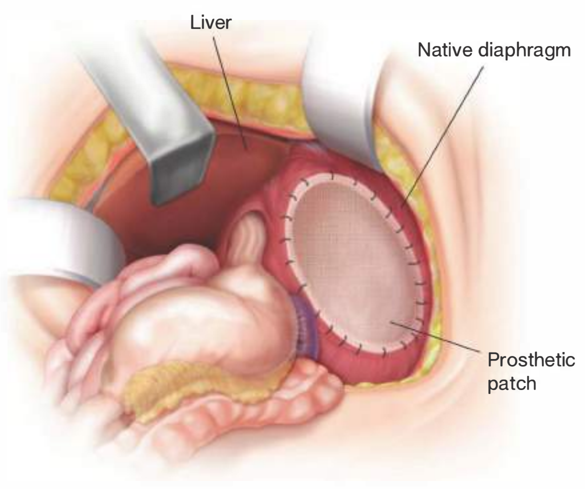

FIG 8 ● The diaphragmatic hernia repair is completed with the patch sewn in place in a tension-free manner.

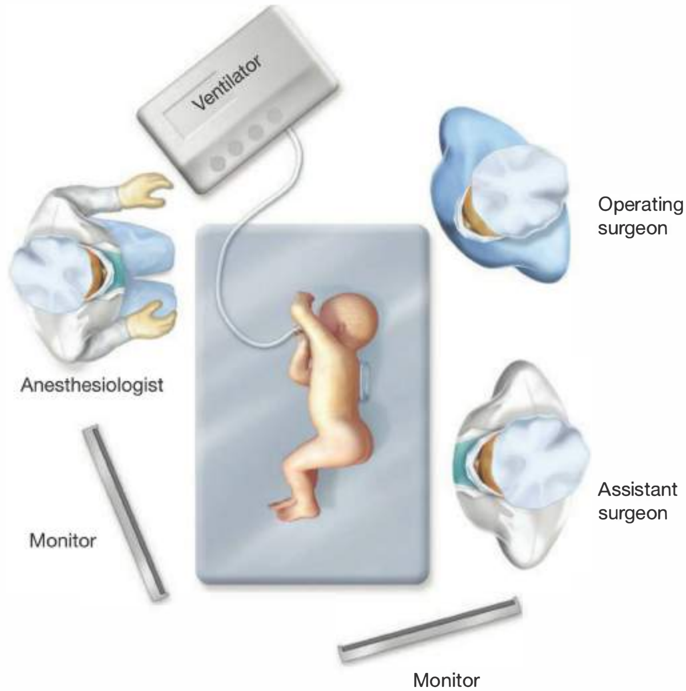

FIG 9 ● The infant is positioned in lateral decubitus position with the affected side up. The infant is placed at one end of the operating table so that the operating surgeon is able to be positioned at the infant's head and the surgical assistant to his or her side.

- At this time, the retractors are released and the bowel is inspected.

Closure

- Position the abdominal viscera in anatomic position. The spleen is placed in the left upper quadrant abutting the repaired diaphragm. The bowel is positioned to keep the mesentery flat and untwisted. Only if there is little chance for the patient to be anticoagulated, such as for ECMO, are Ladd bands divided. An appendectomy is not routinely performed and should be avoided when a prosthetic patch is used. Lastly, the left lateral segment of liver is placed back over the anterior gastric wall.
- The abdominal wall musculature and skin are then closed in layers.
- For some patients, there will be loss of abdominal domain after hernia reduction and primary abdominal closure may not be feasible. If this is the case, a silo or patch may be easily used to avoid potential issues with postoperative abdominal compartment syndrome.

THORACOSCOPIC LEFT CONGENITAL DIAPHRAGMATIC HERNIA REPAIR

Positioning

- The infant is placed in the lateral decubitus position with the affected side up. An axillary roll is placed and care is taken to ensure all pressure points are properly padded.
- The ipsilateral arm is extended anteriorly and superiorly to open the axilla.
- The patient is oriented on the operating room table so that the operating surgeon may stand at the patient's head. The monitor is accordingly positioned over the infant's feet (**FIG 9**).

Trocar Placement

- A Veress needle is first introduced followed by a 5-mm radially expanding trocar placed just caudal to the angle of the scapula.
- Pneumothorax is initially set at 4 mmHg and ventilator changes along with carbon dioxide (CO_2) are closely monitored. Mainstem intubation is typically not needed.
- A 4-mm, 30-degree scope is used for visualization.
- Two additional 4-mm trocars are placed under direct thoracoscopic vision, anterior and posterior to the first trocar, and one to two rib spaces caudally. These will be the primary working ports (**FIG 10**).
- An additional trocar may be needed to retract the lung out of the operative field.

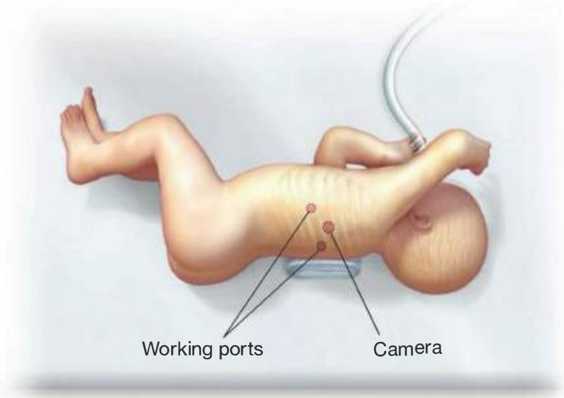

FIG 10 ● The initial 5-mm port is placed at the angle of the scapula following introduction of pneumothorax via the Veress needle. Two additional 4-mm ports are inserted to the right and left, one to two rib spaces inferiorly. This allows the 4-mm camera to be repositioned when necessary. An additional posterior port may be added if needed.

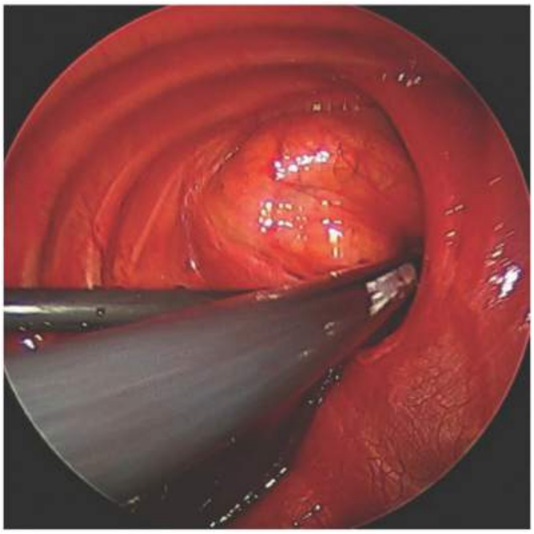

FIG 12 ● A cotton-tipped Endo Kittner can be particularly helpful with reduction of the spleen.

Reduction of the Diaphragmatic Hernia

- The abdominal viscera are carefully reduced with blunt graspers and a cotton-tipped Endo Kittner. The pneumothorax will aid in this process (**FIGS 11** and **12**).
- If the spleen is included in the herniated viscera, this is reduced last, and it may provide an initial "plug" to the defect.
- The hernia sac, if one is present, is carefully excised circumferentially off the diaphragmatic defect using hook cautery. It may be otherwise left attached to any abdominal viscera.

Repair of the Congenital Diaphragmatic Hernia

- When a relatively tension-free primary repair is feasible, the defect is reapproximated using braided nonabsorbable sutures placed in an interrupted fashion. The hernia defect is best repaired beginning from medial, where it is the most narrow, to lateral, where it is at its widest (**FIGS 13** and **14**).
- The most lateral aspects of the diaphragmatic hernia repair typically require pericostal stitches because the costal insertions of the diaphragm are too wide for primary reapproximation. These pericostal stitches close the defect by securing the native diaphragm to the lateral chest wall. A small stab incision is made directly over the rib that the suture is to be secured around. The suture is introduced into the chest inferior to the rib under thoracoscopic vision using a standard needle driver. Once thoracoscopically sutured to the diaphragm, it is retrieved using an endosnare and brought back out the superior

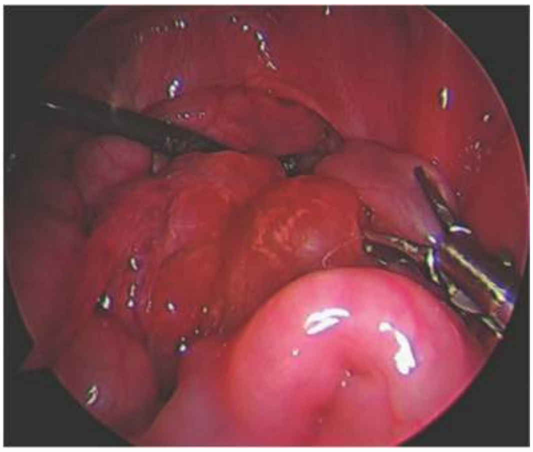

FIG 11 ● The abdominal viscera are carefully reduced through the diaphragmatic hernia defect with blunt graspers. The CO_2 pneumothorax can aid in this as well.

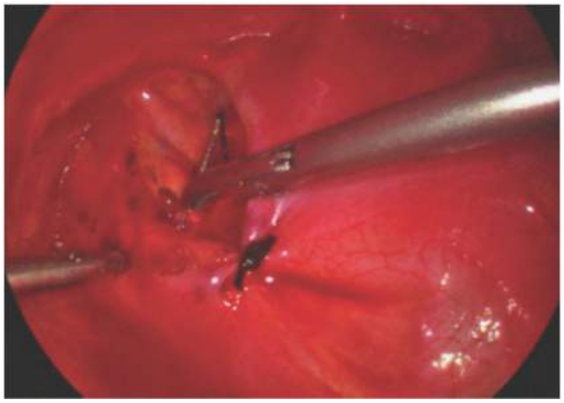

FIG 13 ● The thoracoscopic hernia repair is begun in a medial to lateral fashion using intracorporeal suturing techniques. The diaphragm is reapproximated using interrupted sutures in a tension-free manner.

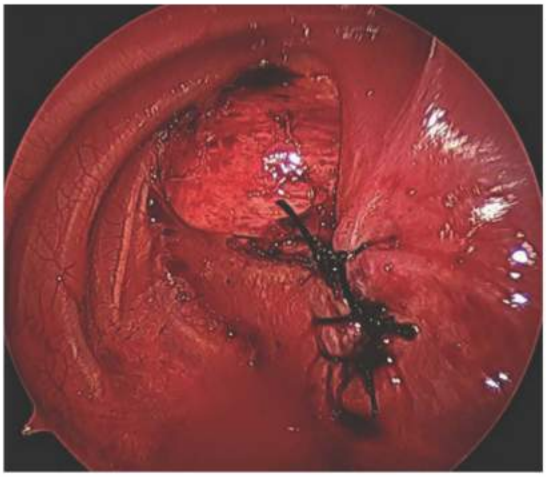

FIG 14 ● As the repair approaches the lateral chest wall, the defect becomes wider due to the fixed nature of the diaphragm on the chest wall. This will not primarily reapproximate without significant tension.

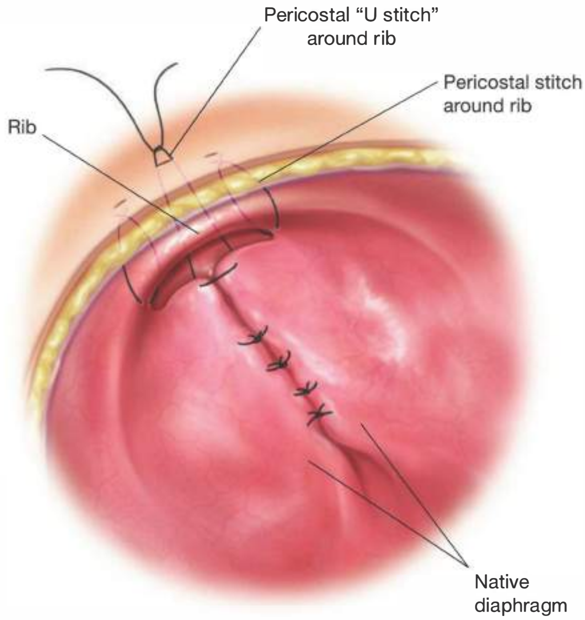

FIG 16 ● A pericostal U stitch is used to close the remaining diaphragmatic hernia defect while securing it to the chest wall.

side of the rib (**FIG 15**). The suture is then tied extracorporeally. The central portion of the diaphragmatic defect usually requires a pericostal "U stitch" that brings the posterior and lateral rim of the diaphragm together, fixing them to the lateral chest wall (**FIG 16**). This allows complete closure of the hernia defect (**FIG 17**).

- If a patch is needed, this may be secured to the diaphragm in a fashion similar to open repair and to the chest wall using the earlier described pericostal U-stitch technique. Additionally, a synthetic patch may also be used as an onlay for weaker areas of the diaphragmatic repair. Using a thin composite mesh may provide for easier introduction and intracorporeal manipulation.

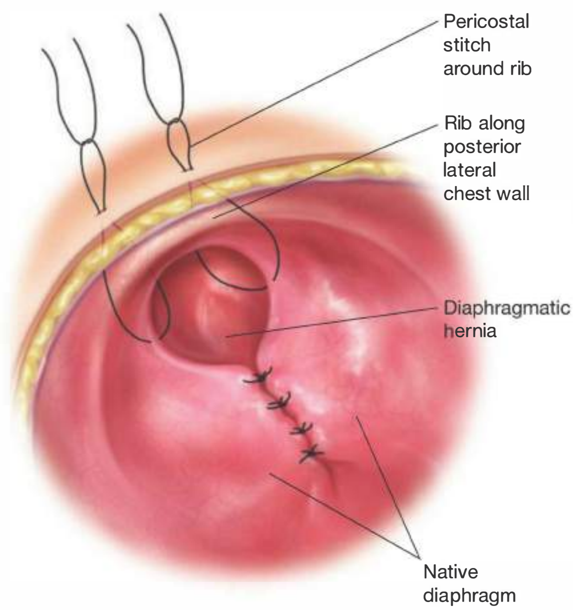

FIG 15 ● Pericostal stitches are placed through small stab incisions in the patient's lateral chest wall. These both secure the diaphragm repair to the rib and reduce the size of the remaining hernia defect without significant tension.

Closure

- The pneumothorax is released and the lung reexpanded. A chest tube may be placed through the anterior trocar site if deemed necessary.
- The incisions are reapproximated with absorbable suture and skin glue is applied as a dressing.

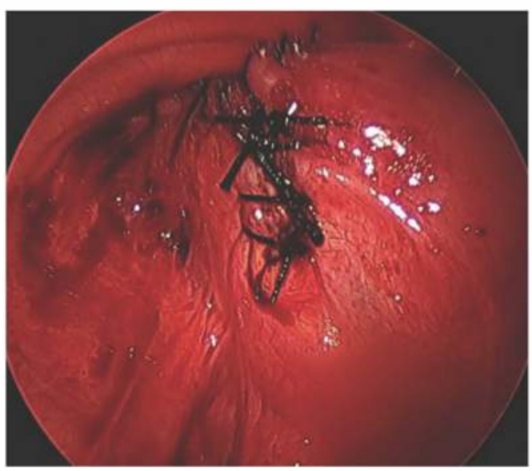

FIG 17 ● The completed CDH repair.

PEARLS AND PITFALLS

Incision	■ If perioperative ECMO is likely, use electrocautery as much as safely possible during repair and avoid mobilization of retroperitoneal area.
Hernia reduction	■ Be on the lookout for abnormally draining hepatic veins when mobilizing and reducing the liver. ■ Avoid trauma to the short gastric vessels and splenic capsule.
Hernia repair	■ The patch may need to be secured to esophagus, pericardium, or aortic adventitia if no medial diaphragm is present. ■ Incorporate enough redundancy in the patch construction so as to allow the repaired diaphragm to have a normal, rounded shape instead of a flattened one.
Thoracoscopy	■ Mark the rib(s) for the pericostal stitches prior to insufflating the thorax to prevent overflattening the diaphragm. ■ External compression by the assistant on the lateral chest wall may aid in the placement of the more difficult lateral sutures.
Closure	■ If in question, use a silo or patch to aid abdominal wall closure.

POSTOPERATIVE CARE

- The principles of postoperative care are similar to the preoperative care of CDHs and close monitoring of pulmonary hypertension is critical. Close attention to fluid status is also required as the fluid demands in the immediate postoperative period will typically rise. The ventilator, once stabilized, is slowly and deliberately weaned as tolerated.

OUTCOMES

- The overall survival of infants with CDH varies between 60% and 90%. For the subset of infants that require ECMO, the survival remains at around 50%.[1]
- The recurrence of CDH is bimodal, with early recurrences typically seen within 2 months of surgery and late recurrences at approximately 2 years of age. Data from the CDH registry suggest that the early, in-hospital recurrence rate is significantly higher for thoracoscopic (7.9%) versus open (2.7%) repair.[2]
- Multiple different patch materials have been used. These include nonabsorbable prosthetic, biologic, and muscle flaps. At this time, there is no clear advantage with regard to survival, recurrence, or bowel obstruction among any of these patch materials.[3–5]
- CDH patient survivors are at risk for chronic pulmonary, cardiovascular, neurodevelopmental, GI, and musculoskeletal problems and should be closely followed for these well into the school ages.

COMPLICATIONS

- Recurrence
- Patch infection
- Postoperative pulmonary hypertension
- Abdominal compartment syndrome
- Postoperative hemorrhage
- Bowel obstruction

Chapter 19

Paraesophageal Hernia Repair: Laparoscopic Technique

John G. Hunter   Mark J. Eichler

DEFINITION

- For millennia, the existence of hiatal hernias was well known. First described by Henry Bowditch in 1853, and later in 1951 officially by Philip Allison, the paraesophageal hernia (PEH) presents a physiologic link to reflux esophagitis, ulceration, stricture, and other esophageal pathology.[1,2]
- Of the four types of hiatal hernias known today, 95% of incidence resides with the type I or sliding hiatal hernia, which typically can be managed medically with gastric acid suppression. The remaining three types are lumped as "paraesophageal hernias." These include the true PEH (type II), combined sliding and paraesophageal (type III), and extragastric (type IV) (**FIG 1**). With the advent of modern antireflux surgery, failed fundoplication overlaps with this classification (**FIG 2**). Furthermore, disruption of the esophageal hiatus for other disease processes, such as esophagectomy, potentiates the PEH, especially type IV.
- This chapter, in concert with other procedures such as fundoplication and esophageal lengthening (Collis gastroplasty), will deal with the surgical management of PEH types II to IV, which anatomically may also encompass redo fundoplication. Principles of repair include definition of anatomy and symptoms, safe reduction of abdominal organs back to the peritoneal cavity, excision of the hernia sac, closure of crura (with or without mesh repair), evaluation of intraabdominal esophageal length, and an antireflux procedure.[3,4]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Necessity for PEH repair lies with the patient symptomatology, medical status, and chance of obstruction or strangulation. PEHs can encompass symptoms of gastroesophageal reflux disease (GERD), which includes typical symptoms of heartburn, acid reflux, and dyspepsia. In contrast, atypical GERD symptoms manifest as laryngeal and pulmonary complaints of noncardiac chest pain, dyspnea, poor dentition, sinusitis, asthma, chronic cough, pneumonia, and halitosis. PEH-specific complications include gastric volvulus, incarceration, gastric outlet obstruction, and higher mortality when performed emergently. Early studies on mortality in the 1960s demonstrated mortality rates over 50% for PEHs with associated gastric volvulus, although more recent analysis suggests that number to be overestimated and is actually more likely to be under 20% for such patients in duress from PEH.[5,6] For all PEH patients, overall mortality is under 1% and can safely be performed with a laparoscopic approach even in the face of obstruction, gangrene, and so forth.[7]
- Indications for PEH repair therefore should be tailored to patients who are symptomatic and medically likely to survive an operation. Ultimately, most patients who have a PEH will become symptomatic.[3,5,6]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative diagnostic studies help dictate the range of elective, urgent, and emergent nature of a symptomatic patient with a PEH. In those patients who are in extremis, the minimum workup needed for urgent or emergent PEH repair is radiographic evidence of incarceration, perforation, obstruction, or failed antireflux surgery. However, the majority of patients present in an elective manner, and we therefore advocate for a complete workup to assist preoperative planning of the symptomatic patient with PEH by the addition of manometry, pH testing, and endoscopy to rule out pseudoobstruction or esophageal motility disorders.
- Chest x-ray: At presentation, whether to an emergency department or a primary care physician's office, the chest x-ray gives quick and cost-effective information to the severity of the PEH. Mediastinal gas bubble can be seen on plain film radiography as well as the presence of pneumoperitoneum or pneumomediastinum.
- Esophagram: The supine and upright plain film esophagram demonstrates static anatomy and can often locate the gastroesophageal junction (GEJ) in relation to the diaphragm as well as deduce the presence of reflux on delayed films. Mucosal abnormalities can be seen with this modality as well (**FIG 3A,B**).
- Computed tomography (CT): Indications for obtaining CT scans include the emergent presentation, inconclusive but worrisome findings on two-dimensional radiography, and PEH type IV (**FIG 4**). CT aids the preoperative planning by alerting the surgeon to the extent of skin preparation and positioning for operative repair but is not necessary.
- Upper endoscopy: All preoperative patients should undergo upper endoscopy if possible. By visualization of the esophageal and gastric lumen, neoplasm, Barrett's esophagus, and esophagitis can be biopsied, and, in case esophagectomy is warranted, provide histologic diagnosis. Furthermore, anatomic landmarks can be seen such as the distance between the hiatus and the GEJ as well as the size of the hiatal hernia.
- Manometry: Several studies of benign esophageal disorders confirm the use of preoperative manometry.[3,8] Distal esophageal pressures greater than 30 mmHg indicate favorable outcome of response to fundoplication, which, according to some surgeons, is a threshold for performing a complete versus partial wrap for the antireflux component of the PEH repair. Manometry also rules out primary esophageal dysmotility including achalasia, diffuse esophageal spasm, nutcracker esophagus, hypertensive lower esophageal sphincter (LES), and ineffective esophageal motility. We do not advocate performing a complete fundoplication for patients with esophageal dysmotility or low distal esophageal pressures.
- pH study: Although the previous modalities of the PEH workup provide a robust description of the PEH patient, pH studies provide data for the decision in failed antireflux

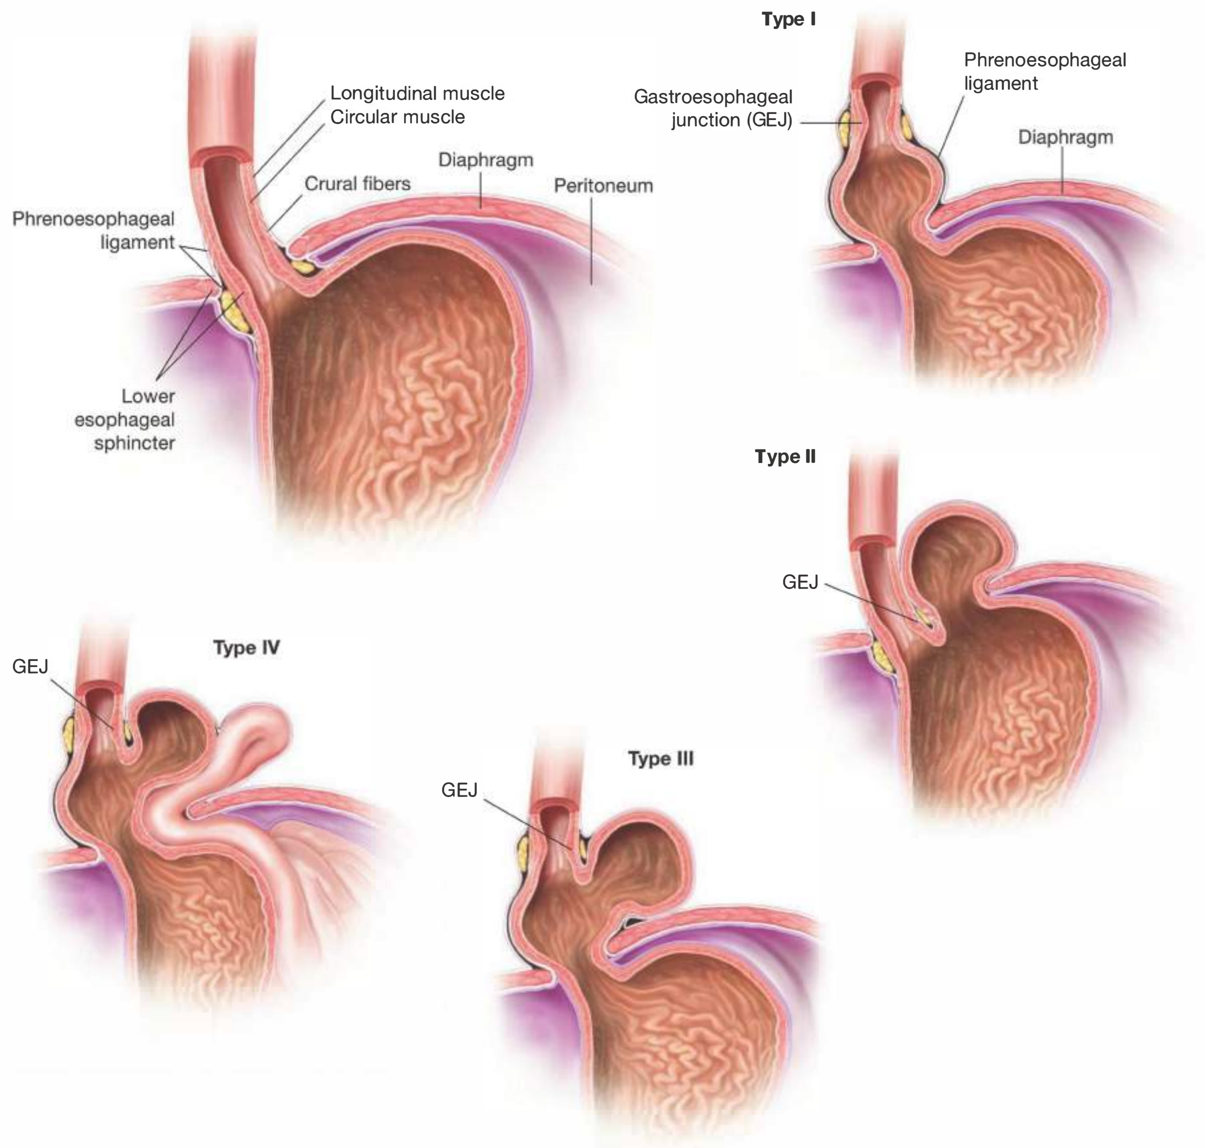

FIG 1 ● The four types of hiatal hernia: type I (sliding): GEJ translates linearly along esophageal axis cephalad into the mediastinum; type II (paraesophageal): GEJ resides intraabdominally with (usually) the gastric fundus or body translating cephalad past the GEJ; type III (combined): GEJ and gastric segments both translate above diaphragm; type IV (extragastric): small bowel, colon, spleen, and even pancreas may translate into the mediastinum and chest.

surgery to dissect and redo a previous fundoplication. In the setting of a negative pH study (by way of DeMeester score <15),[9] a "herniated" fundoplication may indeed be intact, thus saving the risk of tedious and unnecessary redo fundoplication as a component of the PEH repair.

SURGICAL MANAGEMENT

Preoperative Planning

- All studies, including esophagram, esophagogastroduodenoscopy (EGD), manometry, and pH testing should be readily available and reviewed prior to and at the time of surgery. The esophagram should be displayed on a spare or dedicated monitor in the operating theater and EGD images be loaded as well for intraoperative reference.
- Attention to fine detail of the manometric report may avoid an unnecessary and detrimental 360-degree fundoplication, as a complete wrap may worsen symptoms in the light of the following findings[8]:
  - Severe esophageal dysmotility
  - Very low residual postrelaxation LES pressures less than 30 mmHg during wet swallow

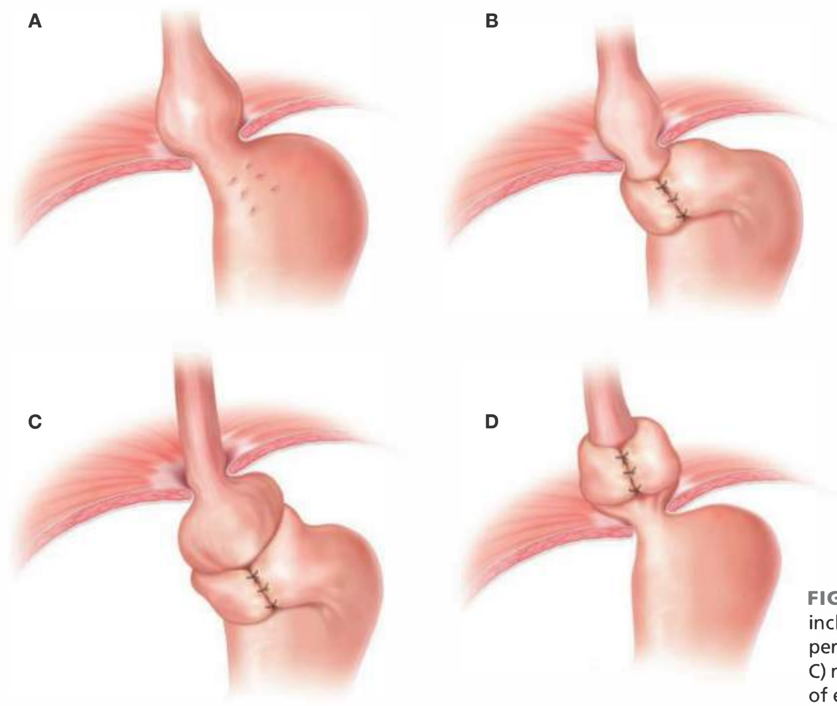

FIG 2 • Anatomy of fundoplication failure, including A) wrap dehiscence B) recurrent or persistent hiatal hernia with wrap slippage C) misplaced or slipped wrap, and D) herniation of entire wrap above the diaphragm.

Positioning

- An operating table capable of steep reverse Trendelenburg position is required. Arms are tucked at the patient's sides but can be out 90 degrees and secured. Footboards on a split-leg table are mandatory, and a preprocedural reverse Trendelenburg test is used for safety confirmation of positioning (**FIG 5A**).
- Assume extensive mediastinal dissection will be warranted, and therefore, pleural compromise is a frequent occurrence. The sterile skin preparation must be wide enough on either flank in case tube thoracostomies are necessary from resultant pneumothorax. However, a red rubber catheter between 10 and 14 Fr may be placed in a witnessed pleural defect intraabdominally, spanning the diaphragm to the hemithorax in question. This reduces the resultant pneumothorax and peak ventilatory pressures with the aid of lowering insufflation pressures as well as anesthesia-assisted ventilatory Valsalva.
- After Veress needle insufflation in either the supraumbilical or the left upper quadrant, trocar placement ensues. Five trocars are used for the laparoscopic PEH repair (**FIG 5B**). After the liver retractor and ports are placed, the patient is positioned into steep reverse Trendelenburg and the dissection begins.

Instrumentation

- As aforementioned, there can be up to a 20% enterotomy rate during PEH repair, especially during redo operations. Therefore, extraordinary care is tantamount to establishing safe dissection planes, especially near the esophagus. Ultrasonic shears are the mainstay of dissection (Harmonic Ace curved shears, Ethicon, Somerville, NJ), whereas when operating extremely close to organs, we advocate switching to laparoscopic scissors as well as blunt dissection to avoid thermal injury.

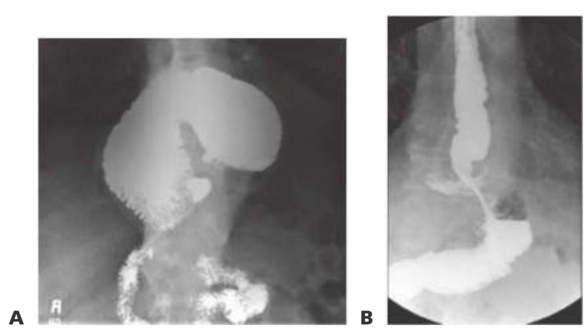

FIG 3 • **A,B.** Esophagram. **A.** Radiography demonstrating a large PEH with herniation of nearly the entire gastric lumen into the posterior mediastinum with mesoaxial volvulus. **B.** Slipped Nissen fundoplication with an intact wrap proximal to the diaphragm.

FIG 4 • CT of massive PEH type IV in which the entire transverse colon has herniated into the left hemithorax.

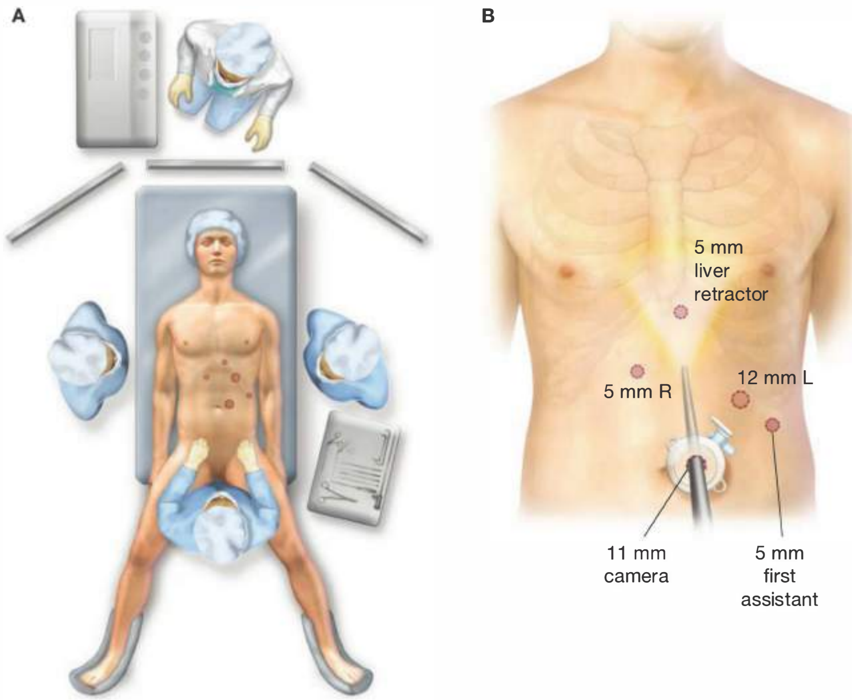

FIG 5 ● Patient positioning **(A)** and trocar placement **(B)**. After pneumoperitoneum is established, lines are drawn at the inferior edge of the costal margin diagonally up to an imaginary point above the xiphoid as a zero point for trocar placement. Five trocars are used for the laparoscopic PEH repair. (1) An 11-mm supraumbilical camera port, offset just to the left of the midline and 15 cm inferiorly. (2) A 12-mm left upper quadrant port, measured 12 cm along the parallel line to the left costal margin, for the surgeon's right hand. This port is placed 1 to 2 cm inferiorly to the 12-cm mark. (3) A 5-mm right upper quadrant trocar, measured 7 to 10 cm from the supraxiphoid point and 1 to 2 cm inferiorly, for the surgeon's left hand. This can be placed to the right of the falciform and then through the falciform. (4) An assistant's 5-mm left flank trocar is placed about a palm's width inferiorly and laterally from the 12-mm trocar. (5) Finally, a 5-mm port is placed and removed in the subxiphoid region for the Nathanson liver retractor. Similarly, a port can be placed at the right flank, symmetrically opposite from the assistant's port for a linear liver retractor, as supplies may vary per operating theater.

REDUCTION OF THE HERNIA

- To whatever extent possible, reduce the contents of the mediastinum previously back into the abdominal cavity by use of both the primary surgeon's hands as well as the assistant's with atraumatic graspers (**FIG 6**). Note that there may be various layers to the hiatal hernia sac (**FIG 7**).

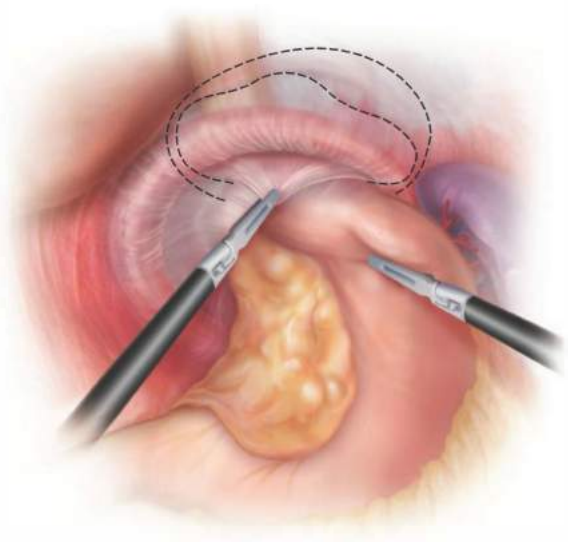

FIG 6 ● Reduction of major viscera with blunt retraction back into the abdomen. The *dotted lines* indicate the plane of dissection about the hernia sac.

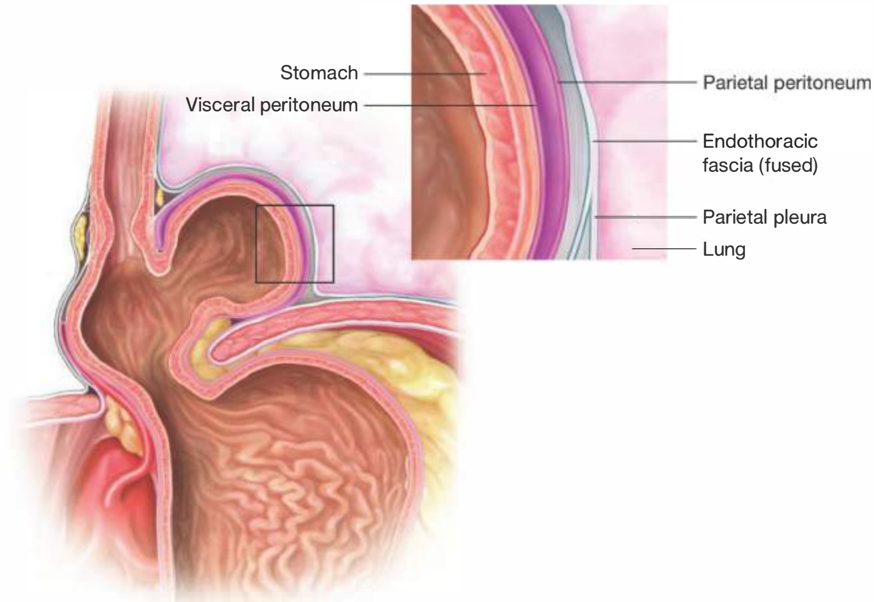

FIG 7 ● Layers of the PEH sac. Note the interface between the visceral peritoneum and endothoracic fascia (sometimes fused to parietal pleura) should be the plane to establish during dissection.

INITIAL HIATAL DISSECTION

- It is usually safe, once countertraction is well established and reduction of the entire PEH is attained, to initiate dissection on the right crus directly to the right of the esophagus, providing a starting point for anterior and posterior dissection. Anterior dissection occurs in a 180-degree fashion anteriorly and then to the left of the hiatus, just in a plane immediately deep to the peritoneum/hernia sac; any deeper and thermal injury or perforation might happen to the esophagus. If the hernia cannot be completely reduced intraabdominally, then we advocate an approach from the left crus, anteriorly 180 degrees to the right crus (**FIG 8A,B**),

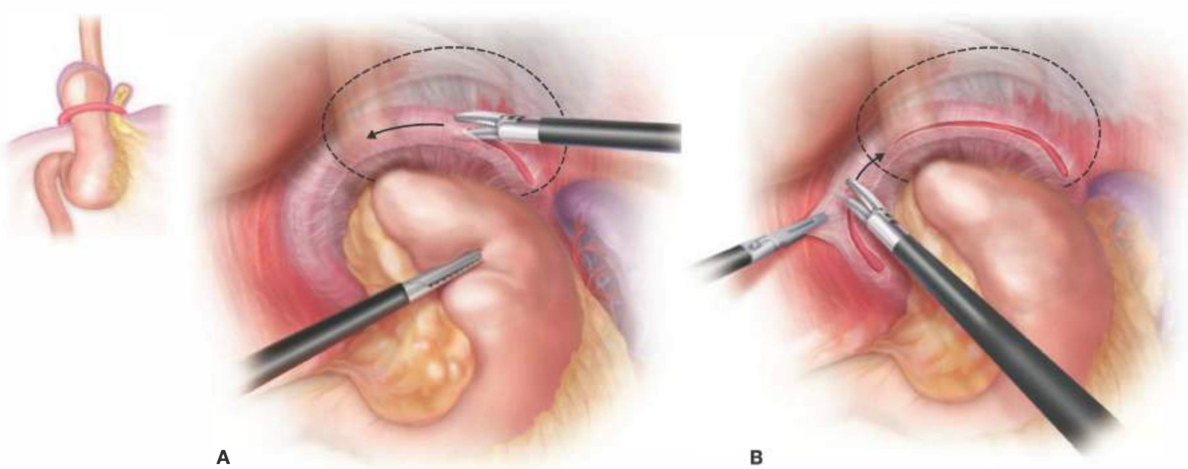

FIG 8 ● **A,B.** Dissection from left to right, anteriorly, starting on the left crus. Ultrasonic dissection takes place directly on the edge of the diaphragm at all times. Countertraction must be kept to prevent retraction of the hernia sac into the mediastinum.

reasoning that the position of the unreduced PEH and true dissection plane on the left can be more readily ascertained. The resultant anterior dissection can be seen in **FIG 9**.

- Posterior dissection ensues from the original starting point to the right of the esophagus to free the right crus posteriorly and deep, then as much as possible, to the left of the GEJ.

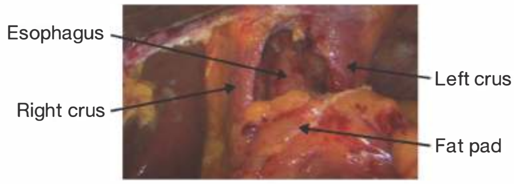

FIG 9 ● Resultant anterior 180-degree dissection.

SHORT GASTRIC VESSEL LIGATION

- Before complete 360-degree dissection can take place, the short gastric vessels must be completely dissected, even if a previous procedure supposedly took place, as some surgeons selectively or incompletely perform short gastric takedown (**FIG 10A–C**). This should be performed on the slow setting of the ultrasonic shears, as premature ligation might allow incompletely ligated vessels to retract into the gastrosplenic ligament uncontrollably. Although endoscopic surgical clips may help, it is more efficacious to regrasp the bleeding ligament and vessels for ultrasonic ligation. Occasionally, depending on the surgeon's skill, an open procedure is necessitated.

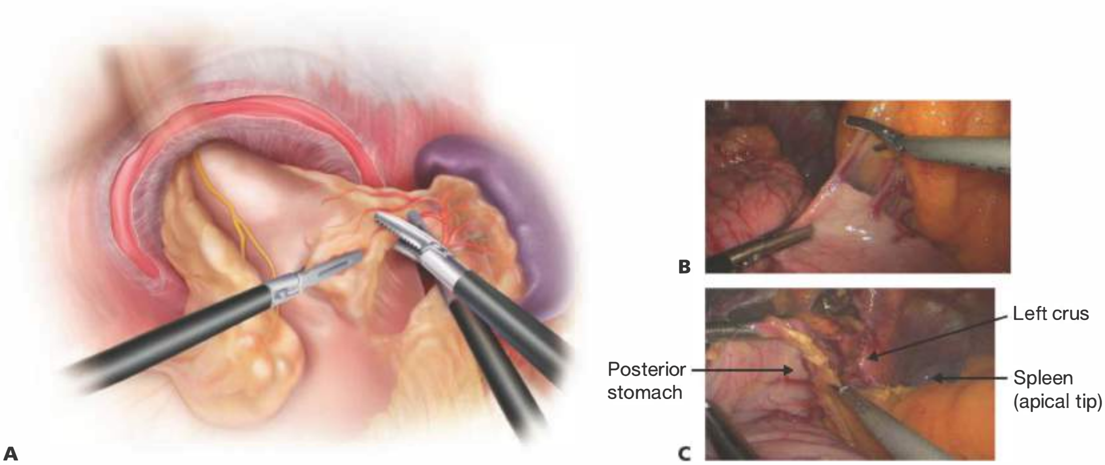

FIG 10 ● **A–C.** Short gastric vessel ligation. **A,B.** Initial dissection begins at a level parallel to the distal splenic tip. **C.** Completion of the short gastric ligation. Note the exposure of the posterior stomach to complete this step.

POSTERIOR GASTRIC ATTACHMENTS

- To complete the circular dissection, the surgeon's left hand and assistant splay the stomach to the anteromedial direction and omentum to the left. This reveals attachments posteriorly from the splenic vessels to the left gastroepiploic vessels. These can be taken also with ultrasonic dissection. After reduction of the posterior sac (**FIG 11**), this completes the 360-degree mobilization (**FIG 12**). A Penrose drain can encircle the GEJ for atraumatic retraction.

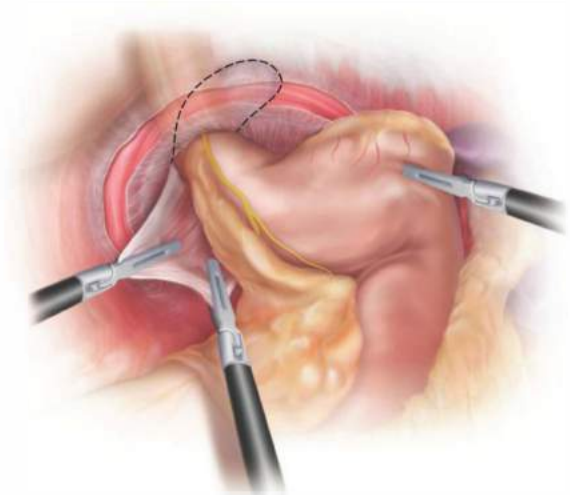

FIG 11 ● Reduction of the posterior sac.

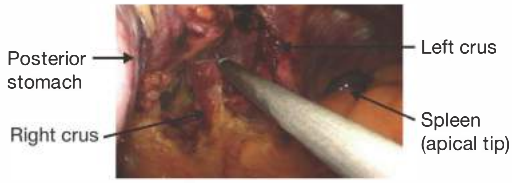

FIG 12 ● Completion of 360-degree dissection.

HERNIA SAC EXCISION

- If properly performed, the hernia sac can be removed en bloc by evidence of the mediastinal component of the hernia sac being contiguous with that of the anterior esophagus and fat pad (**FIG 13A,B**), which may also need excision in order to properly perform the antireflux portion of the operation.
- If the hernia sac is large and will obstruct mediastinal dissection, excision of the sac is warranted. Start on the left crus with traction on the hernia sac and use combinations of blunt dissection when near the esophageal body and ultrasonic dissection to remove the hernia sac when at a safer distance. Manipulation of tissues too far away from the esophagus may compromise the pleural cavity and manipulation too close to the esophagus may incur thermal injury, often unrecognized at time of operation. **FIG 14** demonstrates a close, but safe, distance of dissection to the esophagus.

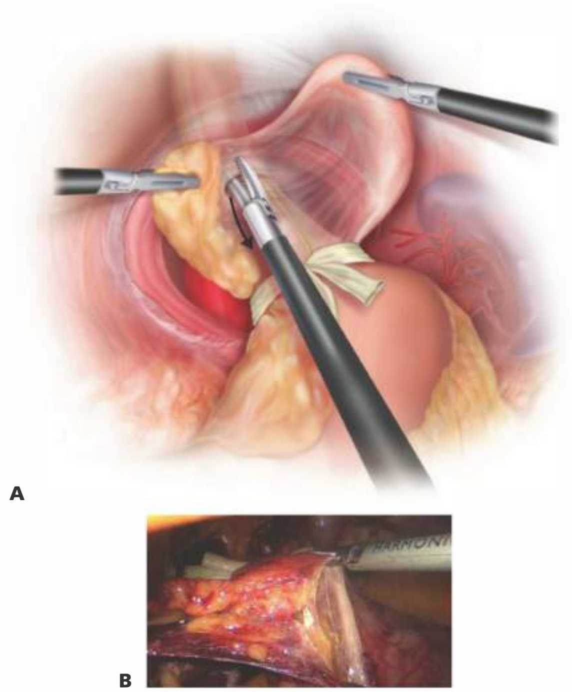

FIG 13 ● **A,B.** Excision of the hernia sac off the anterior esophagus. The sac is placed under countertraction and bivalved just to the left of the vagus nerve.

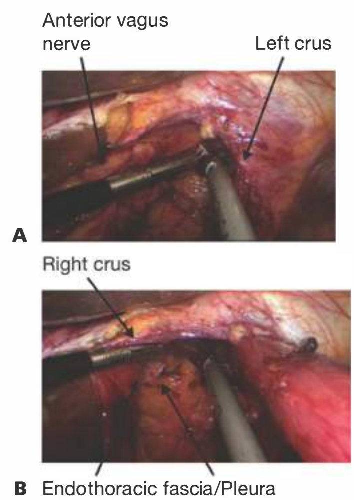

FIG 14 ● **A,B.** Demonstration of proper range of proximity to the esophagus during ultrasonic dissection. **A.** View from left, near esophagus. **B.** View from right, approaching endothoracic fascia and pleura.

FUNDOPLICATION TAKEDOWN

- If there exists a previous fundoplication and preoperative testing demonstrates incompetence of the antireflux procedure, the wrap is mandated to be taken down and redone.
- Extreme care should be implemented as this is the step that carries the most risk of enterotomy either at the stomach or at the esophagus. Once completely dissected, inspection and reinspection of the taken down wrap should take place. Often, the gastric lumen may resemble the shiny planes between the fundus and esophageal body.

MEDIASTINAL DISSECTION

- Adequate mediastinal dissection for esophageal length is encountered when the endothoracic fascia/pleura is placed laterally, and the mediastinal esophagus is visualized in a 360-degree fashion up to the level of the carina or right atrium (FIG 15).

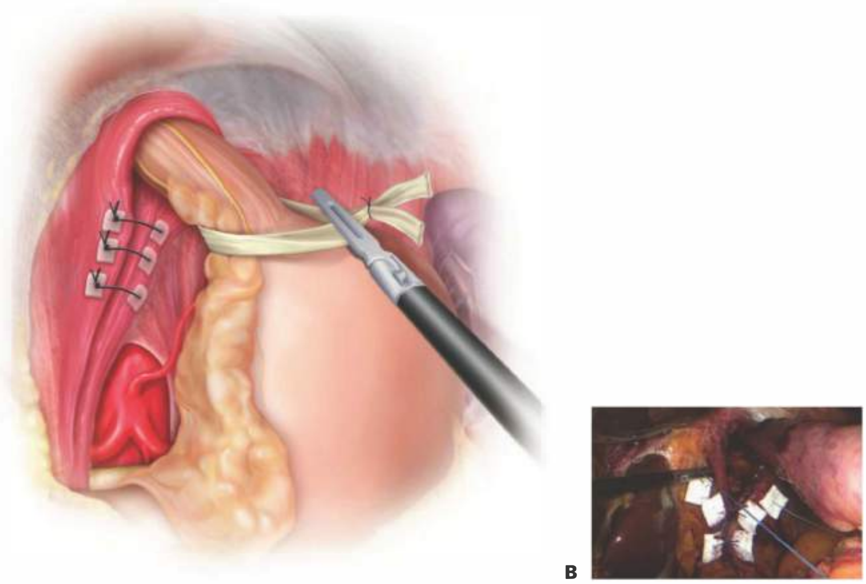
FIG 15 ● Adequate mediastinal dissection as evidenced by 360-degree encirclement of the esophagus up to the level of the carina superiorly, endothoracic fascia/pleura bilaterally, and aorta posteriorly.

ASSESSMENT OF INTRAABDOMINAL ESOPHAGEAL LENGTH

- The left crus is now pulled from left to right, and without any bougie or orogastric tube in place, the intraabdominal esophageal length can be assessed in a relaxed position. If the length is shorter than 2.5 to 3 cm, perform a Collis gastroplasty (see Part 1, Chapter 20).

CRURAL CLOSURE

- Over a 42-Fr bougie, the hiatus is sutured with the appropriate number of coated, braided nonabsorbable suture (0 Ti-Cron, Covidien, Mansfield, MA). Spacing of sutures is approximately 1 cm apart from each other and is placed 1 cm back from the crural edges (FIG 16A,B).
- Pledgets are used on the sutures with the exception of the last sutures needed to avoid pledget ingrowth into the esophagus.
- The quantity of sutures usually numbers two to four, until there is a gap left between the esophagus and crura to easily interpose laparoscopic graspers between the closure.
- If the esophageal hiatus is gigantic, then anterior, in addition to posterior, crural closure can be safely performed to prevent severe angulation of the esophagus at the newly reconstructed hiatus.



A B

FIG 16 ● **A,B.** Crural closure with 0 Ti-Cron pledgeted sutures with 1-cm spacing, both from each suture and from the left and right crural edges. Depending on proximity to the esophagus, the last suture may be unpledgeted to avoid erosion.

TECHNIQUES

MESH PLACEMENT

- If mesh is to be used, two main strategies exist, and both may be affixed by Ti-Cron suture (see "Pearls and Pitfalls"):
  - Keyhole (three-sided) mesh can be sutured or glued to the diaphragm (**FIG 17A**).
- Rectangular mesh is secured along the diaphragm posteriorly (**FIG 17B**).

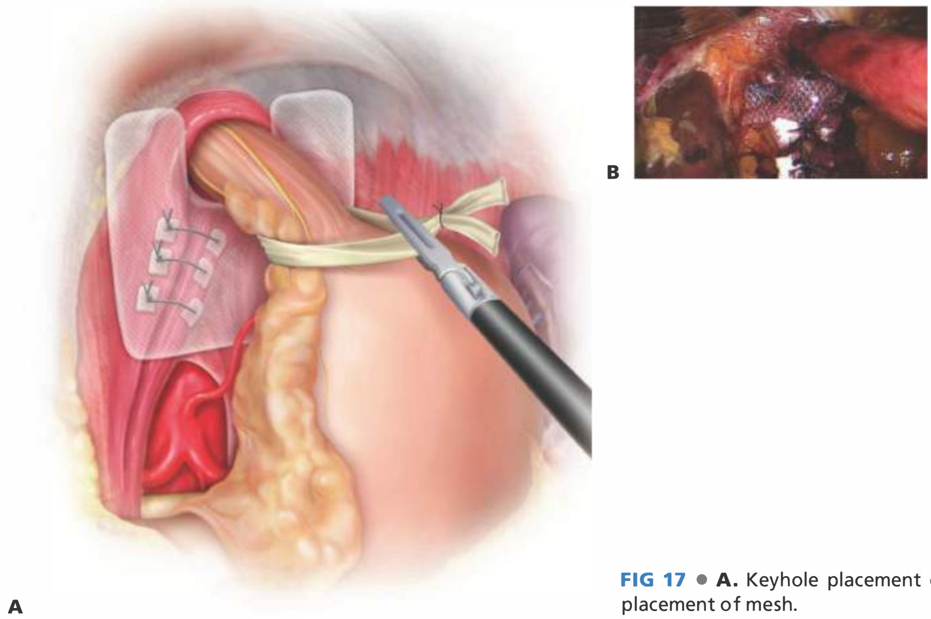


FIG 17 ● **A.** Keyhole placement of mesh. **B.** Rectangular placement of mesh.

ANTIREFLUX PROCEDURE

- The principles of fundoplication apply here, whether a complete (Nissen) (**FIG 18A,B**) or partial (Toupet) wrap is indicated. This completes the goal of reconstructing the angle of His and valvular mechanism of the LES. Refer to the corresponding chapters accordingly.

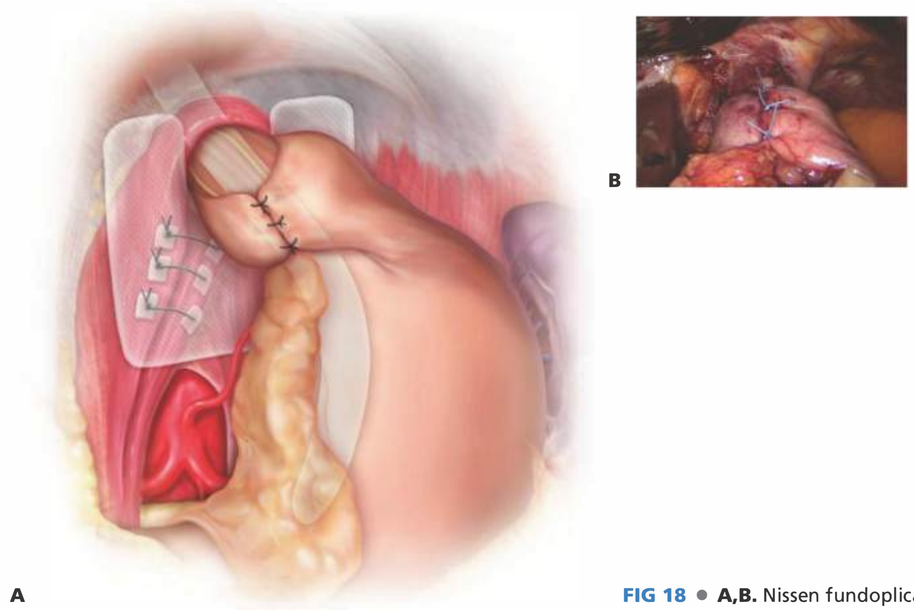

FIG 18 ● **A,B.** Nissen fundoplication.

LEAK TEST

- Two leak tests can be performed.
  - Methylene blue: With dilute methylene blue dripped liberally into a nasogastric tube with the tip above the GEJ, intracorporeal placement of two radiopaque white sponges can detect subtle leaks. Inspect the removed sponges against a white background and back-table light. Any positive test is mandated to be investigated thoroughly with the tear or enterotomy repaired.
  - Bubble leak test (alternative to methylene blue): With the placement of an endoscope and Trendelenburg positioning, irrigate sterile saline intracorporeally and distend the stomach and lower esophagus with insufflation. Any bubbles emanating mandates investigation.

UPPER ENDOSCOPY

- The last portion of the procedure entails direct visualization with an upper endoscope to see the position of the Z line, GEJ, and integrity of the wrap. With retroflexion, the endoscope should move back and forth freely without buckling of the mucosa of the newly reconstructed LES.

PEARLS AND PITFALLS

Enterotomy	■ It is well established that the PEH repair carries up to a 20% risk of enterotomy along the esophagus or stomach, especially in redo operations. If an enterotomy is noticed, for example, during dissection of a slipped Nissen fundoplication, a linear staple firing is warranted across the enterotomy.
Deep hernia sac dissection	■ There is a fine line between removing the hernia sac and perforating or causing thermal injury to the esophagus and/or vagal nerves. With proper superficial dissection at the outset of hiatal dissection allows the surgeon to stay above the esophagus and allows the hernia sac to be excised en bloc.
Pneumothorax	■ Prepare into the field the bilateral lower chest cavities that would access each hemithorax in case a percutaneous tube thoracostomy is needed. Our first recommendation, however, if peak ventilatory pressures are high from a pneumothorax, is to decompress the affected side with the placement of a red rubber catheter through a working 12-mm port and lay it from the hemithorax in question with the opposite end intraabdominally. The lower chest wall should be prepped into the field in case chest tube placement is needed. However, when a pneumothorax is identified, a 14 French red rubber catheter can be placed through the hole with the tip in the chest and the butt in the abdomen. At the completion of the procedure the butt is pulled out a trocar site and is placed in a tub of water (water seal) while the anesthesiologist reinflates the lung with positive pressure ventilations. When the bubbling stops the tube is pulled out the trocar site. A chest x ray in the recovery room confirms re-expansion of the lung.
Inadequate antireflux procedure	■ If redo fundoplication is being performed, it is imperative to obtain preoperative manometry to test the integrity of a "slipped" Nissen versus a simple herniation. If manometry indicates reflux above the wrap, the previous fundoplication should be completely dissected and redone.
Short gastric vessel ligation	■ Do not assume during a redo operation that the previous surgeon has performed adequate short gastric dissection. This tethers the fundoplication, therefore placing improper physiologic vectors on the wrap. Dissect completely the short gastric vessels to avoid tethering.
Intraabdominal esophageal length	■ Inadequate mediastinal dissection results in incomplete abdominal length of the esophagus. Complete and high 360-degree mediastinal dissection allows the true determination if an esophageal lengthening procedure (Collis) is required when performing the antireflux portion of the operation.
Mesh use and material	■ Several studies have investigated the controversy to use or not to use mesh, but no standardization in practice exists due to the many types of mesh material available, shapes into which it is fashioned, and length of study investigated.[10–13] The efficacy of mesh to reinforce the closed crura tapers over time, although the degree of this degeneration is a moving target in the literature. The material choice is widely subject to debate with longer term studies showing no effect on recurrence with small intestine submucosa (Surgisis, Cook Medical, Bloomington, IN), while shorter term studies with human acellular dermal matrix (AlloDerm, LifeCell Corporation, Bridgewater, NJ). Studies ongoing currently involve bioabsorbable woven suture (BIO-A, W. L. Gore & Associates, Inc, Flagstaff, AZ) and porcine acellular dermal matrix (AlloDerm, LifeCell Corporation, Bridgewater, NJ). We currently espouse the use of a rectangular, lightweight, polypropylene, synthetic mesh with four fixation points along the crura (Parietex, Covidien, Inc, Mansfield, MA).
Mesh erosion	■ To avoid mesh erosion, do not place a circular piece of mesh around the closed crura. Keyhole or U-shaped mesh is acceptable with the open end facing anteriorly. Also, a rectangular mesh can be used instead of the U shape with placement from left to right along the closed crura. Care with suture fixation to not place the mesh in contact with the esophagus can alleviate mesh ingrowth and perforation of that organ.

POSTOPERATIVE CARE

- There are two main strata of postoperative care given to patients who undergo PEH repair: with significant adhesiolysis and without significant adhesiolysis.
- Without significant adhesiolysis: For those undergoing their first repair, the dissection can be as simple as an "easy" type I or sliding hiatal hernia. Therefore, if adhesiolysis is simple and straightforward, we elect to give the patients sips of clear liquids immediately postoperatively and advance to full liquids by postoperative day (POD) 1, with discharge for 4 weeks on a proton pump inhibitor. We do not advocate for same day discharge. Home medications should be in liquid or crushable form, and patients are prescribed antinausea, analgesia, and bowel regimen medications. Diet consists of full liquids for 2 weeks then soft mechanical for another 2 weeks.
- With significant adhesiolysis: Redo antireflux disease and technically challenging PEH repairs are usually the mainstay of such operations. The risk of perforation, missed or noticed at the time of surgery, is increased, and therefore, these patients follow a different postoperative pathway. They are kept *nihil per os* (NPO) overnight and studied with a formal esophagram in fluoroscopy, regardless of the ultimate outcome of our intraoperative leak test. If the radiologic exam is negative on the morning of POD 1, the patient's diet is advanced per earlier mentioned protocol with discharge anticipated for POD 2 and the earlier mentioned medication routine. Although it is acceptable to discharge a healthy, good candidate on POD 1, the majority of our patients leave on POD 2 and so forth, depending on medical comorbidities.

OUTCOMES

- Results depend on the nature of the disease process for which an operation is indicated and the number of components of the operation used.
- PEH repair: Mori et al.[6] refer to eight studies that had a mean or median follow-up of 6 to 40 months with a range of 2% to 43% recurrence. Andujar et al.[14] describe laparoscopic PEH repairs being associated with a low incidence of recurrence and reoperation in a series of 166 patients. Improvement was seen in heartburn, regurgitation, dysphagia, and chest pain with an overall 6% reoperation rate for symptomatic PEH (1.2%), reflux (2.4%), and dysphagia (2.4%). With the exception of fundoplication wrap failure in which all required reoperation, one-third of recurrences required surgery, whereas one-tenth of sliding hiatal hernias required surgery; so overall, the reoperation rate is quite low.
- Redo antireflux procedures: In a series of 124 patients, four major failure mechanisms were noticed by Ohnmacht et al.[15]: recurrent hiatal hernia (65%), disrupted fundoplication (32%), perigastric fundoplication (14.5%), and tight fundoplication and hiatal closure (10%).
- Use of mesh: A sentinel series by Oelschlager et al. of patients undergoing crural repair with small intestine submucosa (Surgisis, Cook Medical, Bloomington, IN) mesh initially showed promising data for decreased PEH recurrence rate at 6 months (9% Surgisis, 24% primary repair),[10] but the same group demonstrated that long-term follow-up at a median of 58 months showed no statistical difference (54% Surgisis, 59% primary repair).[11] Notwithstanding shape and material (bioprosthetic vs. synthetic) of mesh used, these studies may be updated in years to come with the use of bioabsorbable mesh, acellular dermal matrix, and various types of synthetic mesh. Ringley et al.[12] reported the use of acellular dermal matrix (AlloDerm, LifeCell Corporation, Bridgewater, NJ) with an initial 6-month follow-up without recurrence versus primary closure involving 9% recurrence. We do not advocate, therefore, prohibiting the use of mesh in PEH repair at this time.
- Choice of antireflux operation: A prospective, randomized trial by Koch et al.[16] of 50 patients in each arm of Nissen versus Toupet fundoplication demonstrated that Nissen procedures favored improvement in hoarseness and showed significant improvement in outcomes manometrically and via multichannel impedance imaging, whereas the Toupet fundoplication was favored by lower dysphagia, inability to belch, and bowel symptoms. Nonetheless, both procedures improved gastrointestinal quality of life indices, GERD symptoms, reconstructed LES pressures, cough and asthma symptoms.

COMPLICATIONS

- PEH recurrence
- Mesh erosion
- Dysphagia
- Esophageal stricture
- Gas bloat syndrome
- Recurrent GERD
- Slipped antireflux procedure

Chapter 20

Collis Gastroplasty

John G. Hunter Mark J. Eichler

DEFINITION

- Encountering a foreshortened esophagus during surgery at the hiatus, a lengthening procedure is necessary for adequate distal abdominal esophageal length for an antireflux procedure. First described in *Thorax* by John Leigh Collis in 1957 for patients with a short esophagus and hiatal hernia, with or without reflux, a gastroplasty is performed via a thoracotomy on the left aspect of the herniated proximal stomach.[1] This technique has subsequently evolved through thoracoscopic and laparoscopic means for hiatal hernia repairs as well as reflux disease in order to lengthen the abdominal portion of the esophagus for an adequate axial distance around which to perform gastric fundoplication. The Collis gastroplasty commonly involves a laparoscopic stapling technique about the gastroesophageal junction (GEJ) by removing a wedge of stomach at the angle of His, thereby lengthening the effective distal esophageal dimension intraabdominally, about which a fundoplication can be wrapped.[2]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Secondary to chronic acid inflammation and subsequent fibrotic remodeling of the distal esophagus, approximately 10% to 25% of patients with reflux have a shortened esophagus.[3,4] The majority of these patients, however, do not need an esophageal lengthening procedure for a tension-free fundoplication if adequate mediastinal dissection gains return of abdominal esophageal length.[5] Sufficient intraabdominal length can be evidenced by the GEJ lying intraabdominally with a distance between the diaphragmatic hiatus and the GEJ of *at least 2.5 cm*. It is at this threshold of 2.5 cm (approximately the length of a fully opened atraumatic laparoscopic grasper) after adequate mediastinal and crural dissection should the decision to perform a Collis gastroplasty take place,[3] with an overall incidence of implementation of 3% to 4% of reflux operations.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The preoperative workup for reflux disease spans endoscopy (esophagogastroduodenoscopy [EGD]), esophagography (upper gastrointestinal contrast swallow or esophagram), manometry, and pH probe testing. However, there is no gold-standard radiologic imaging study for preoperative preparation in reflux disease, as the surgical decision making to perform a Collis gastroplasty is done ultimately intraoperatively. Yet, esophagography and endoscopy may be the optimal studies to demonstrate a foreshortened esophagus by the following signs[6]:
  - Hiatal hernia of 5 cm or more
  - Giant type III paraesophageal hernia (**FIG 1**)
  - Esophagitis, Barrett's changes, and/or stricture

SURGICAL MANAGEMENT

Preoperative Planning

- Because the Collis gastroplasty is an adjunctive procedure during gastric fundoplication, the principles of a proper antireflux procedure (wrap) or gastropexy apply, including left and right crural exposure, adequate mediastinal dissection, atraumatic esophageal retraction, and division of the short gastric vessels. Please refer to Part 1, Chapters 19 and 22 for further details.
- All studies, including esophagram, EGD, manometry, and pH testing should be readily available and reviewed prior to and at the time of surgery. The esophagram should be displayed on a spare or dedicated monitor in the operating theater and EGD images be loaded as well for intraoperative reference.
- Attention to fine detail of the manometric report may avoid an unnecessary and detrimental 360-degree fundoplication, as a complete wrap may worsen symptoms in the light of the following findings[7]:
  - Severe esophageal dysmotility
  - Very low residual postrelaxation lower esophageal sphincter (LES) pressures less than 30 mmHg during wet swallow

Positioning

- Although there are many port placement techniques, the stapled Collis gastroplasty necessitates a left upper quadrant, endoscopic, angulating stapler by the surgeon's right hand through a 12-mm trocar. Steep reverse Trendelenburg is the position of choice (**FIG 2**).

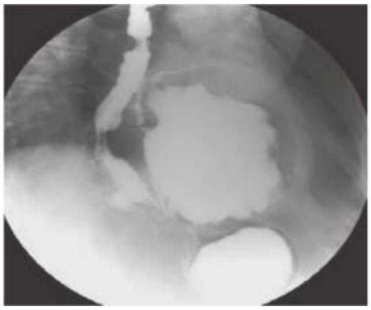

FIG 1 ● Esophagram demonstrating tortuous esophagus with shortening, distal narrowing or strictures, and a type III paraesophageal hiatal hernia.

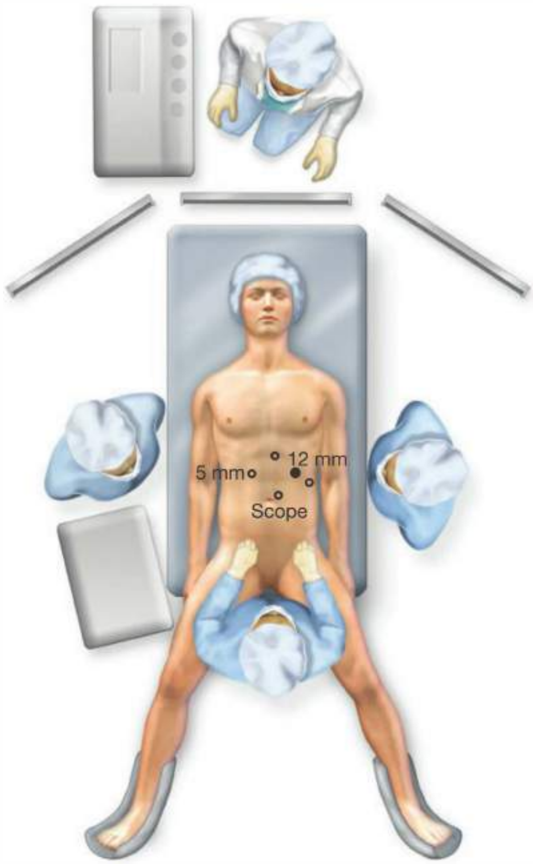

FIG 2 ● Patient positioning for foregut and antireflux procedures and trocar placement. The left upper quadrant 12-mm port is used for the angulated stapler in the surgeon's right hand.

- Assume extensive mediastinal dissection will be warranted, and therefore, risk of pleural compromise (FIG 3). The sterile skin preparation must be wide enough on either flank in case tube thoracostomies are necessary from resultant pneumothorax. However, a red rubber catheter between 10 and 14 Fr may be placed in a witnessed pleural defect intraabdominally spanning the diaphragm to the hemithorax in question. This reduces the resultant pneumothorax and peak ventilatory pressures with the aid of lowering insufflation pressures as well as anesthesia-assisted ventilatory Valsalva.

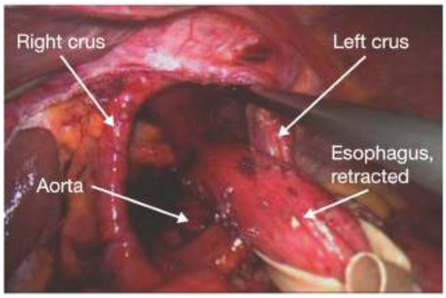

FIG 3 ● Demonstration of adequate dissection of the mediastinum with clear visibility of the left and right crura, aorta posteriorly, and proximal length achieved of the distal esophagus.

MEASUREMENT OF GASTROPLASTY

- As mentioned in the "Positioning" section, this is an adjunctive maneuver, and thus, as previously described, adequate mediastinal, hiatal, and perigastric dissection should have already taken place.
- Dissect the fat pad from the GEJ to expose the trajectories of stapler firing (FIG 4).
- Remove any orogastric, nasogastric, or bougie first to recreate the nascent relaxed anatomy of the GEJ. From a posterior gastric approach, pull the left crus to the right, approximating it with the right crus. This demonstrates the relaxed position of the crura upon closure of the hiatus.

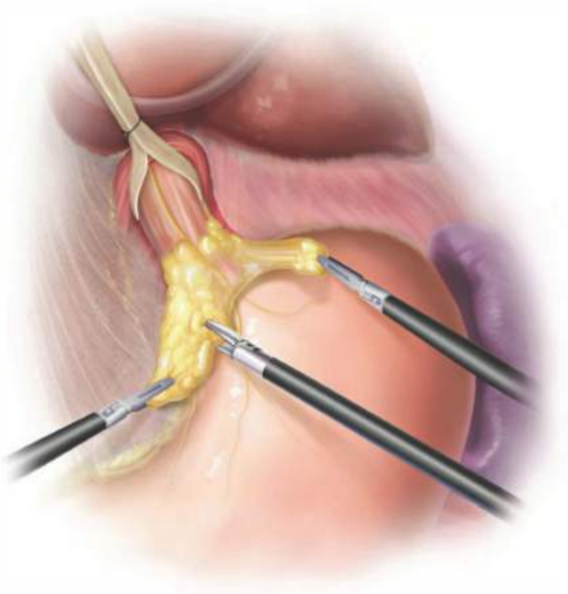

FIG 4 ● GEJ fat pad dissection. The fat pad is elevated with an atraumatic grasper by the first assistant while the surgeon, with his left hand, defines the gastric wall, thus providing countertraction.

- With an open, premeasured grasper, the intraabdominal length for the gastroplasty is then estimated (**FIG 5**). A distance from the anterior hiatus to the GEJ of less than 2.5 to 3 cm warrants the Collis gastroplasty. Measure from the relaxed hiatus 3 cm distally along a trajectory past the GEJ, if a bougie were inserted endoluminally, and 1 cm laterally. Here, mark with electrocautery the placement of the first perpendicular staple firing.

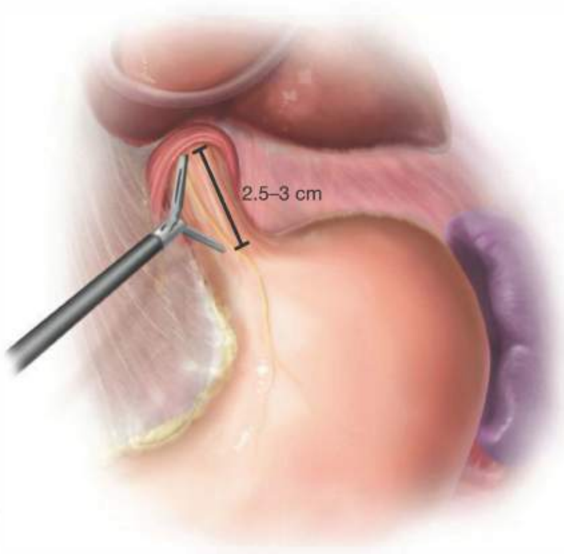

FIG 5 ● Measurement of intraabdominal length of esophagus. With a closed crura, the minimum distance between the GEJ and the diaphragm should be at least 2.5 cm, or the approximate length of an opened atraumatic grasper.

INTRAABDOMINAL RETRACTION AND BOUGIE PLACEMENT

- A 48-Fr dilator is placed transorally up to 55 cm from the incisors (**FIG 6**). This serves as the stent about which the Collis gastroplasty is performed. The surgeon's left hand retracts the cardia toward the patient's left shoulder while the assistant retracts the greater curve laterally to the left flank.

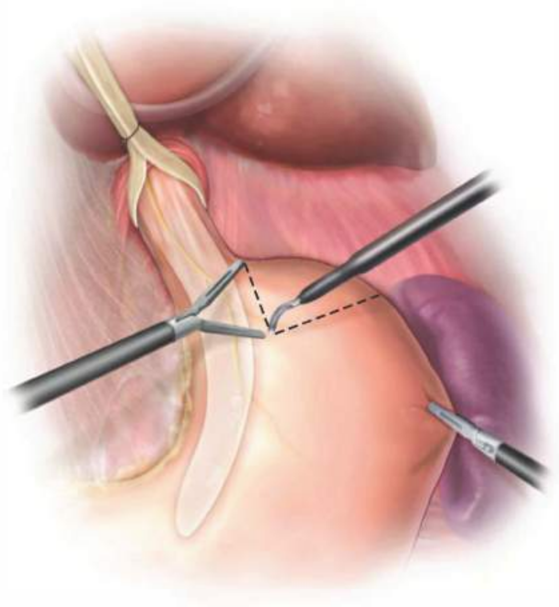

FIG 6 ● Marking of Collis gastroplasty. With a 48-Fr dilator in place and Penrose drain released, measure 2.5 to 3 cm distal to the closed diaphragm from the angle of His and then due left laterally.

FIRST STAPLE TRAJECTORY

- The first stapled trajectory is usually performed with one or two firings of a rotating and articulating endoscopic stapler with medium-sized loads (3 to 4 mm) using a 45-mm length Endo GIA purple load (Covidien, Mansfield, MA). With the endoscopic stapler articulated to the maximum degree in the surgeon's right hand, a 90-degree stapling is performed up to the body of the dilator on the left side of the patient just distal to the point predetermined and marked with electrocautery (**FIG 7A–C**).

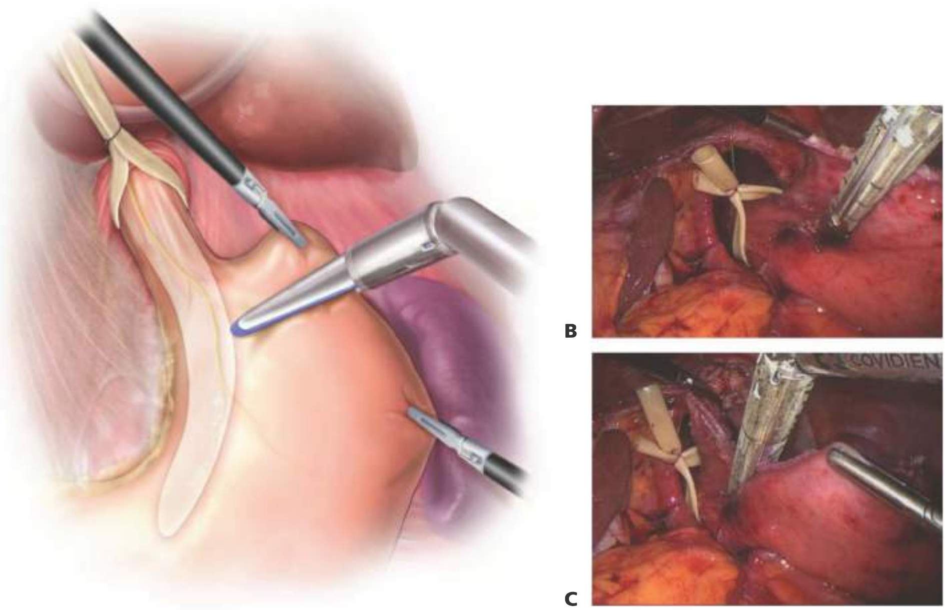

FIG 7 ● **A.** First staple trajectory. **B.** Maximal articulation of the stapler to the surgeon's left, aiming toward the previously marked spot adjacent to the dilator. This may take one or two firings to approximate the staple line so it abuts the inserted dilator **(C)**.

SECOND STAPLE TRAJECTORY

- The second stapled trajectory is parallel to the dilator and cephalad (**FIG 8A,B**). Again, one or two medium-sized staple loads might be needed. Be careful to not include the Penrose drain in the staple line; it may be placed into the mediastinum temporarily during the second set of staple firings. The proper Collis gastroplasty juxtaposes the resultant parallel staple line abutting the esophagus (**FIG 8C**).

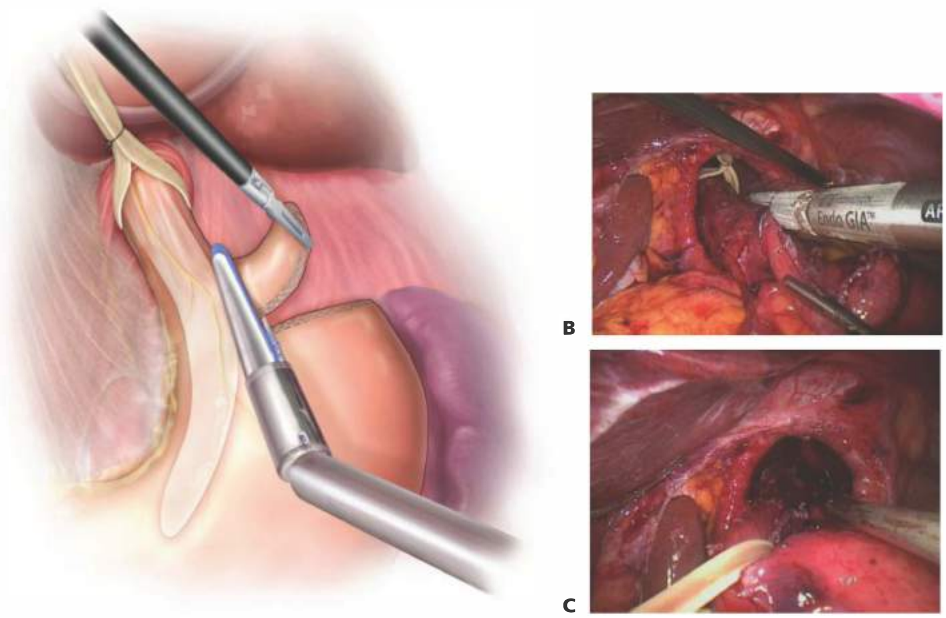

FIG 8 ● **A.** Second staple trajectory. **B.** The vertical staple line is created by firing the gastrointestinal anastomosis (GIA) stapler parallel and flush against the upward dilator to create a tight tube. **C.** The resultant gastric staple line abuts the esophagus.

TECHNIQUES

REMOVAL OF THE STOMACH WEDGE

- Remove the wedge of stomach through any means, whether directly through the trocar, via an endoscopic bag, or by removing the entire trocar. This concludes the Collis gastroplasty portion of the procedure.

COMPLETION OF THE FUNDOPLICATION

- Perform the intended complete or partial wrap as described in other chapters, along with crural closure. Whether a complete (Nissen; 360 degrees) or partial (Toupet; 270 degrees) fundoplication is performed (**FIG 9**), the stapled wedge Collis gastroplasty should eventually orient the staple line posteriorly as assessed on EGD.

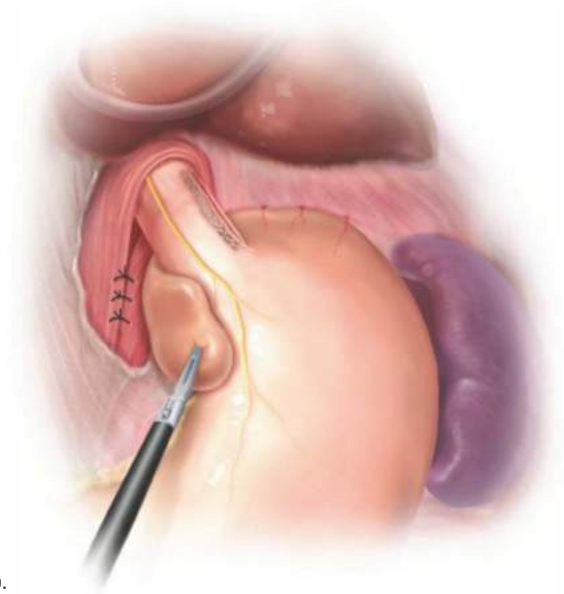

FIG 9 ● Completion of the antireflux procedure (fundoplication).

PEARLS AND PITFALLS

Inadequate first staple firing	■ It is sometimes disconcerting to staple onto an endoluminal foreign body (dilator), but it is virtually impossible to staple across a 48-Fr dilator. Failure to staple up to and abutting the dilator will result in a floppy distal esophagus and decrease the efficacy of the fundoplication.
Use of short staple loads for first staple firing	■ The region of the esophageal hiatus is tight quarters. The articulating stapler of 45 mm is preferred over a longer stapler because of the steep angulation needed in these tight spaces. Multiple firings may be needed.
Mismeasure of intraabdominal length	■ Key to the measurement of true intraabdominal length is the natural lay of the esophagus in the steep reverse Trendelenburg position. Do not insert a dilator, nasogastric, or orogastric tube during this step. Remember to close the crura manually and assess the lay of the esophagus before measuring this length.
Inadequate mediastinal dissection	■ Inadequate mediastinal dissection results in incomplete abdominal length of the esophagus. Hence, the use of a Collis gastroplasty, and therefore risk of staple line leak, can be avoided with intraoperative diligence.
Pneumothorax	■ Prep into the field the bilateral lower chest cavities that would access each hemithorax in case a percutaneous tube thoracostomy is needed. Our first recommendation, however, if peak ventilatory pressures are high from a pneumothorax, is to decompress the affected side with the placement of a red rubber catheter through a working 12-mm port and lay it from the hemithorax in question with the opposite end intraabdominally. The anesthesiologist can assist with manual bagging Valsalva maneuvers. If this step is refractory, place the tip of the red rubber catheter intrathoracically and pull the end through a trocar port into a bowl of sterile saline, desufflate the abdomen, and again, ask the anesthesiologist to assist with Valsalva.
Left lateral wedge	■ Upon full dissection, the wedge removed should lie on the left lateral aspect along the GEJ, that is, the angle of His, in a plane parallel to the operating table.

POSTOPERATIVE CARE

- Nasogastric tube decompression is not routine. Even if injury or perforation occurs to the stomach during dissection, as long as the tissue is repaired properly and a resultant negative intraoperative leak test (methylene blue infusion through the intraoperative orogastric tube or EGD air insufflation in pooled intracorporeal saline in Trendelenburg position) occurs, nasogastric decompression is not a necessity.
- With extensive mediastinal dissection and stapled gastroplasty, the risk of (missed) perforation and leak should be assessed. Strict *nil per os* (NPO) status overnight, followed by a postoperative day (POD) 1 water-soluble contrast esophagram is performed to assess leak as well as functional clearance of contrast material. If negative, the patient is advanced to a clear liquid diet on POD 1 and discharged on either the eve of POD 1 or on POD 2 with a full liquid or pureed diet.
- Acid suppression therapy is warranted as the gastroplasty involved gastric mucosa in the region of the newly reconstructed GEJ.

OUTCOMES

- The use of the Collis gastroplasty is usually relegated to the foreshortened esophagus during antireflux surgery, with etiology including large type III paraesophageal hernias and acid-related strictures. This procedure has historically evolved, especially with the advent of laparoscopy. The outcomes of the procedure are difficult to quantify in terms of efficacy because the procedure is often combined with fundoplication (partial and complete) and/or hiatal hernia repair (types I to IV). In general, in experienced hands, the rate of recurrence of hernia, postoperative leak rate, and stricture are low[8,9] and can be quantified as low as 0% in 4-year follow-up to low double-digit percentages in longer studies.

COMPLICATIONS

- Recurrent hiatal hernia
- "Slipped" Nissen
- Postoperative staple line leak
- Leak from extensive mediastinal dissection
- Esophageal stricture

Chapter 21

Transthoracic Hiatal Hernia Repair

Jules Lin Mark Orringer

DEFINITION

- The combined Collis-Nissen transthoracic hiatal hernia repair described in this chapter involves mobilization of the distal esophagus, herniated stomach and hernia sac, preservation of the vagus nerves, and a fundoplication through a left posterolateral thoracotomy with an esophageal lengthening procedure when necessary (to allow a 3- to 5-cm tension-free intraabdominal segment of distal "esophagus").
- The two major categories of hiatal hernias include sliding (type I) and paraesophageal (type II, pure paraesophageal hernia with the gastroesophageal junction fixed at the hiatus; type III, combined hiatal hernia where the cardia is above the diaphragm and the fundus is herniated alongside the esophagus; and type IV, with herniation of the stomach along with the colon, small bowel, or spleen) (**FIG 1**).[1–3]

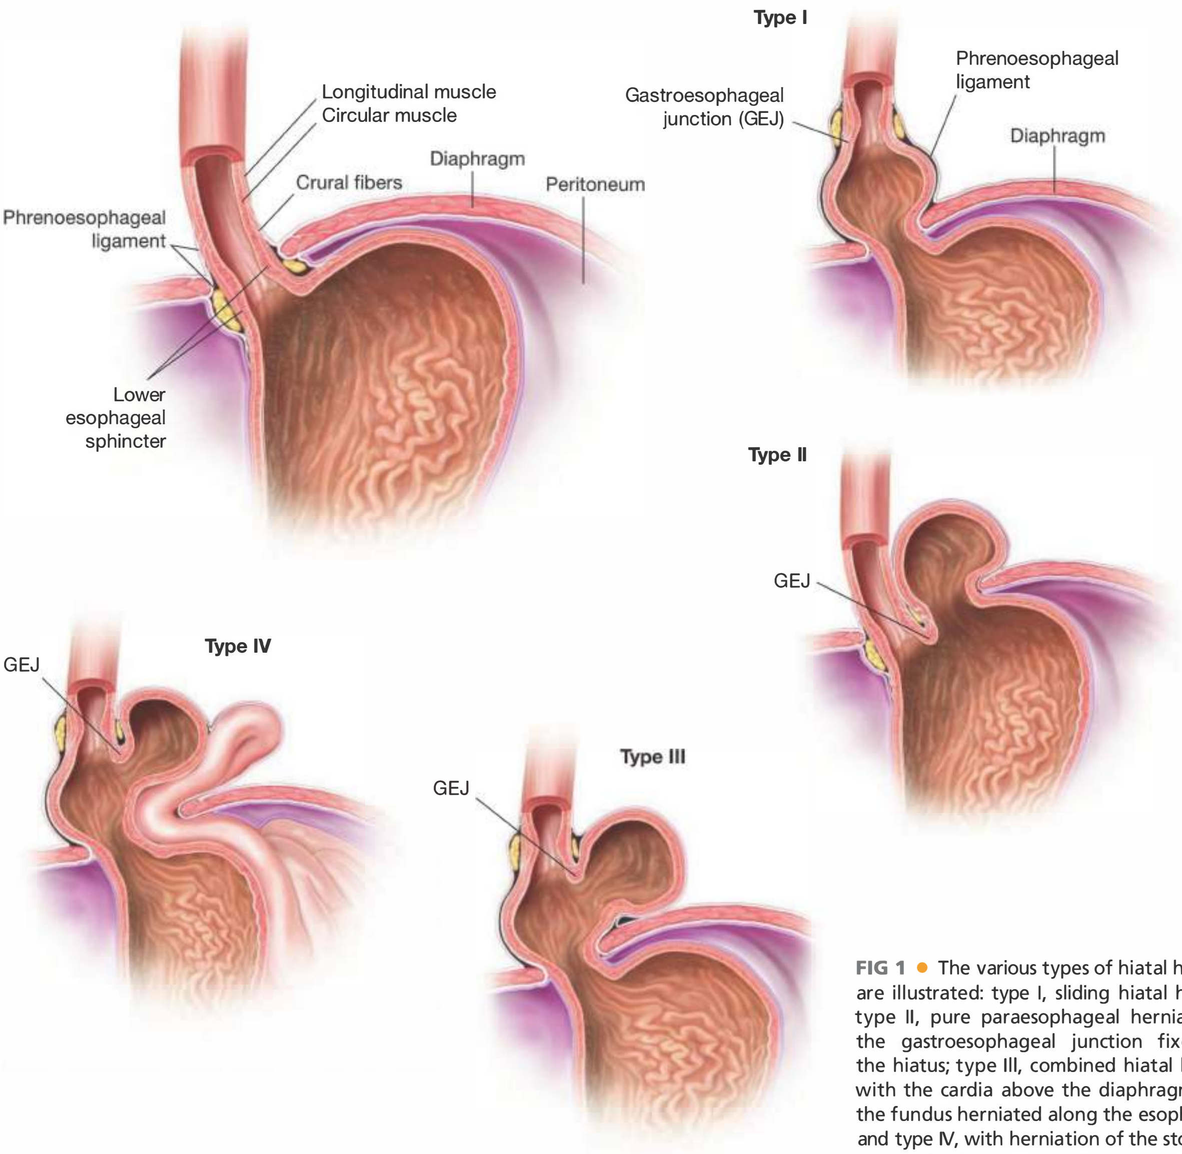

FIG 1 ● The various types of hiatal hernias are illustrated: type I, sliding hiatal hernia; type II, pure paraesophageal hernia with the gastroesophageal junction fixed at the hiatus; type III, combined hiatal hernia with the cardia above the diaphragm and the fundus herniated along the esophagus; and type IV, with herniation of the stomach along with the colon, small bowel, or spleen.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history and physical must be performed focusing on heartburn and reflux symptoms, response to medical treatment as well as the characteristics and degree of dysphagia, regurgitation, pain, bloating, or anemia. In a series of 240 patients with a paraesophageal hernia, Patel et al.[4] found that 68% of patients had reflux symptoms, 67% abdominal or chest pain, 33% anemia, and 33% dysphagia. The absence of severe reflux symptoms in most patients with paraesophageal hiatal hernias does not diminish the seriousness of this problem with its unpredictable potential for strangulation, perforation, bleeding, and aspiration pneumonia. More subtle symptoms may include early satiety and/or left shoulder and back pain with eating, loud borborygmi often heard across the room by the patient's family, or acute shortness of breath with bending forward.
- Any previous chest or abdominal operations or endoscopic dilations should be noted.
- The history should include the patient's current functional status and exercise tolerance.
- A complete physical examination should be performed with attention to auscultation of the heart and lungs and palpation of the abdomen.
- Routine laboratory studies, including a complete blood count and a basic chemistry panel, should be included as part of the preoperative evaluation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A chest x-ray (**FIG 2**) may show a mediastinal air fluid level, suggesting the presence of a paraesophageal hernia.
- A barium swallow (**FIG 3**) should be performed to delineate the esophageal and gastric anatomy and may show reflux, although this is not a reliable finding. Accompanying esophageal dysmotility from the "accordioned" esophagus is common. The esophagram can also be useful when obstruction from gastric volvulus is suspected (**FIG 4**).

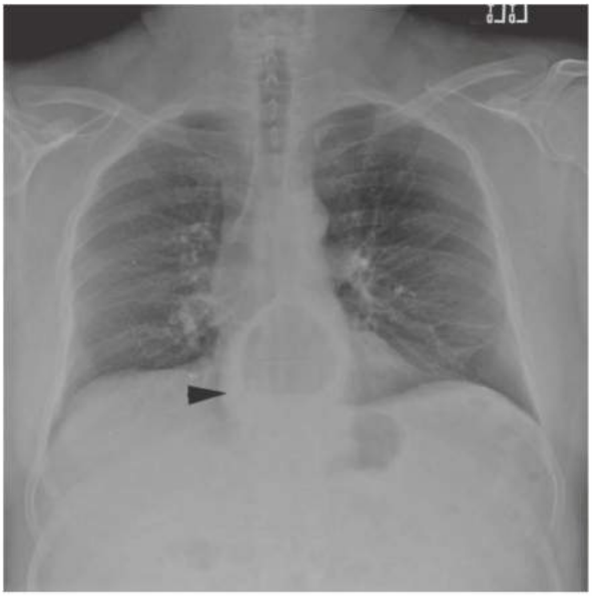

FIG 2 ● Chest x-ray demonstrates an air fluid level *(arrowhead)* consistent with a type III hiatal hernia.

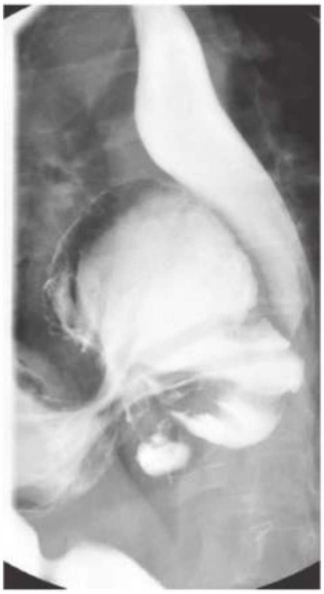

FIG 3 ● Barium swallow demonstrating a type III paraesophageal hernia.

- An esophagoscopy (**FIG 5**) should be performed to evaluate for evidence of esophagitis, Barrett's mucosa, esophageal carcinoma, or esophageal shortening. Suspicious areas should be biopsied. The gastric mucosa should also be examined for Cameron erosions, especially when there is a history of anemia. Caution should be exercised to avoid excessive air insufflation during flexible esophagogastroscopy in the patient with a paraesophageal hiatal hernia lest the intrathoracic stomach becomes overdistended, resulting in hemodynamic instability.
- For patients complaining of persistent nausea, a gastric emptying study may be obtained to evaluate for gastroparesis.
- When there is no hiatal hernia or a small sliding hiatal hernia, esophageal manometry and 24-hour pH probe monitoring with impedance are performed, with antireflux medications discontinued for 72 hours, to document the presence of gastroesophageal reflux, association with the patient's symptoms, and to evaluate for esophageal dysmotility. However, in the presence of a paraesophageal hernia, we do not routinely perform these studies. Many of these patients will have some degree of dysmotility in the presence of a chronic hiatal hernia that frequently improves after hiatal hernia repair. The presence of a symptomatic hiatal hernia is a mechanical issue, and the indication for repair is the paraesophageal hernia itself regardless of the presence of acid reflux.
- Patients suspected of having an incarcerated hiatal hernia (**FIG 4**) with severe epigastric pain and regurgitation should undergo an esophagram and nasogastric tube decompression followed by an emergent hiatal hernia repair.

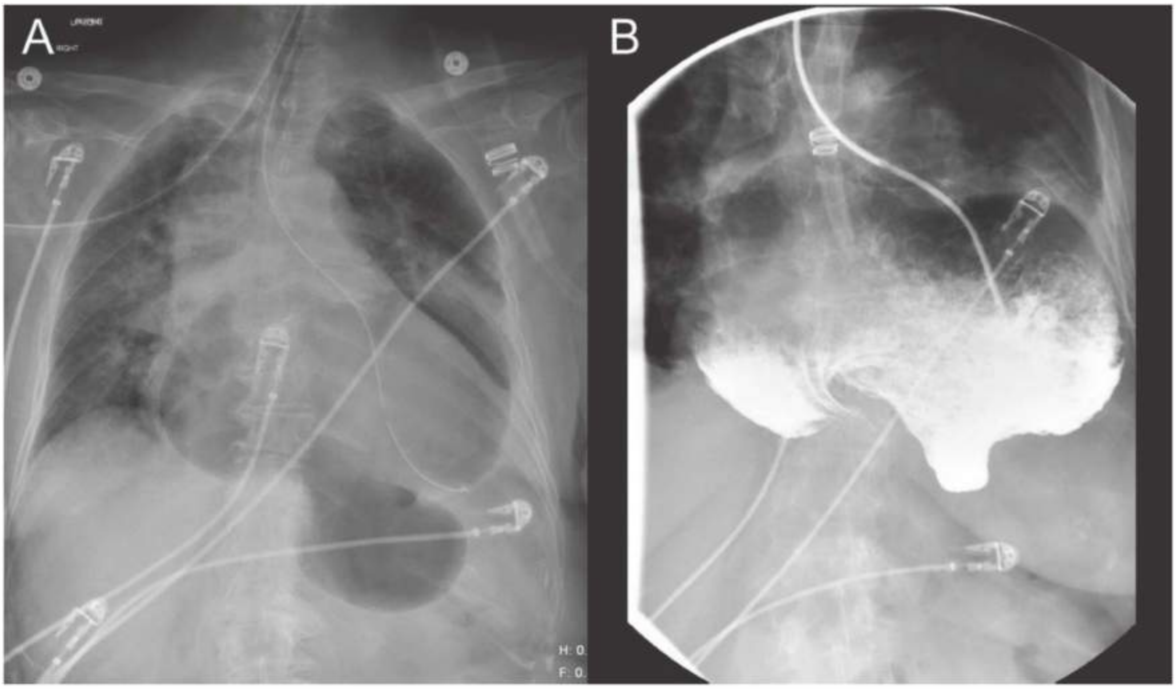

FIG 4 ● **A.** Chest x-ray and **(B)** barium esophagram showing an incarcerated type III hiatal hernia with complete obstruction requiring emergent repair.

SURGICAL MANAGEMENT

Indications

- Sliding hiatal hernias are repaired when there has been incomplete control of reflux symptoms despite medical therapy (Table 1) and after confirmation of abnormal acid reflux on 24-hour pH probe. Other indications include complications of gastroesophageal reflux disease (GERD)—recurrent aspiration, the development of a reflux stricture, and recurrent bleeding from esophagitis.
- Paraesophageal hernias are more likely to present with obstructive symptoms due to the chronic gastric volvulus and repair is generally recommended in the functional patient.[3]
- There has been controversy regarding the optimal surgical approach (laparoscopic vs. transthoracic), the need for an antireflux procedure, and the assessment of esophageal shortening.[1,5–19] The pneumoperitoneum used during laparoscopic repair displaces the diaphragm upward, making intraoperative assessment of esophageal shortening more challenging. In addition, performing a lengthening procedure laparoscopically is more difficult due to the angle of the approach. Taking adequate bites of the attenuated crura is also more difficult due to the tension induced by the pneumoperitoneum, which could contribute to hernia recurrence after laparoscopic repair. A transthoracic approach with an esophageal lengthening procedure, similar to a relaxing incision for an inguinal hernia repair, may be optimal even for a small sliding hiatal hernia in morbidly obese patients due to the increased risk of recurrence. In a series of 240 patients with paraesophageal hiatal hernias, documented acid reflux decreased from 88% preoperatively to 4% after a transthoracic Collis-Nissen procedure, whereas Williamson et al.[6] reported an 18% incidence of postoperative reflux after a selective approach to adding an antireflux procedure. As a

FIG 5 ● Esophagoscopy with retroflexed views showing **(A)** a hiatal hernia, **(B)** erosive gastropathy, and **(C)** an intact Nissen fundoplication.

Table 1: Indications for Transthoracic Hiatal Hernia Repair

Sliding hiatal hernia
Reflux symptoms with incomplete control on medical therapy
Complications of gastroesophageal reflux
Recurrent aspiration
Development of a reflux stricture
Recurrent bleeding from esophagitis
Confirmation of acid reflux on 24-hour pH probe
Paraesophageal hernia
Repair should be considered in all physically fit patients due to risk of strangulation, perforation, or bleeding.
Esophageal lengthening procedure
Intraoperative assessment of esophageal shortening after complete mobilization of the hernia
Obesity
Reflux esophagitis or stricture

result, we advocate an antireflux procedure with all paraesophageal hiatal hernia repairs.[4,6]

- With larger paraesophageal hernias, transthoracic Collis-Nissen repair remains the standard against which other approaches must be compared.[4]

Preoperative Planning

- Preoperative risk assessment determines whether a patient will tolerate a thoracotomy based on exercise tolerance and pulmonary function testing (PFT) if there is a substantial smoking history or shortness of breath. Patients with cardiovascular risk factors or symptoms should undergo preoperative cardiac evaluation.
- Patients should be informed of changes in their diet after undergoing a fundoplication, including avoiding large pills and carbonated drinks and the possibility of gas bloat and dumping syndrome.
- In the preoperative area, the history and physical should be reviewed and consent should be obtained. The operative site on the left chest should be appropriately marked.
- For pain control, an epidural catheter can be placed in the preoperative area, or a paraspinous catheter can be inserted prior to thoracotomy closure.
- Once in the operating room (OR), a flexible esophagoscopy should be performed to evaluate the anatomy and any esophageal mucosal lesions. Overdistention of the stomach with air insufflation must be avoided. After the scope is removed, a 16-Fr nasogastric tube is placed to decompress the stomach.
- Single-lung ventilation is achieved with either a left-sided double lumen endotracheal tube or a bronchial blocker.

Positioning

- The patient should be placed in the right lateral decubitus position (**FIG 6**). The arms should be placed in an arm holder in neutral position. The bed is flexed and the patient should be secured with all pressure points padded.
- Following positioning, the endotracheal tube position should be confirmed again by the anesthesiologist.

FIG 6 ● The patient is placed in the right lateral decubitus position. The chest is entered through a standard posterolateral 6th or 7th intercostal space thoracotomy.

THORACOTOMY

- A standard posterolateral thoracotomy is generally performed through the 6th intercostal space, although the 7th intercostal space can be used with smaller hiatal hernias.
- The serratus anterior muscle can be spared, although dividing the muscle can provide more anterior exposure when needed and results in little, if any, functional impairment.
- After carefully counting the ribs to confirm the intercostal space, the chest is entered. If a paraspinous catheter will be used for postoperative pain control, a posterior pleural flap can be raised at this time to prevent tearing the pleura. Chest retractors such as a Finochietto or Rienhoff are used to provide exposure.

Exposure and Dissection of the Esophagus and Stomach

- The dome of the diaphragm is retracted downward to improve exposure using cloth-covered Harrington retractors. The inferior pulmonary ligament is divided, and the mediastinal pleura is opened (**FIG 7A**).
- The esophagus is identified by palpating the previously placed nasogastric tube and dissected free from surrounding tissues. Care is taken to identify and preserve the anterior and posterior vagus nerves, which, along with the esophagus, are encircled with a Penrose drain that is used to provide tension on the esophagus as needed (**FIG 7B**).
- The hernia sac is dissected from the right pleura, taking care not to enter the right chest.
- With upward traction on the Penrose drain, the hernia sac overlying the cardia is incised. The peritoneal cavity is entered anterolateral to the cardia, and the phrenoesophageal attachments and hernia sac surrounding the cardia are divided (**FIG 8A,B**).
- The cardia is retracted anteriorly and the peritoneum medial to the cardia is incised, entering the lesser sac. The cephalad portion of the lesser curvature is mobilized

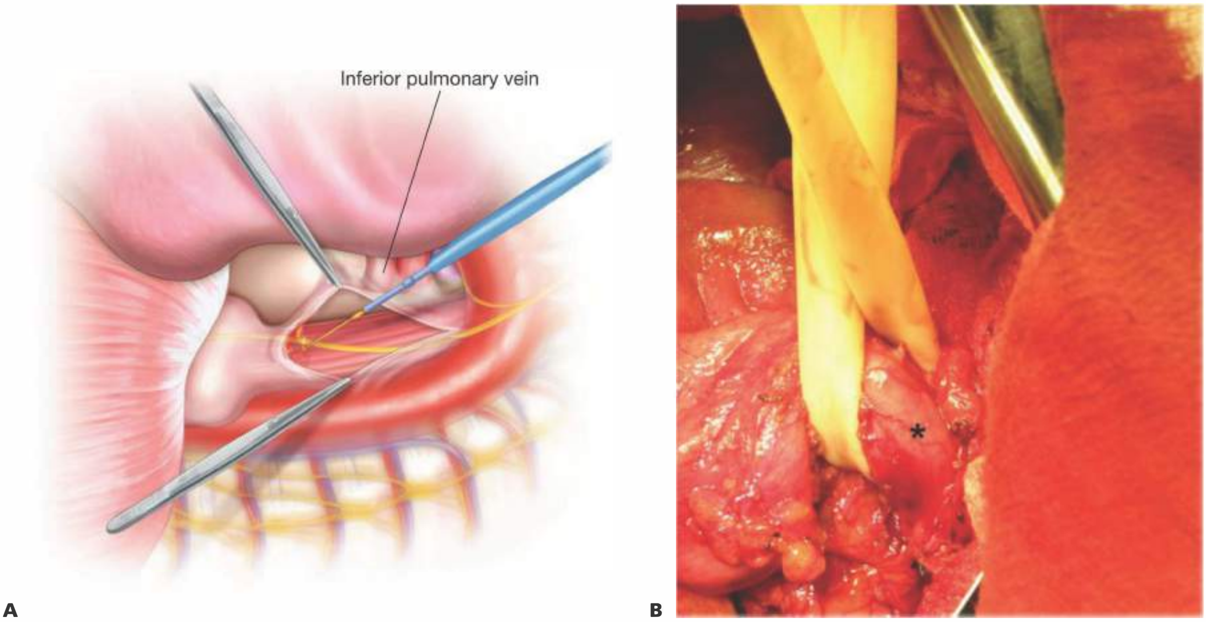

FIG 7 ● **A.** After the inferior pulmonary ligament is taken down with electrocautery, the mediastinal pleura is opened to the level of the interior pulmonary vein exposing the distal esophagus. **B.** The esophagus *(asterisk)* is mobilized, taking care to preserve the anterior and posterior vagus nerves, which are encircled along with the esophagus using a Penrose.

by partially dividing the gastrohepatic ligament, which allows the fundus to be passed posterior to the upper stomach for the fundoplication. These attachments are divided between clamps using 2-0 silk ties and may contain the ascending branch of the left gastric artery (**FIG 8C,D**). A finger is swept circumferentially underneath the diaphragm, confirming mobilization of the cardia away from the hiatus (**FIG 8E**).

- Four to six short gastric vessels are then divided between clamps and ligated with 2-0 silk sutures (**FIG 9**). Care must be taken to avoid excess tension on the stomach to prevent splenic injury. The short gastric vessels must be carefully tied. Once the vessels retract underneath the diaphragm, bleeding may be difficult to recognize and could require a laparotomy for control.
- The hernia sac is resected with electrocautery, taking care not to damage the blood supply to the proximal lesser curvature of the stomach. The gastroesophageal fat pad is excised to expose the gastroesophageal junction, taking care to protect the anterior and posterior vagus nerves (**FIG 10**).

Placement of the Crural Sutures

- The mobilized fundus is then reduced through the hiatus.
- An Allis clamp is placed on the tendinous portion of the medial crus. The esophagus is retracted anteriorly. Using a spoon retractor to protect the intraabdominal contents, interrupted no. 1 silk sutures are placed through the medial crus of the diaphragm approximately 1 cm apart starting posteriorly and proceeding toward the esophagus (**FIG 11A**). Sutures must be passed through the strong tendinous portion of the crus, which is identified by lifting the Allis clamp. All sutures are placed in the medial crus, snapped, and placed in an Allis clamp to keep them in order.

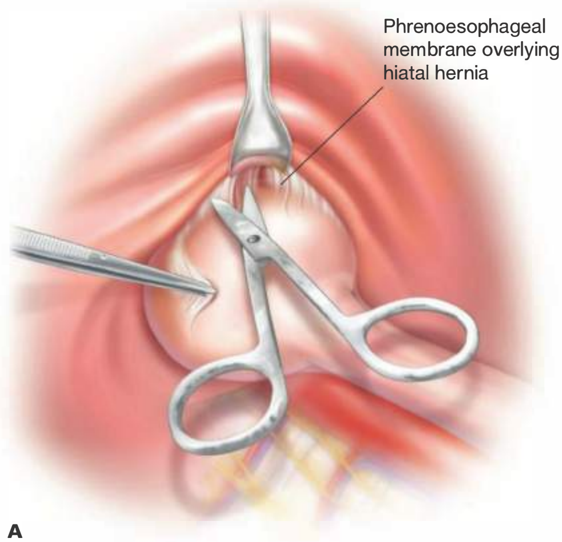

FIG 8 ● **A.** With upward traction on the Penrose drain encircling the esophagus and countertraction on the diaphragm, the phrenoesophageal ligament is incised. *(continued)*

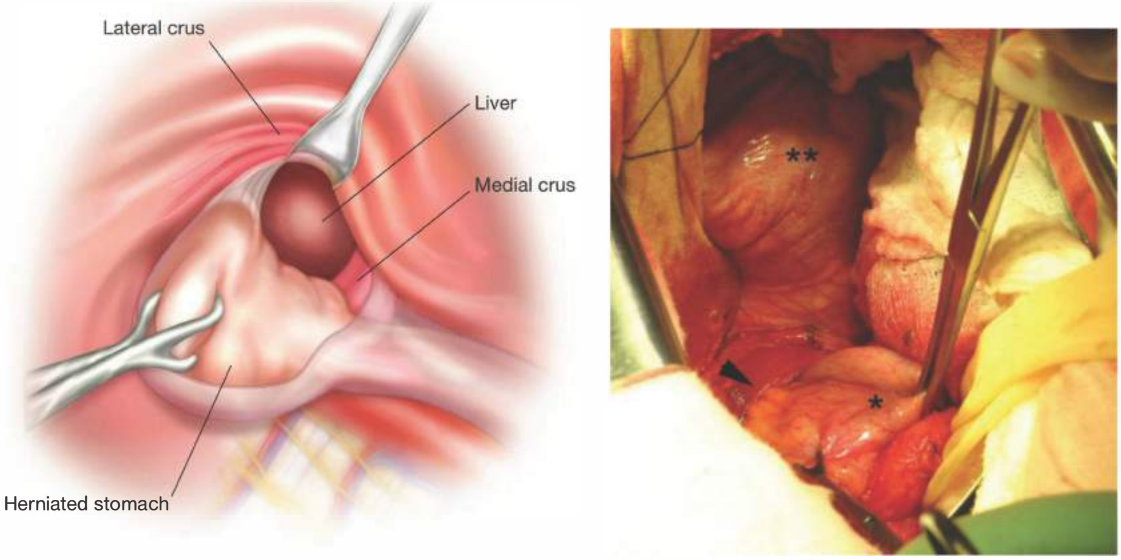
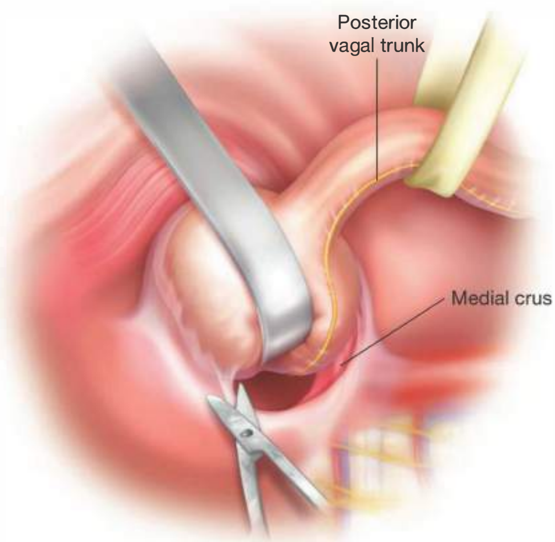
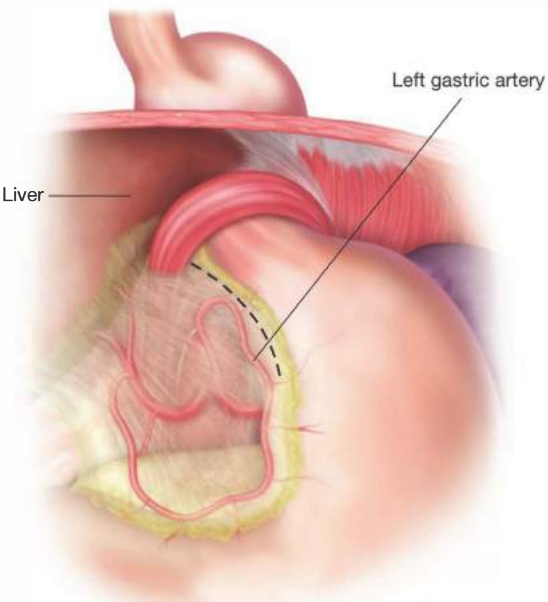


B



C



D

FIG 8 ● *(continued)* **B.** The peritoneal cavity is entered and the left lobe of the liver is visible. The phrenoesophageal attachments and peritoneum surrounding the cardia are divided, exposing the lateral crus *(arrowhead)* (stomach, *asterisk*; diaphragm, *double asterisk*). **C.** The gastroesophageal junction is then retracted anteriorly and the medial crus exposed by incising the peritoneum along the posteromedial aspect of the cardia. **D.** The high lesser curvature is mobilized by partially dividing the gastrohepatic ligament *(dotted line)*, which allows the fundus to be passed posterior to the upper stomach for the fundoplication. These attachments are carefully ligated and may contain the ascending branch of the left gastric artery. *(continued)*

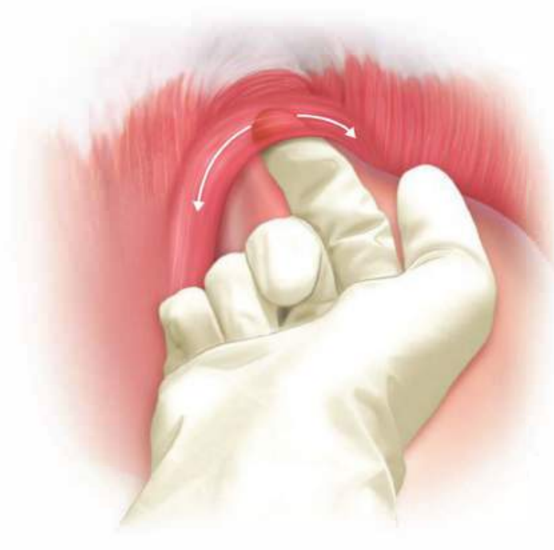


FIG 8 ● *(continued)* **E.** A finger is swept circumferentially along the underside of the hiatus to confirm that the cardia has been completely mobilized.

- The sutures are then each reloaded and passed through the lateral crus (**FIG 11B**). Again, the intraabdominal contents are protected with the spoon retractor and the spleen is displaced away from the lateral crus using a Harrington retractor, pulling downward on the dome of the diaphragm. The crural sutures are not tied at this point and are snapped and placed in an Allis clamp to keep them in order.
- Esophageal shortening is often present with large hiatal hernias, increasing the risk of a recurrent hernia, and is best assessed intraoperatively.[8,9,18] If the esophagogastric junction and distal 3 cm of esophagus do not reduce beneath the diaphragmatic hiatus without tension, an esophageal lengthening Collis gastroplasty is performed as described in the following text.

Collis Gastroplasty and Nissen Fundoplication

- A Maloney esophageal bougie (54 Fr in women and 56 Fr in men) is then placed by the first assistant or anesthesiologist (**FIG 12A**). It is essential at this stage to communicate with the person passing the bougie to ensure that the surgeon's hand is palpating and guiding the bougie as it is being passed to prevent perforation. The bougie is advanced until 6 in remains outside of the mouth as long as it is advancing without resistance.
- With upward traction on the fundus, which is mobilized back through the hiatus and into the chest, the dilator is displaced against the lesser curvature of the stomach. An angled ductus clamp is used to help apply the 3.5-mm gastrointestinal anastomosis (GIA) surgical stapler to the stomach adjacent to the dilator and parallel to the lesser curvature, lengthening the esophageal tube by approximately 5 cm (**FIG 12B**). Care should be taken not to apply the stapler either too tightly against the bougie, narrowing the gastroplasty tube or, so loosely, creating a pouch that empties poorly.
- The staple suture line is reinforced with two running 4-0 polydioxanone (PDS) Lembert sutures, each proceeding from the apex of the gastroplasty incision to either the stomach or esophagus (**FIG 12C**). Hemoclip markers are placed at the new esophagogastric junction for localization on imaging.
- The elongated gastric fundus is passed posteriorly to the left of the gastroplasty tube and positioned for the

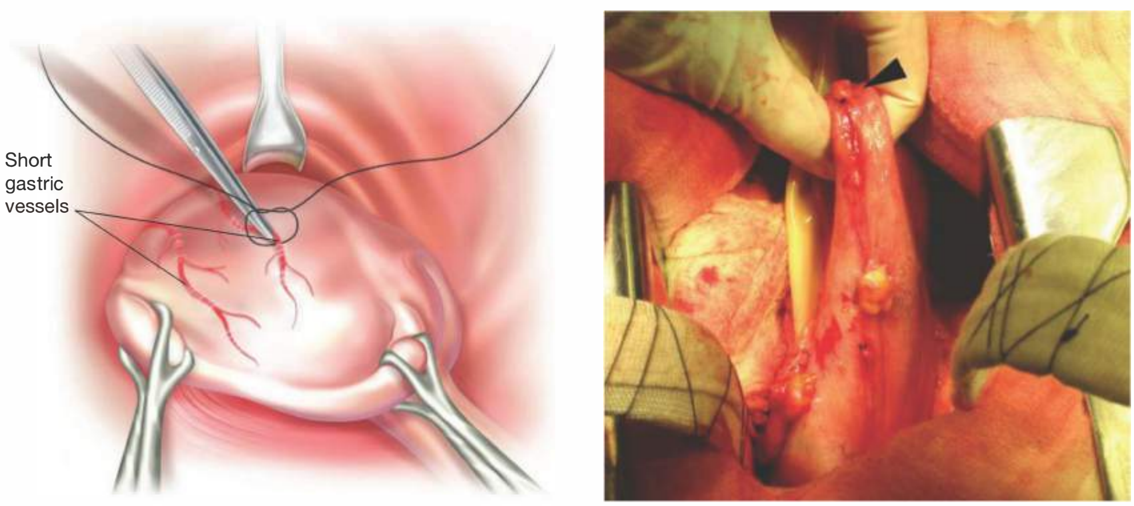

FIG 9 ● The gastric fundus is retracted with a Babcock clamp and four to six short gastric vessels are ligated and divided *(arrowhead)*, mobilizing 10 to 15 cm of the greater curvature.

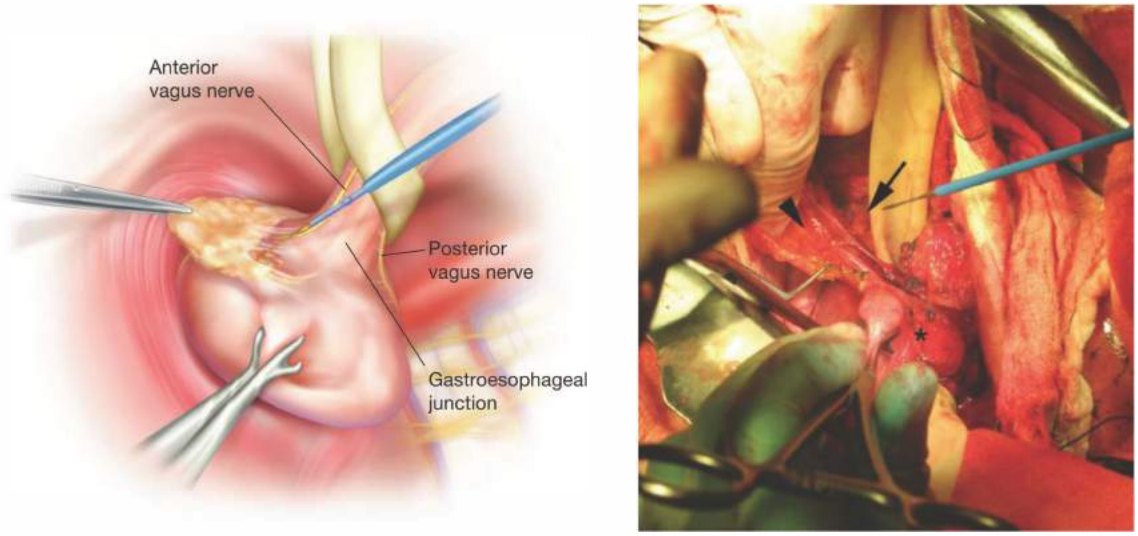

FIG 10 ● The fat pad *(arrowhead)* must be dissected from the anterolateral aspect of the esophagogastric junction to allow accurate localization of the gastroesophageal junction for the Collis gastroplasty and Nissen fundoplication (stomach, *asterisk*; esophagus, *arrow*). Care must be taken to identify and preserve the anterior vagal nerve.

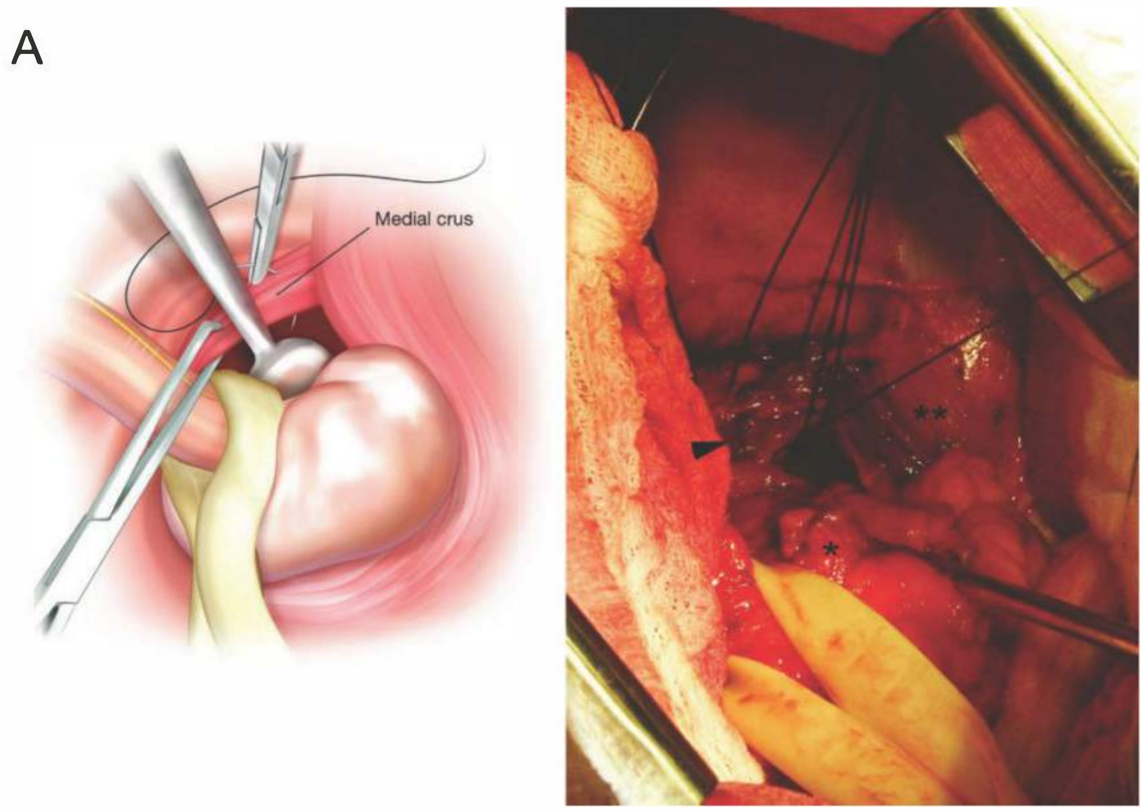

FIG 11 ● **A.** An Allis clamp is placed on the tendinous portion of the medial crus *(arrowhead)*. The esophagus is retracted anteriorly. Sutures must be passed through the strong tendinous portion of the crus, which is identified by lifting the Allis clamp. The sutures are placed through the medial crus starting posteriorly and proceeding toward the esophagus, spacing the sutures 1 cm apart (stomach, *asterisk*; diaphragm, *double asterisk*). *(continued)*

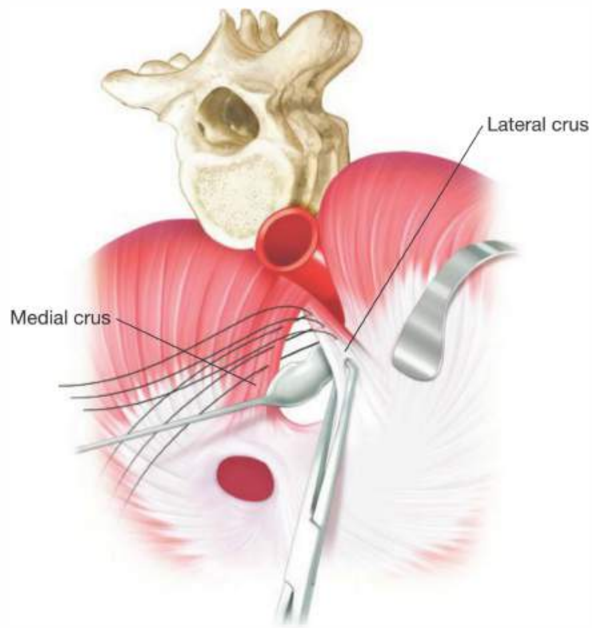

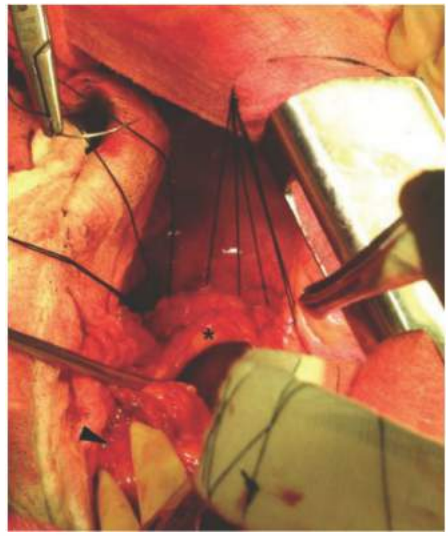

B

FIG 11 ● *(continued)* **B.** The sutures are then each reloaded and passed through the lateral crus *(asterisk)*. The intraabdominal contents are protected with the spoon retractor and the spleen is displaced away from the lateral crus using a Harrington retractor, pulling downward on the dome of the diaphragm (esophagus, *arrowhead*).

Nissen fundoplication. A 2- to 3-cm long fundoplication is constructed using interrupted 2-0 silk sutures placed 1 cm apart, with each stitch passing from the gastric fundus to the gastroplasty tube and then to gastric fundus again (**FIG 13A,B**).

- After tying these fundoplication sutures, the silk suture line is oversewn with a 4-0 PDS running Lembert suture to minimize the risk of a leak from the fundoplication sutures (**FIG 13C**).

Completion of the Hiatal Hernia Repair

- The esophageal dilator is removed and a 16-Fr nasogastric tube is placed.

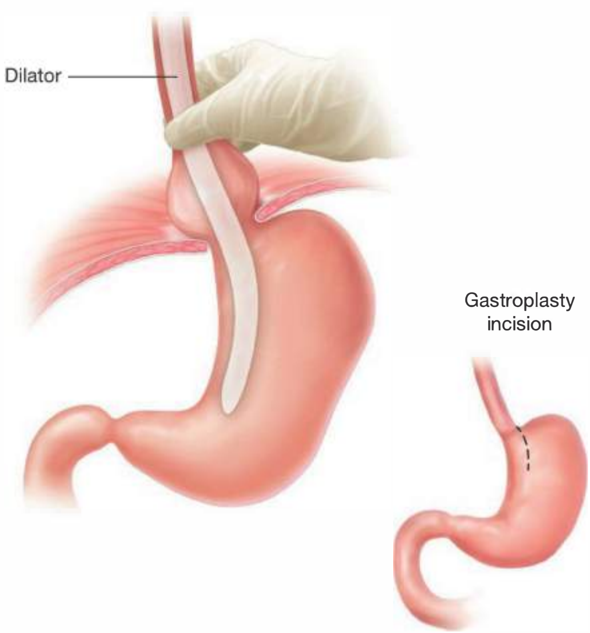

FIG 12 ● If esophageal shortening is present, a Collis gastroplasty is performed. **A.** An esophageal bougie (54 to 56 Fr) is placed with the surgeon's hand palpating and guiding the bougie as it is being passed to prevent perforation. *(continued)*

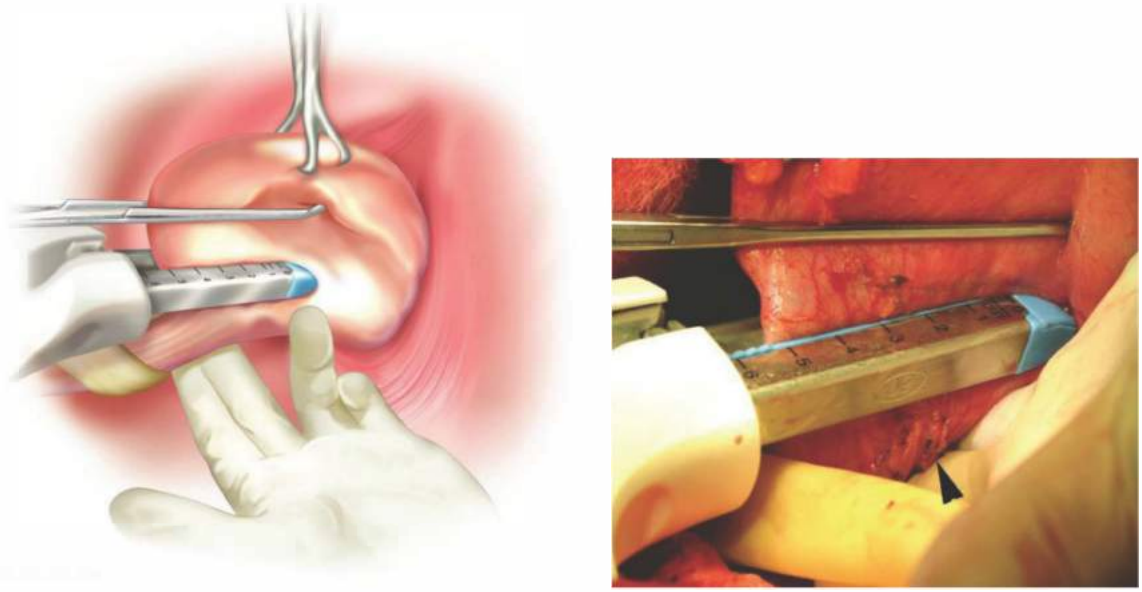
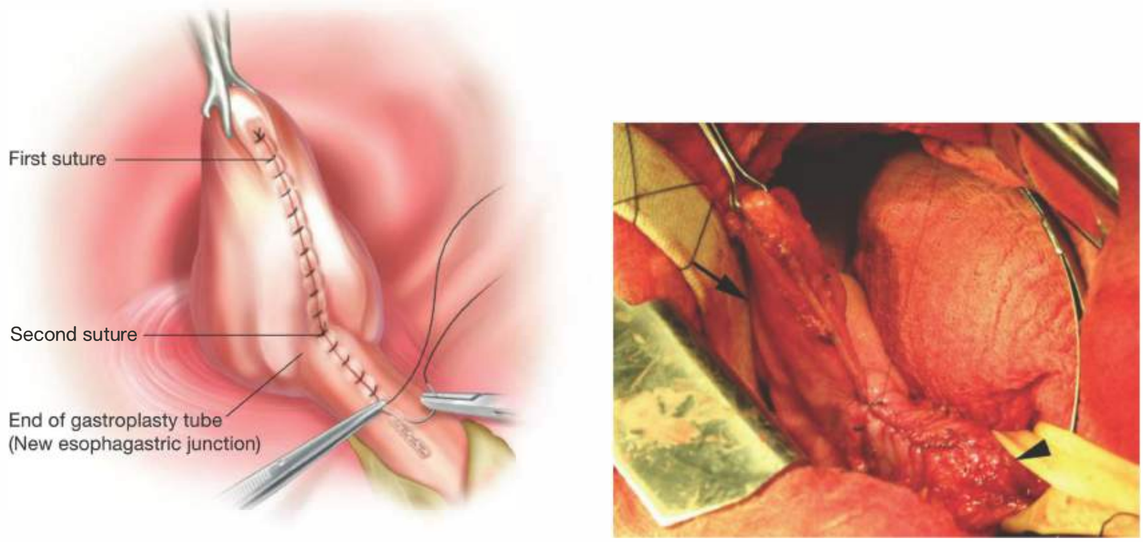


B



C

FIG 12 ● *(continued)* **B.** The esophageal dilator is displaced against the lesser curvature *(arrowhead)* of the stomach and an angled ductus clamp is used to help apply the 3.5-mm GIA stapler to the stomach adjacent to the dilator and parallel to lesser curvature, lengthening the esophageal tube by approximately 5 cm. **C.** The staple line is oversewn with two running 4-0 PDS Lembert sutures, each proceeding from the apex of the gastroplasty incision to either the stomach *(arrow)* or esophagus *(arrowhead)*. Hemoclip markers are placed at the new esophagogastric junction.

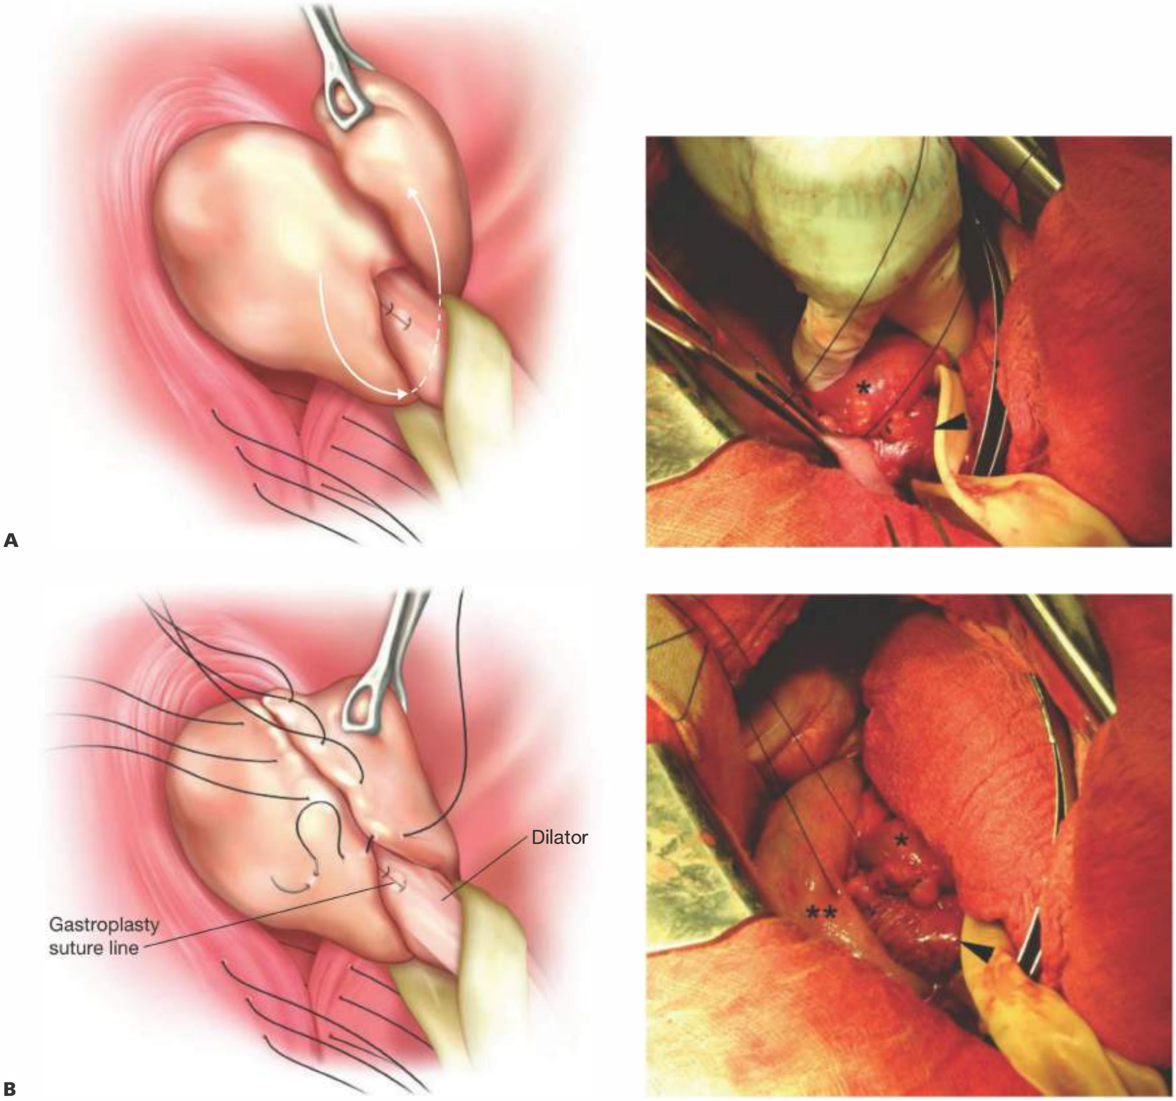


FIG 13 ● **A.** The fundus *(asterisk)* is passed behind the gastroplasty tube *(arrowhead)*. **B.** A floppy 2- to 3-cm Nissen fundoplication is performed with 2-0 silk sutures placed 1 cm apart, passing through the fundus *(asterisk)*, gastroplasty tube *(arrowhead)*, and the gastric fundus again *(double asterisk)*.*(continued)*

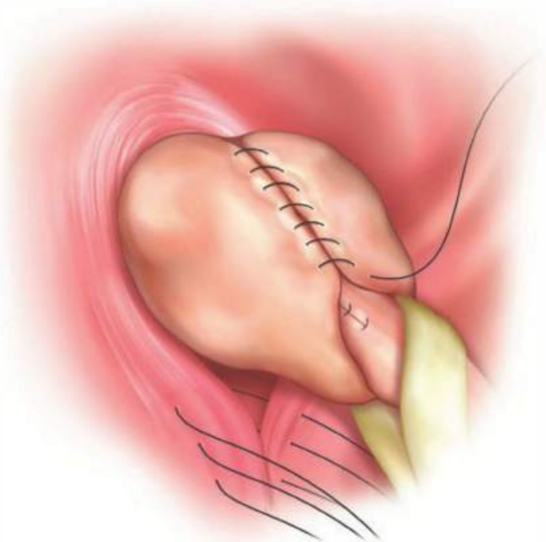

C

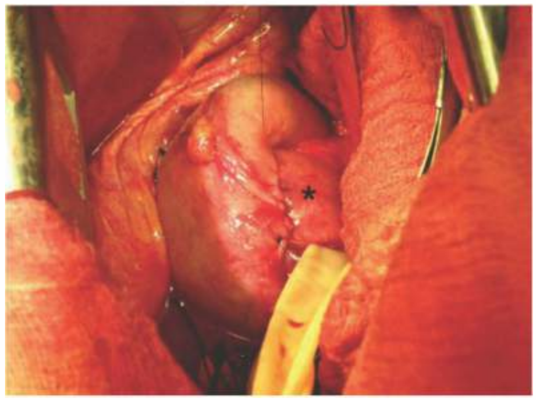

FIG 13 ● *(continued)* **C.** The suture line is oversewn with a 4-0 PDS running Lembert suture *(asterisk)*.

- The fundoplication is reduced through the hiatus and is secured to the undersurface of the diaphragm with three interrupted 2-0 Prolene horizontal seromuscular mattress "Belsey" sutures, which are passed through the diaphragm around the circumference of the hiatus (**FIG 14B,C**). Care must be taken during passage of the most anteromedial suture to prevent inadvertent injury to the heart and pericardial tamponade.
- The posterior crural sutures are tied until the diaphragmatic hiatus permits the passage of an index finger alongside the distal esophagus (**FIG 15A,B**). The Belsey sutures are then tied, and the completed fundoplication should rest below the diaphragm without tension (**FIG 15C**).
- Hemoclips are used to mark the hiatus for localization on imaging.

Thoracotomy Closure

- If a paraspinous catheter will be used for pain control, a pleural flap is raised posteriorly. A paraspinous catheter is placed percutaneously under the flap and secured to the skin with 2-0 nylon suture. The pleural flap is reapproximated to the chest wall with 4-0 Vicryl, allowing local anesthetic to be infused directly to the affected intercostal nerves.
- A 28-Fr chest tube is inserted through a low intercostal incision, advanced to the apex, secured to the skin, and connected to underwater seal drainage. The ribs are reapproximated with interrupted no. 2 Vicryl sutures placed around the 6th rib and through holes drilled in the 7th rib using a microdrill to avoid nerve entrapment against the lower rib.
- The wound is then closed in layers reapproximating the serratus and latissimus muscles with running 2-0 Vicryl, the subcutaneous tissues with 2-0 Vicryl, and the skin with a running 4-0 Monocryl subcuticular suture.

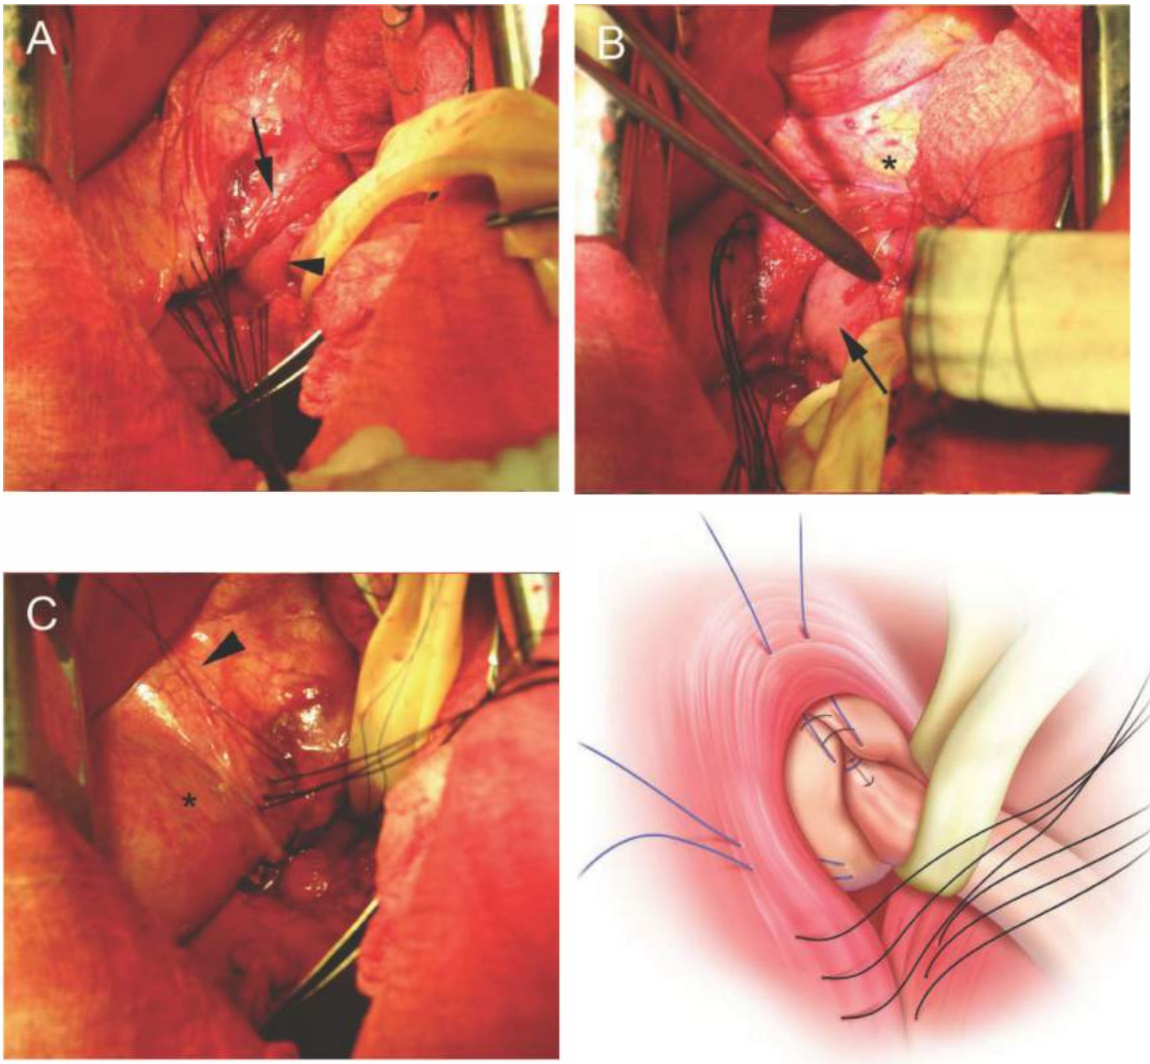

FIG 14 ● **A.** The previously placed silk crural sutures are retracted upward and the fundoplication *(arrowhead)* is reduced below the diaphragm (lateral crus, *arrow*). **B,C.** The fundoplication is secured to the undersurface of the diaphragm *(asterisk)* with three interrupted 2-0 Prolene horizontal seromuscular mattress sutures *(arrowhead)*, which are passed through the stomach *(arrow)* and then the diaphragm around the circumference of the hiatus.

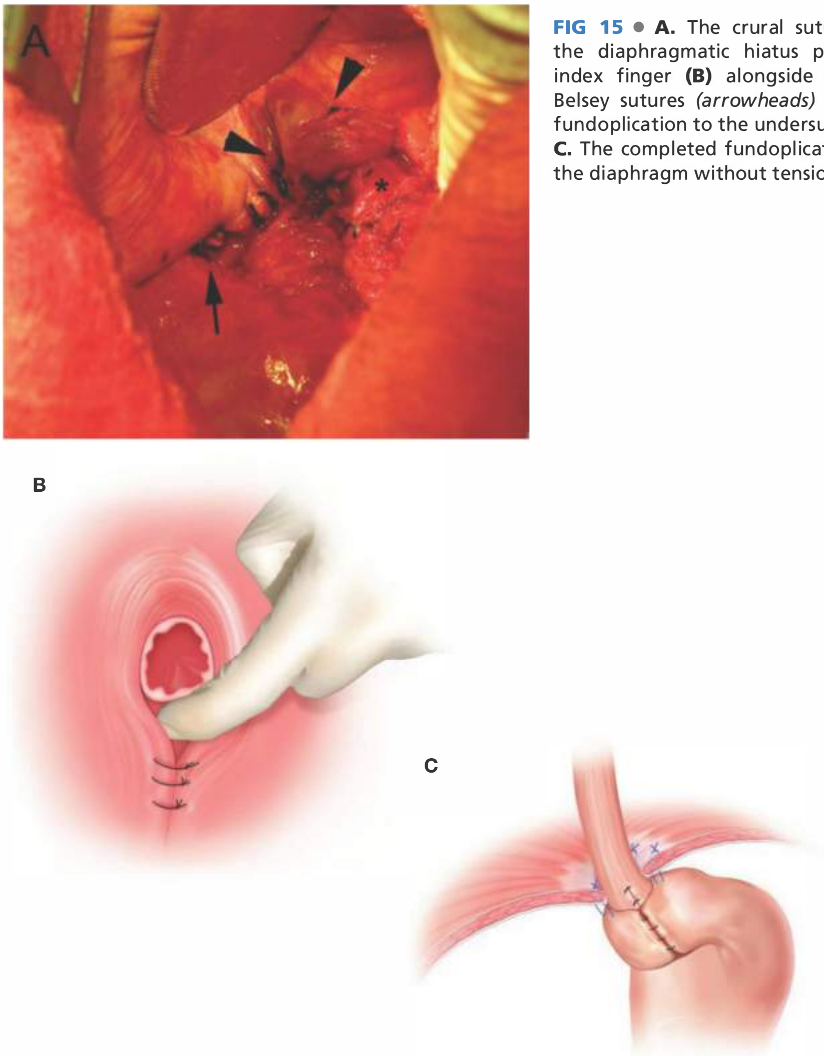

FIG 15 ● **A.** The crural sutures *(arrow)* are tied until the diaphragmatic hiatus permits the passage of an index finger **(B)** alongside the distal esophagus. The Belsey sutures *(arrowheads)* are then tied securing the fundoplication to the undersurface of the diaphragm **(A)**. **C.** The completed fundoplication is shown resting below the diaphragm without tension.

PEARLS AND PITFALLS

Preoperative evaluation	■ Discuss and modify risk factors for recurrent hernia preoperatively, especially weight loss with a goal body mass index (BMI) <32. ■ A transthoracic approach with an esophageal lengthening procedure, similar to a relaxing incision for an inguinal hernia repair, may be optimal even for small sliding hiatal hernias in morbidly obese patients due to the increased risk of recurrence.
Positioning	■ Due to the position of the liver, the hiatus cannot be adequately approached through the right chest. All transthoracic hiatal hernia repairs should be approached through a left thoracotomy even when the hernia is in the right chest.
Incisions	■ For smaller hernias, the hiatal hernia repair may be easier to perform through the 7th intercostal space, but the lower the interspace incision, the greater the degree of postthoracotomy pain because more chest wall sensory nerves are divided.

Intraoperative	■ Using a stockinette, a cloth-covered Harrington retractor is used to retract the diaphragm downward to improve exposure of the hiatus, and a spoon retractor is useful to protect the intraabdominal contents when placing the crural sutures. ■ The anterior attachments of the high lesser curvature may contain the ascending branch of the left gastric artery and should be ligated and divided. ■ A counterincision parallel to and 1 to 2 cm from the hiatus can be made in the diaphragm if additional exposure is needed during a redo hiatal hernia repair. ■ It is essential to communicate with the person passing the bougie to ensure that the surgeon's hand is palpating and guiding the bougie as it is being passed to prevent perforation. ■ Care should be taken during formation of the Collis gastroplasty not to apply the stapler either too tightly against the bougie, narrowing the gastroplasty tube or, so loosely, creating a pouch that empties poorly. ■ We do **not** recommend the routine use of mesh due to the risk of esophageal erosion. A transthoracic approach allows adequate bites to be taken of the crura, which are then tied without undue tension. ■ Hemoclip markers are placed at the new gastroesophageal junction and the diaphragmatic hiatus for localization on imaging. The distance between the two levels of clips represents the intraabdominal length of the distal "neoesophagus."
Closure	■ The ribs are reapproximated with interrupted no. 2 Vicryl sutures placed around the 6th rib and through holes drilled in the 7th rib using a microdrill to avoid nerve entrapment against the lower rib. ■ A chest x-ray is obtained in the OR at the end of the case to confirm reexpansion of the lungs and to evaluate for a right pneumothorax or effusion, which may require chest tube placement if the right pleura was entered.

POSTOPERATIVE CARE

- The nasogastric tube is placed to low continuous suction. On postoperative day 2, the nasogastric tube is placed to gravity and removed on postoperative day 3 if tolerated and the output remains less than 200 mL per shift. The patient is then started on clear liquids with no pills. On postoperative day 4, the diet is advanced to full liquids and then a soft diet.
- The chest tube is placed to 20 cm of water suction. Chest tubes may be removed on postoperative day 2 once the drainage has decreased to less than 60 mL per shift.
- Patients should be given an adequate pain control regimen and encouraged to ambulate and use the incentive spirometer.
- On postoperative day 5, a barium swallow is obtained to assess that contrast flows freely through the esophagus and into the stomach and duodenum and that the fundoplication is intact below the diaphragm. Patients are seen by a dietician for education on a post–Nissen fundoplication diet. They are discharged on a soft diet for 2 to 3 weeks and reminded to avoid large pills and carbonated beverages.
- Most patients are discharged home between postoperative days 5 and 7. At discharge, the importance of avoiding risk factors associated with hernia recurrence, including heavy lifting, constipation, or chronic coughing, is emphasized.
- Mild dysphagia occurs in less than 10% of patients and usually improves over 4 to 6 weeks as the postoperative edema subsides.[2]

OUTCOMES

- Transthoracic hiatal hernia repair remains the standard against which other approaches are compared. Patel et al.[4] described 240 patients undergoing repair of a paraesophageal hernia (92% type III and 8% type IV) with an antireflux procedure in all patients and a Collis gastroplasty in 96%. Five patients (2.1%) required an emergent repair. There were three perioperative deaths (1.7%), and the median length of stay was 7 days.[4] Early complications included recurrent hernia (four patients), leak (three patients), excessive narrowing of the hiatus (three patients), and bleeding (one patient). Eighty-six percent of patients were satisfied at last follow-up, with a mean follow-up of 42 months. An anatomic recurrence was found in 23 patients (10%), with four requiring early repair and four requiring late reoperation.
- Allen et al.[9] reported transthoracic hiatal hernia repairs in 147 patients with 81 patients (68.1%) undergoing a Collis-Nissen, 19 (16.0%) a Belsey-Mark IV, 17 a Nissen (14.3%), and 2 a Harrington repair (1.7%). There were no operative deaths, and complications occurred in 32 patients (26.9%). With a median follow-up of 42 months, results were excellent in 69 patients (60%), good in 38 patients (33%), fair in 6 patients (5.2%), and poor in 2 patients (1.7%). Of five patients who underwent emergent repair, three had gastric necrosis and one died.
- Maziak et al.[5] described 94 patients with massive, incarcerated paraesophageal hernias. Organoaxial volvulus was present in 50% of patients. A gastroplasty was performed in 75 patients (80%) because of a shortened esophagus. There were two operative deaths. The mean follow-up was 94 months, with 72 patients (80%) free of symptoms and 13 patients (13%) having inconsequential symptoms. Three patients (4%) required medical therapy or esophageal dilations and two patients had recurrent hernias or severe reflux successfully treated with a reoperation.
- Rogers et al.[20] reported a series of 60 patients with a paraesophageal hernia. Thirteen patients underwent emergent repair. A transthoracic hiatal hernia repair was performed in all patients with an antireflux procedure added selectively. There was one death after an emergent repair and one recurrence (1.5%). Seven patients (12%) required a single esophageal dilation and two patients (3%) developed symptomatic reflux.

COMPLICATIONS

- Bleeding
- Splenectomy
- Pericardial tamponade
- Right pneumothorax or pleural effusion
- Damage to the vagus nerves resulting in gastric outlet obstruction or dumping syndrome
- Gastric leak
- Persistent dysphagia requiring dilations
- Recurrent hernia

Chapter 22

Laparoscopic Nissen Fundoplication

Elizabeth A. Warner Brant K. Oelschlager

DEFINITION

- Gastroesophageal reflux disease (GERD), as defined by the Montreal Consensus Group in 2006, is caused by gastric reflux, causing troublesome symptoms and/or complications to the patient that adversely affect their well-being.[1] Symptoms can include heartburn, acid brash, regurgitation, dysphagia, noncardiac chest pain, and pulmonary symptoms such as cough and hoarseness. Complications include esophagitis, Barrett's esophagus, esophageal stricture, and aspiration pneumonia.
- GERD results from incompetency or dysfunction of the lower esophageal sphincter (LES). Important factors for adequate LES function include esophageal contraction, gastric cardia sling fibers, diaphragmatic crus, and intraabdominal position of the LES complex. Hiatal hernias efface the natural valve anatomy, allowing the GE junction to be displaced into the chest, exposing the LES to negative intrathoracic pressure and increased gastroesophageal reflux. A certain amount of gastroesophageal reflux is physiologic and not pathologic. However, once symptoms become troublesome to the patient, a diagnosis of GERD can be made.
- GERD can also be due to inadequate esophageal motility resulting in poor clearance of physiologic reflux. Similarly, delayed gastric emptying can lead to GERD due to the increased volume and duration of gastric contents that can potentially reflux into the esophagus.
- A fundoplication is the use of the gastric fundus to recreate the LES valve function. Various fundoplication configurations exist (e.g., Nissen, Dor, Toupet) and differ by the number of degrees that encircle the esophagus, the location of the wrap, and the approach used to create the fundoplication.

DIFFERENTIAL DIAGNOSIS

- Peptic ulcer disease
- Esophageal motility disorder (e.g., achalasia)
- Malignancy (e.g., esophageal or gastric)
- Anatomic abnormality (e.g., hiatal hernia)
- Eosinophilic esophagitis
- Coronary artery disease
- Biliary colic
- Pancreatitis
- Functional heartburn
- Hypersensitive esophagus
- Functional dyspepsia
- Other functional bowel diseases (i.e., inflammatory bowel syndrome [IBS])

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most common gastroesophageal reflux symptoms reported are heartburn, acid regurgitation, and dysphagia. There is a growing awareness of more atypical presentations, most of which are related to laryngeal or pulmonary manifestations such as cough, chest pain, hoarseness, wheezing, globus sensation, and aspiration.[2]
    - It is important to ask the patient to explain the sensations they are having when they use the term "heartburn." Heartburn, as related to GERD, is a retrosternal burning or caustic sensation. Some patients incorrectly use the term heartburn to describe epigastric pain (associated with peptic ulcer disease, gastritis, and functional dyspepsia), right upper quadrant pain (from cholelithiasis or other hepatobiliary diseases), or chest pain (from coronary artery disease). It is helpful to ask patients to point on their body as to where they have discomfort when they note that they have heartburn. Classic heartburn does not radiate to the back nor is it usually described as a pressure sensation.
    - Regurgitation symptoms can include gastric fluid regurgitation, known as water brash, and/or partially digested food. Regurgitation of food particles can also be associated with esophageal clearance problems such as an esophageal diverticulum or achalasia.
    - Dysphagia from a reflux-associated stricture is usually worse with solids than liquids. If both are equally bothersome, a neuromuscular disorder must also be considered.
    - Airway-related symptoms (e.g., cough, wheezing, voice changes) can be present alone or in conjunction with esophageal symptoms.
- Disease states that are sometimes related to GERD are idiopathic pulmonary fibrosis, asthma, and recurrent pneumonia.
- Patients presenting to a surgeon to discuss GERD treatment have often already trialed antacid medications. It is important to query the patient's response to these medications. If the patient does not have at least symptomatic improvement to antacid therapy, alternative diagnoses should be considered. Heartburn will almost always improve with antacid therapy, at least partially, within days to a few weeks. Similarly, they will notice worsening of heartburn symptoms with cessation of antacid therapy. Airway symptoms may take longer (2 to 3 months) and may not respond at all (even when GERD is the etiology).
- Physical examination findings are often limited in a patient with GERD. In all patients with gastroesophageal complaints, it is important to query about weight loss and hematemesis and to examine for lymphadenopathy, as these could represent an underlying malignancy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Diagnostic testing to confirm objective evidence of abnormal gastroesophageal reflux is imperative before considering surgical management for GERD. A recent study revealed that 42% of patients referred for antireflux surgery had a normal pH study when tested objectively.[3] The following studies are

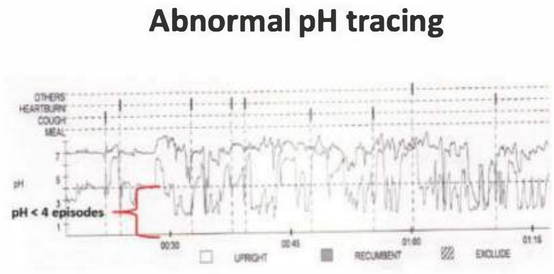

FIG 1 ● Sample of 24-hour pH tracing demonstrating significant acid reflux with good symptom correlation.

essential to confirm the diagnosis of GERD, the underlying functionality of the LES and esophagus, and investigate any anatomic considerations necessary for successful operative outcomes:

- pH monitoring (**FIG 1**) assesses distal esophageal pH over a period of time (routinely 24 to 48 hours) and a composite DeMeester score is calculated. An abnormal DeMeester score is greater than 14.7.[4] Factors contributing to this score include percent total time pH less than 4, percent upright time pH less than 4, percent supine time pH less than 4, number of reflux episodes, number of reflux episodes more than 5 minutes, and longest reflux episode.
- Upper endoscopy evaluates for esophageal injury and Barrett's esophagus secondary to GERD while excluding malignant pathology with biopsies as necessary. Endoscopy allows the surgeon to evaluate for the presence of a hiatal hernia as well as to visually inspect the LES.
- Esophageal manometry (**FIG 2**) assesses LES pressure and relaxation as well as esophageal motility. Patients with esophageal motility disorders can easily be mislabeled as having GERD based on symptoms. Understanding a patient's esophageal motility is necessary to plan successful antireflux surgery.
- Esophagogram evaluates gastroesophageal anatomy and abnormalities such as hernia, stricture, diverticula, motility, or tumors.

- Ancillary tests that may also be useful include laryngoscopy, gastric emptying scintigraphy, and impedance testing.

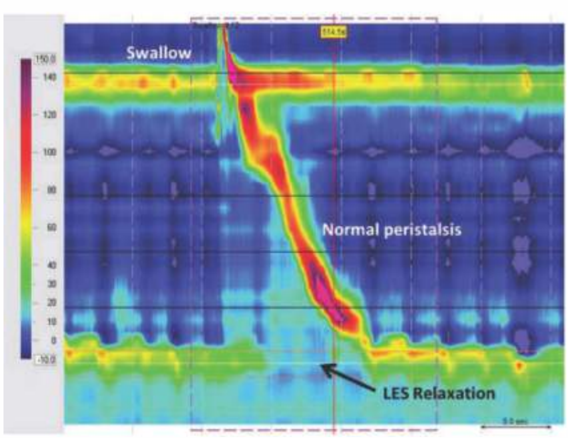

FIG 2 ● Normal high-resolution manometry.

SURGICAL MANAGEMENT

- There is rarely an absolute indication for antireflux surgery in a patient with GERD. Medical management, including acid suppression therapy and lifestyle modifications (e.g., dietary changes, weight loss), is usually sufficient to manage most patients' GERD symptoms. Many factors must be considered in making the decision to proceed with antireflux surgery. These include symptom severity, symptom control with medical therapy, complications of GERD (e.g., severe esophagitis, esophageal stricture, Barrett's esophagus, chronic respiratory complaints), and the generalized health of the patient.
- Patients best suited for an antireflux procedure are those with documented and confirmed GERD for whom medical and lifestyle changes are not providing adequate quality-of-life improvement. When the quality-of-life impairment justifies accepting the risk of surgery, antireflux surgery is indicated.

Preoperative Planning

Positioning

- Patient can be positioned in either modified lithotomy position or supine depending on surgeon preference. Lithotomy position requires more time and equipment and has more risks of nerve injury. However, lithotomy position provides superior ergonomics for the surgeon. Both arms should be tucked to not interfere with instrumentation and the patient should be adequately stabilized on the bed to safely accommodate steep reverse Trendelenburg (which allows organs to naturally fall away from the hiatus and left upper quadrant).
- Standard trocar placement includes three working trocars, a fourth trocar for the camera, and a fifth for liver retraction. **FIG 3** illustrates standard trocar placement, surgeon, and assistant positioning.
- Elevation of the left lateral lobe of the liver is necessary to visualize the esophageal hiatus. This is most commonly accomplished with a retraction device of the surgeon's choice.

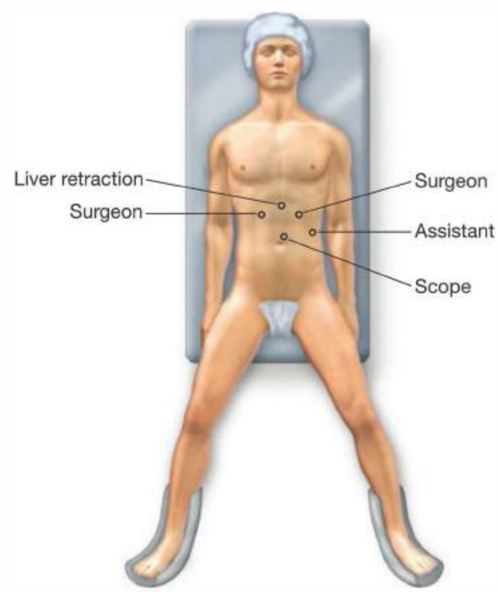

FIG 3 ● Typical port placement for laparoscopic foregut surgery using a split-leg approach.

TECHNIQUES

TAKE DOWN THE LEFT PHRENOGASTRIC LIGAMENT

- After obtaining laparoscopic access to the abdomen and placement of trocars and the liver retractor, the phrenogastric ligament is divided, exposing the left crus. This is most easily accomplished by traction on the gastroesophageal (GE) junction fat pad and the gastric fundus (**FIG 4**). Many surgeons start on the right side by dividing the gastrohepatic ligament and right phrenoesophageal ligament. We have found that it is safer to first approach the hiatus from the left, which provides better visualization, but both approaches are acceptable.

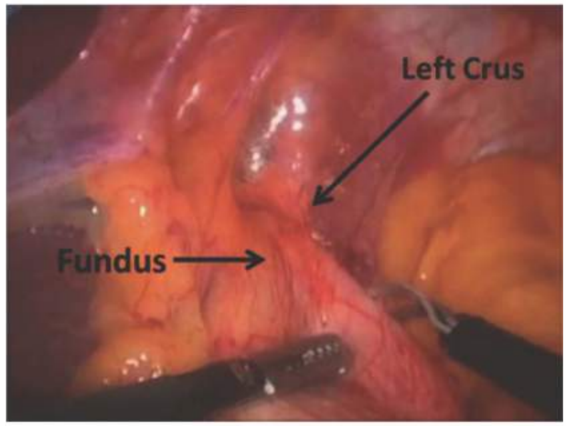

FIG 4 ● The dissection begins on the left side.

LIGATE AND DIVIDE THE SHORT GASTRIC VESSELS

- The short gastric vessels between the greater curvature of the stomach and the spleen are ligated and divided from the gastric midbody to the angle of His (**FIG 5**).

The most superior short gastric vessels can be difficult to expose. Care must be taken to avoid capsule tears to the spleen during this maneuver. More posterior short gastric vessels and retroperitoneal adhesions must also be released to facilitate full mobilization of the fundus (**FIG 6**).

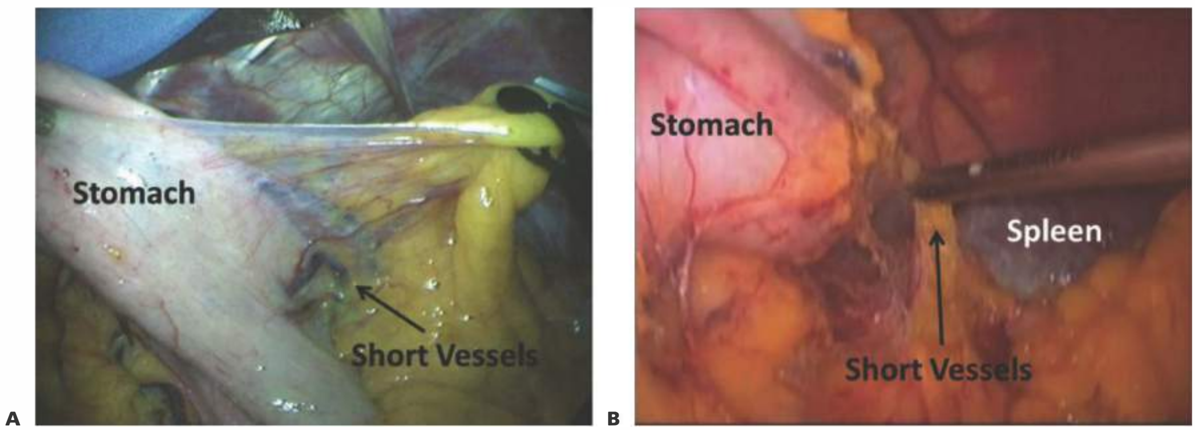

FIG 5 ● **A.** The short gastric vessels are placed on tension to allow for safe division without injury to the stomach. **B.** The short gastric vessels are divided close to the greater curve of the stomach.

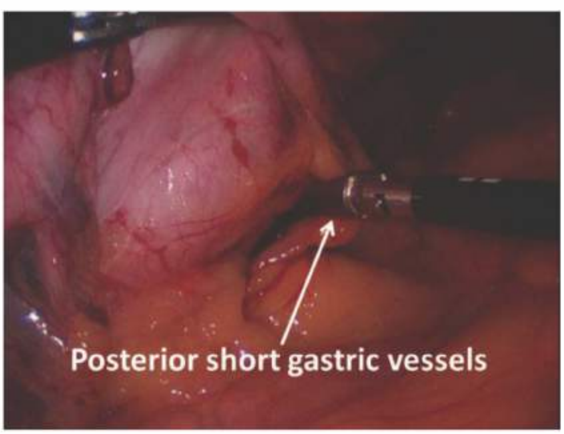

FIG 6 ● The most upper short gastric vessel is posterior and should be divided to free the fundus.

EXPOSE THE ENTIRE LEFT CRUS

- The left phrenoesophageal membrane is opened along its length (FIG 7).

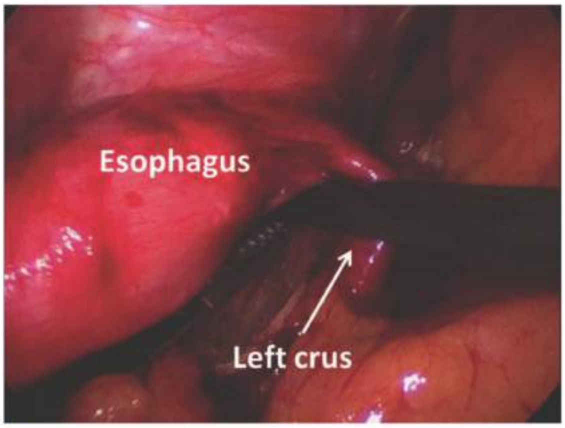

FIG 7 ● After division of the short gastric vessels, the peritoneal attachments along the left crus are incised.

OPEN GASTROHEPATIC LIGAMENT

- The right crus is exposed by opening the gastrohepatic ligament widely, taking care to avoid injury to nerve of Latarjet (FIG 8).

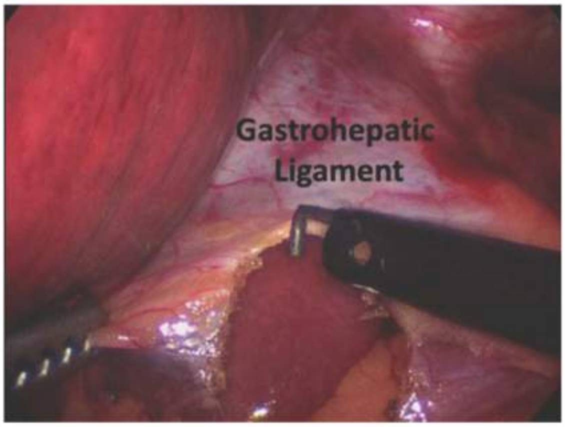

FIG 8 ● The gastrohepatic ligament is divided with cautery, exposing the caudate lobe of the liver.

ENTER THE RIGHT PHRENOESOPHAGEAL MEMBRANE

- The right phrenoesophageal membrane is identified overlying the right crus and is divided to expose the crural fibers beneath. The right phrenoesophageal membrane is opened along its length (FIG 9).

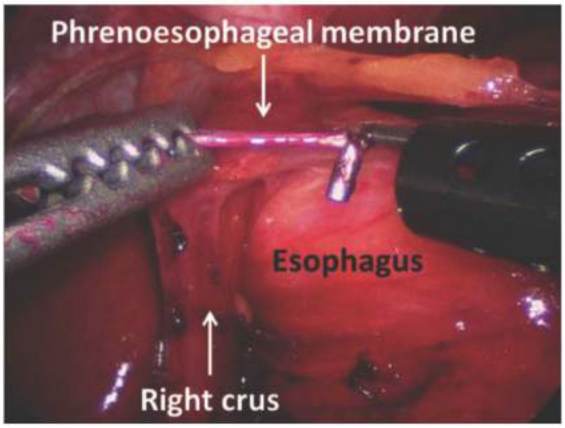

FIG 9 ● The peritoneal attachments along the right crus are incised.

TECHNIQUES

CONNECT LEFT AND RIGHT HIATAL DISSECTIONS

- The left and right dissections of the phrenoesophageal membrane are connected both anteriorly and posteriorly with caution so as not to injure the anterior and posterior vagus nerves. A Penrose drain is placed around the esophagus to aid in gastroesophageal junction retraction and esophageal exposure (**FIG 10**).

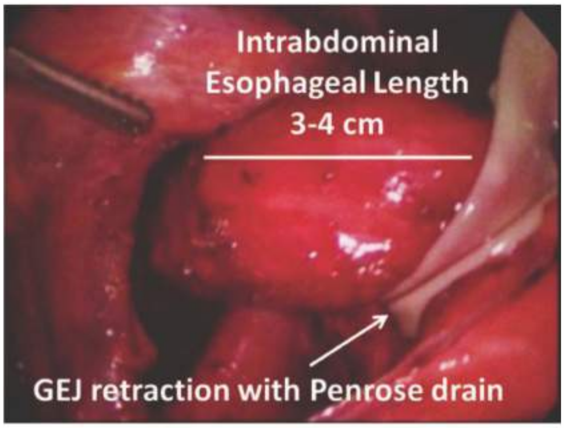

FIG 10 ● At least 3 cm of esophagus are mobilized into the abdominal cavity.

ESOPHAGEAL MOBILIZATION

- The areolar connective tissue surrounding the esophagus is exposed and dissected free by retracting the GE junction with the Penrose drain to mobilize adequate intraabdominal esophageal length (minimum of 3 cm) (**FIG 10**). The anterior and posterior vagus nerves as well as the pleura are protected during this dissection.

POSTERIOR CRUS REAPPROXIMATION

- The right and left crura are reapproximated posteriorly with heavy permanent suture (**FIG 11**) so that the hiatus comfortably accepts a 52-Fr intraesophageal bougie.

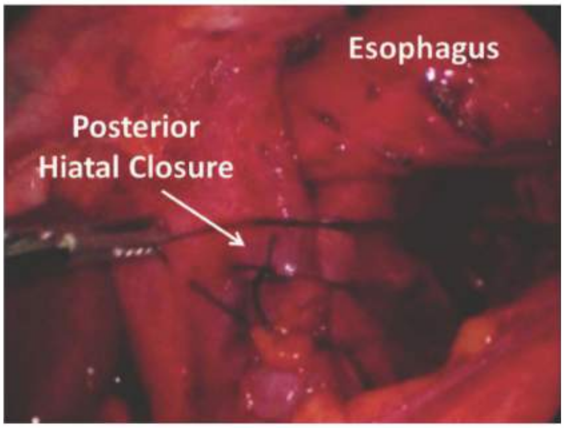

FIG 11 ● A posterior cruroplasty is performed with 0-0 silk sutures.

POSTERIOR STOMACH WALL MARKING STITCH

- Construction of the fundoplication itself is the single critical step where errors are made that affect the short- and long-term success of the operation. To combat this, we place a loose stitch on the posterior gastric wall to mark the proposed site for the first stitch of the fundoplication. Ideally, this stitch is placed 3 cm distal to the GE junction and 2 cm from the greater curvature (**FIG 12**).

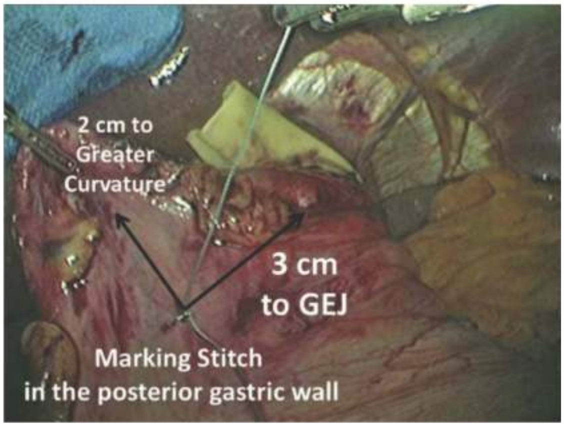

FIG 12 ● A marking stitch is placed on the posterior gastric wall to identify the portion of the fundus to be brought to the right of the esophagus.

PASS THE FUNDUS POSTERIOR TO THE GASTROESOPHAGEAL JUNCTION

- The GE junction is then retracted with the Penrose drain and the posterior gastric fundus is grasped from the patient's right and brought posterior to the GE junction (**FIG 13**). (Note: If the previously placed marking stitch was well placed, it will become visible as the fundus is passed from the patient's left to the right and will serve to mark the location of the first fundoplication stitch to be placed.)

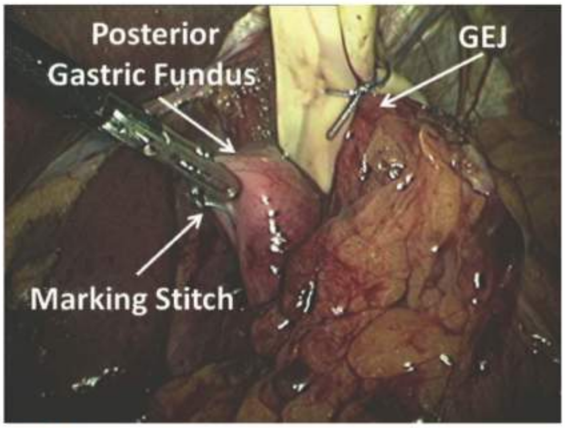

FIG 13 ● The fundus is brought posterior to the esophagus.

IDENTIFY AND GRASP THE ANTERIOR STOMACH

- An optimal fundoplication will be achieved by symmetric geometry. This is accomplished by identifying the place on the anterior gastric wall that is of similar distance from the GE junction and the greater curvature as the previously placed posterior gastric wall marking stitch (**FIG 14**). Once this location is identified, both the anterior and posterior gastric walls are approximated around the distal esophagus at the 10 o'clock position. The wrap should be snug without excessive redundancy but not too tight either.

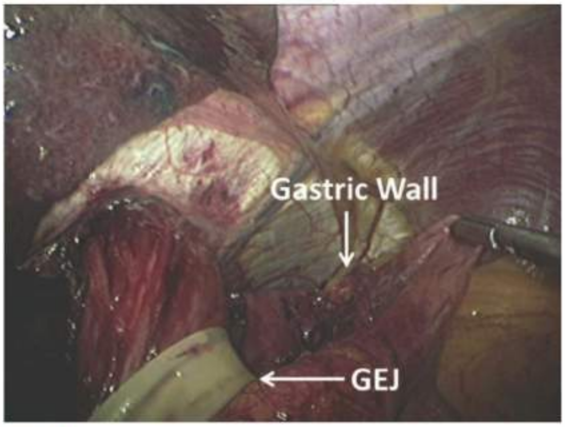

FIG 14 ● The relationship of the stomach to the esophagus for the fundoplication.

FUNDOPLICATION CREATION

- Once symmetric fundoplication geometry is confirmed, four seromuscular permanent sutures are placed from anterior fundus to posterior fundus to secure the fundoplication over a total of 3 cm. Once the first seromuscular stitch is placed, the Penrose drain is removed and a 52-Fr intraesophageal bougie is guided into the stomach to aid in fundoplication sizing. To orient the fundal folds appropriately for the second, third, and fourth fundus-to-fundus stitches, grasp the first fundus-to-fundus stitch and retract it cephalad to the right crus (**FIG 15**). This will result in appropriate alignment of the fundal suture line at the 10 o'clock to 11 o'clock positions (**FIG 16**).

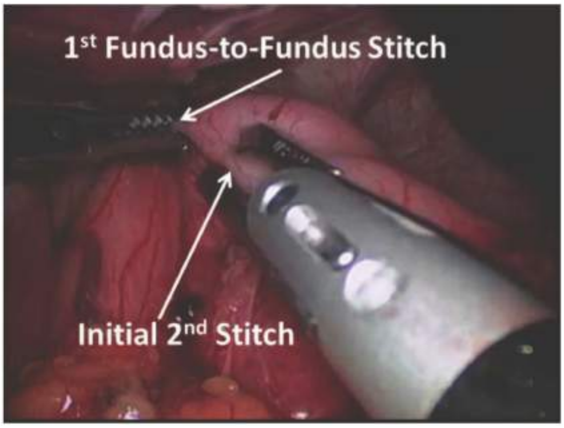

FIG 15 ● The first stitch of the fundoplication is placed most cephalad.

TECHNIQUES

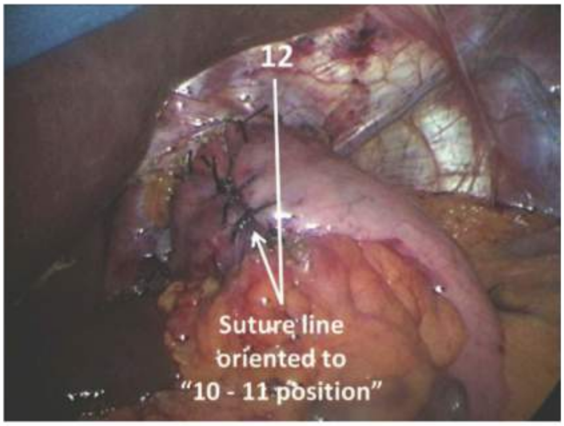

FIG 16 ● The completed fundoplication with the suture line at the 11 o'clock position.

FUNDOPLICATION ANCHORING

- The fundoplication is then anchored with separate stitches to the right and left crura as well as esophagus (fundus-esophagus-crus) to anchor the fundoplication in the abdomen and prevent herniation. Caution must be used so as not to tear the esophageal or crural fibers with these stitches. A final stitch from the posterior fundus to the crural closure can be placed to prevent posterior herniation. (The anterior space is protected by the left lateral lobe of the liver.)

INTRAOPERATIVE ENDOSCOPY

- Intraoperative endoscopy is used to confirm a well-positioned fundoplication prior to desufflation of the abdomen and removal of trocars.

PEARLS AND PITFALLS

Indications	■ Objective evidence of abnormal gastroesophageal reflux by 24-hour pH monitoring is essential to consider antireflux surgery because symptoms alone can be misleading. ■ Additional mandatory preoperative studies for operative planning: esophageal manometry, upper endoscopy, and esophagogram.
Hiatus dissection	■ Either a left-to-right or a right-to-left hiatal dissection is acceptable. We prefer starting the dissection on the left as it minimizes the risk of inadvertently tearing short gastric vessels and splenic injury when working from the right. ■ Mediastinal esophageal mobilization is necessary to gain adequate intraabdominal esophageal length for proper fundoplication creation.
Fundoplication calibration	■ A 52-Fr intraesophageal bougie is necessary to calibrate the fundoplication size. ■ The first fundoplication stitch is easier without the bougie in place. After the first stitch, advancing the bougie into the stomach must be done with caution as the bougie can perforate the GE junction.
Fundoplication orientation	■ An ideal fundoplication will lay so that the suture line is at the 10 o'clock to 11 o'clock positions on the esophagus.

POSTOPERATIVE CARE

- Postoperative dietary modifications: Clear liquids are started postoperatively and are advanced to full liquids the following day. The patient is typically discharged on the first postoperative day. Over 2 weeks, diet is advanced to a soft and then finally a regular diet as the patient's dysphagia resolves.
- Other postoperative instructions: To decrease postoperative bloating, no straws are used and carbonated beverages are avoided.
- Activity restrictions: No lifting greater than 10 to 15 lb or aggressive physical activity is strictly observed for 6 weeks to avoid stress to the diaphragmatic sutures.

OUTCOMES

- Long-term outcomes (median 69-month follow-up) for laparoscopic antireflux surgery reveal 90% of patients have resolved or improved heartburn and regurgitation. Seventy-five percent of patients have resolved or improved dysphagia. Sixty-nine percent of patients have resolved or improved cough and hoarseness.
- Postoperative side effects include new-onset bloating (9%), diarrhea (11%), and dysphagia (2%).
- Ninety percent of patients report that they were happy with their decision to undergo laparoscopic antireflux surgery.[2]

COMPLICATIONS

- Splenic or liver injury
- Hollow viscus perforation
- Dysphagia
- Pneumothorax

Chapter 23

Laparoscopic Mesh Hiatal Hernia Repair

Ellen H. Morrow   Brant K. Oelschlager

DEFINITION

- A hiatal hernia is an enlarged diaphragmatic hiatus, allowing for passage of the stomach or other organs into the chest.
- Hiatal hernia is traditionally divided into several types; the principle difference is sliding versus paraesophageal. The sliding type is much more common. This is type I.
- Paraesophageal is type II. This involves herniation of the stomach above the gastroesophageal (GE) junction, which remains in the abdomen.
- Type III is a combination of types I and II, with the GE junction in the chest, but with stomach herniating above it. This is also referred to as a paraesophageal hernia (PEH) and is much more common than a type II.
- A type IV PEH involves herniation of additional organs other than stomach such as the transverse colon.

DIFFERENTIAL DIAGNOSIS

- The type of hiatal hernia should be discerned as described under definition and differentiated from other nonhiatal diaphragmatic hernias.
- This is a diagnosis that is often made with imaging prior to surgical referral. If imaging has not yet been performed, there are other entities that could have similar clinical presentation.
- These include gastroesophageal reflux disease (GERD), gastritis, peptic ulcer disease, chronic mesenteric ischemia, angina, myocardial infarction, or aortic dissection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Like type I hernias, these patients may present with GERD symptoms (e.g., heartburn, regurgitation, symptoms related to aspiration, etc.); however, at least half of patients will not complain of significant GERD. Patients will often present with a history of postprandial abdominal or chest pain, early satiety, dysphagia, and regurgitation. Symptoms are frequently related to the volume of food they have consumed. They may have associated weight loss.
- PEHs can also present with respiratory symptoms such as dyspnea or cough. Anemia is a common presenting symptom of a large hiatal hernia and is often the only finding in a gastrointestinal (GI) workup.
- Rarely, PEHs can present with acute obstruction.
  - This is often caused by gastric volvulus.
  - This will present with increased severity of symptoms; complete intolerance to oral intake; severe pain; and occasionally, even systemic inflammatory response or sepsis if the stomach becomes ischemic.
- There are not generally physical findings specific to this condition.
  - The patient can be examined for changes associated with GERD in the oropharynx.
  - Abdominal exam may reveal some epigastric tenderness.
  - There may be signs of weight loss or overall frailty.
  - There may be diminished breath sounds.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The workup for hiatal hernia is similar to the GERD workup.
- An esophagram is often the most valuable study; this provides images of the hernia in a dynamic fashion using fluoroscopy (**FIG 1**). This is the best study for getting an overall size and position of the stomach within the hernia.
- Hernias are frequently diagnosed on computed tomography (CT) for abdominal pain, although this is not the initial test to obtain if you are most suspicious of hiatal hernia. It will, however, usually make the diagnosis and can rule in or out other things.
- Upper endoscopy can be helpful for visualizing the size of the hernia and more for examining the mucosa for associated conditions.
  - Cameron's erosions are linear erosions that can be found in the stomach related to constriction by the diaphragm.
  - Changes related to associated GERD can also be seen in the esophagus such as erosive esophagitis and Barrett's esophagus.
  - Any neoplastic lesion should be ruled out prior to operative repair.

FIG 1 ● Upper GI study demonstrated large hiatal hernia with stomach in the chest.

- Manometry is valuable in planning the antireflux procedure that will be performed in conjunction with repair of the hernia. Normal motility will allow for creation of a full wrap, as opposed to partial.
- pH testing is not generally required, unless the patient is presenting primarily with GERD symptoms. In this case, it may be useful as a baseline.

SURGICAL MANAGEMENT

Preoperative Planning

- Indications for repair of hiatal hernias:
  - Sliding hiatal hernias (type I) should not be repaired unless the indication is associated GERD, in which case, they should be repaired at the time of planned fundoplication.
  - PEHs (types II to IV) should generally be repaired if symptomatic. In younger (<60 years of age) and healthier patients, repair of even relatively asymptomatic hernias is indicated given the risk of incarceration, although this risk is smaller than once thought.
  - Mesh hiatal hernia repairs generally need to be considered only in patients with PEHs (larger hernias).
- Many patients with hiatal hernias are elderly, and they may have serious comorbidities or frailty. In these patients, a thorough medical evaluation should be completed prior to any elective hernia repair.
- Some of them may be too frail or high risk for a full hiatal hernia repair with fundoplication but are very symptomatic and need intervention. In these patients, it may be more prudent to plan for a shorter procedure without full dissection of the hernia sac; hernia reduction with gastrostomy tube gastropexy may be more appropriate in these patients.

Positioning

- As for other foregut procedures, patients should be in low lithotomy with a beanbag support and both arms tucked (**FIG 2**).
- The patient will be in steep reverse Trendelenburg for most of the case.
- The surgeon can operate from the foot of the table, with the assistant on the patient's left.

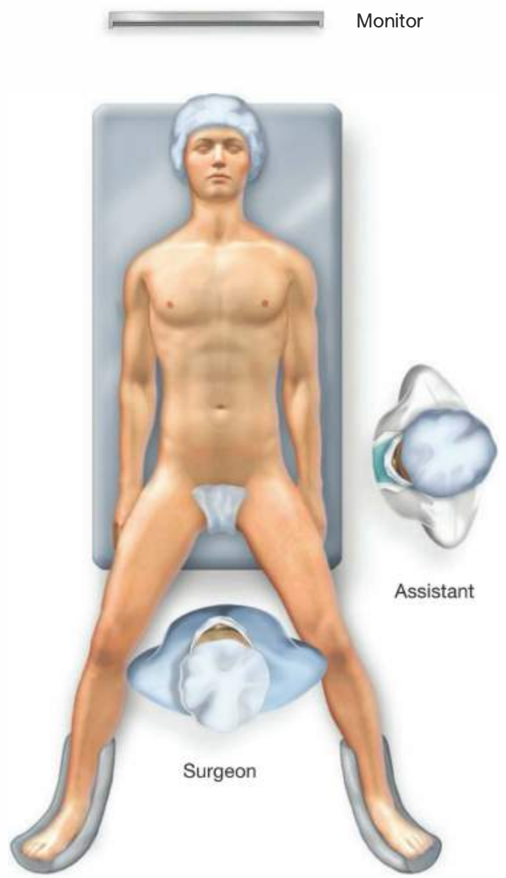

FIG 2 ● Patient positioning for hiatal hernia repair; low lithotomy. The surgeon stands between the patient's legs with the assistant on the patient's left.

SETUP AND PORT PLACEMENT

- After sterile prep, the upper abdomen is draped. Equipment for laparoscopy is passed off and secured.
- The peritoneal cavity is accessed using a Veress needle, and pneumoperitoneum is obtained.
- An 11-mm cutting optical trocar is inserted in the left subcostal position.
- Additional ports are placed under direct vision as follows (**FIG 3**):
  - Camera port (11 mm) in epigastric position; a 5-mm port can also be placed here depending on surgeon preference for scope size.
  - Assistant (5 mm) port in left lateral position
  - Surgeon's left hand port (5 mm) in right upper quadrant
- A Nathanson liver retractor is then placed in the upper midline for retraction of the left lobe.

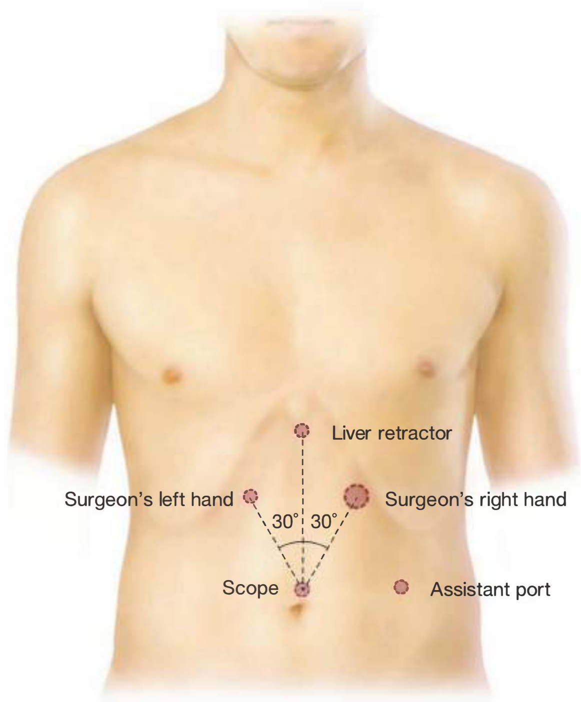

FIG 3 ● Port placement for hiatal hernia repair.

REDUCTION

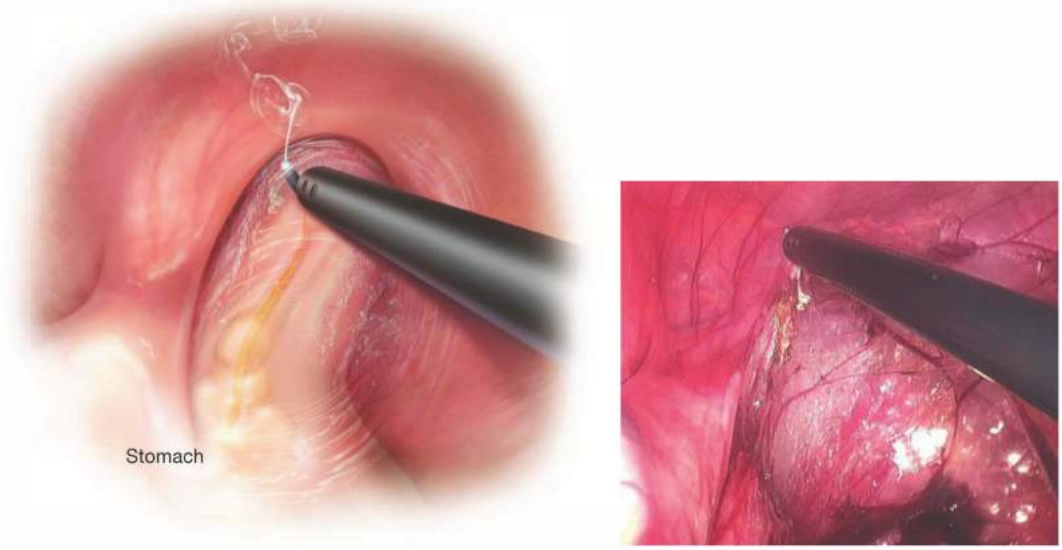
- The stomach and any other hernia contents are reduced into the abdominal cavity as possible; with a PEH, the stomach will almost never fully reduce and the surgeon should not attempt to do so. Just reduce the stomach that is free and not attached within the mediastinum.

MOBILIZATION

- The short gastric vessels are ligated with an electrical or ultrasonic sealing device in order to mobilize the fundus fully. Begin ligation near the inferior border of the spleen (see **FIG 3**).
- Care must be taken to also divide any attachments or vessels between the fundus and the retroperitoneum as adhesions are common.

DISSECTION OF HIATUS AND HERNIA SAC

- The phrenoesophageal membrane and hernia sac are divided at the muscular edge of the crus.
- Once the crus is visualized, the surgeon can be assured that all layers of the sac have been divided. In this way, the surgeon begins to develop a plane outside of the hernia sac and not within it.
- The attachment of the sac to the hiatus is divided until it is freed circumferentially. After this is complete, the sac is released from the mediastinum, with care to avoid the pleura (**FIGS 4** and **5**). This is facilitated with the use of gentle traction and the diffusion of carbon dioxide (CO_2) from the pneumoperitoneum.
- The appropriate plane should appear areolar and largely avascular.



A B

FIG 4 ● Line drawing **(A)** and intraoperative photo **(B)** of mediastinal dissection. The herniated stomach is seen on the left side of the screen. Electrocautery is used to divide the sac, revealing an areolar plane in the mediastinum outside the sac.

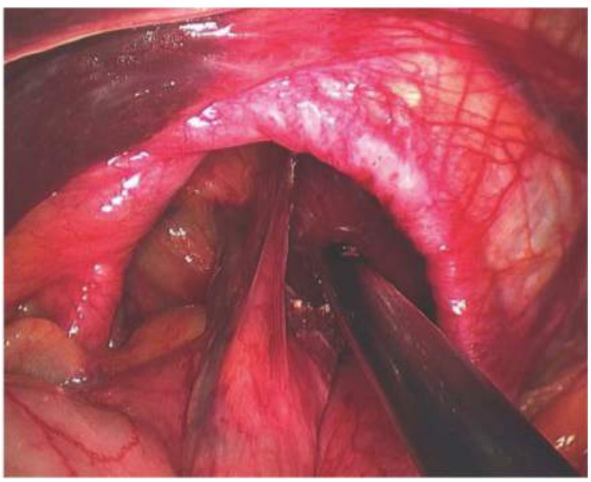


FIG 5 ● A large hiatal hernia defect. Dissection of the sac was begun from the patient's left side. The sac is still connected to the herniated stomach in the central anterior mediastinum.

ESOPHAGEAL MOBILIZATION

- A Penrose drain is then placed around the distal esophagus and used to place downward and alternating lateral traction on the esophagus as it is circumferentially mobilized in the mediastinum.
- Care is taken to ligate or cauterize small vessels in the mediastinum as needed.
- Mobilization is continued until the GE junction lies in the abdomen without tension, preferably with 3 cm of esophagus in the abdomen.
- In the setting of a large hiatal or PEH, the esophagus is always relatively foreshortened. If aggressive mobilization of the mediastinal esophagus is performed, in our experience, adequate esophageal length can be obtained. If not, then an esophageal lengthening procedure will be needed (see Part 1, Chapter 20).
- A lighted bougie is then placed into the esophagus and stomach by the anesthesia team. Careful communication between the anesthesia and surgical teams is required to avoid complications during placement of the bougie. The

anesthetist should be able to see one of the laparoscopy monitors. If there is any question as to the location of the esophagus earlier in the procedure, the lighted bougie can be helpful in locating it.

- The hernia sac is then amputated and removed. The anterior vagus nerve should be identified and preserved here as long as adequate esophageal mobilization has been obtained. This is done by only removing the anterior sac to the left of the vagus nerve.
- Adequate removal of the hernia sac facilitates the fundoplication later.
- If esophageal mobilization has been inadequate, the vagus can be ligated here,[1] or a Collis or wedge gastroplasty can be performed.[2]

CRURAL CLOSURE

- The crura are reapproximated using permanent suture (**FIG 6**).
- Most of the closure should be posterior, as the muscle is more robust there.
- Occasionally, adequate closure cannot be achieved with only posterior suturing due to the size of the defect; in this case, a relaxing incision or anterior sutures may be required.
- A relaxing incision can be made on the right side of the right crus to release the right crus toward the left and allow for hiatal closure.

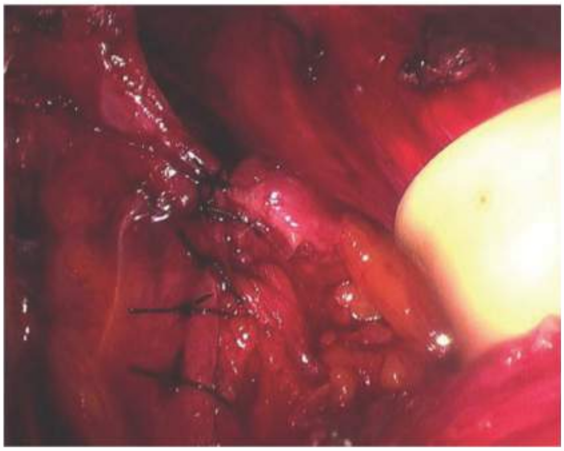

FIG 6 ● Primary repair of the crural defect posteriorly with interrupted sutures.

MESH PLACEMENT

- A biologic mesh is then cut to cover the defect, usually in a U or C shape.
- This is introduced through an 11-mm port and placed flat against the hiatus.
- Permanent sutures are then used to secure the superior aspects of the mesh to the crus on either side (**FIG 7**).
- The mesh can be completely secured with suture, or the remaining fixation can be performed with fibrin glue.
- If a relaxing incision was necessary, it should also be covered by the mesh.

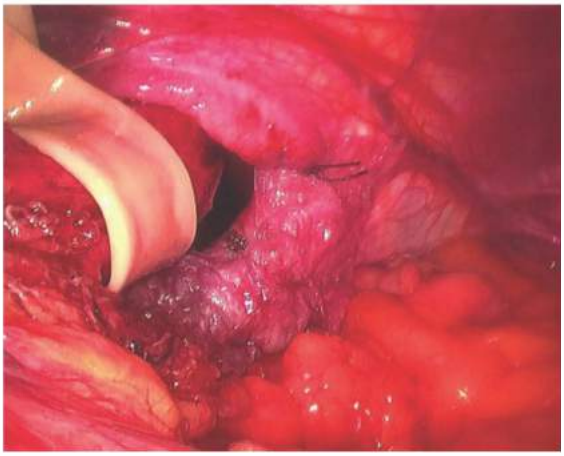

FIG 7 ● View of mesh placement from the patient's left side. It is secured with suture superiorly and fibrin glue inferiorly. The mesh covers the posterior defect.

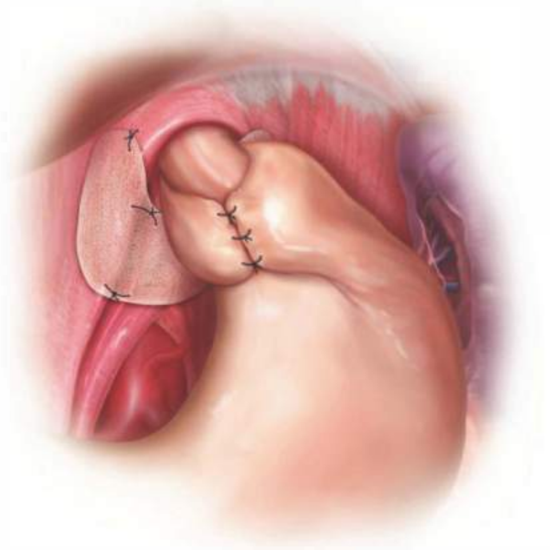
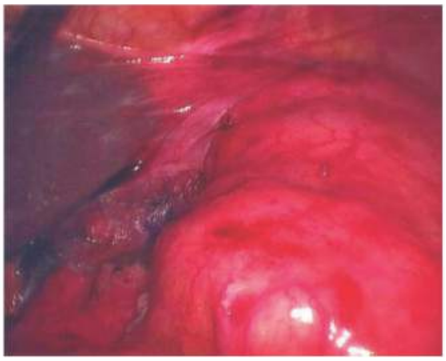
FUNDOPLICATION

- Full fundoplication should be performed as long as the patient's esophageal motility allows, to treat reflux and to prevent reherniation. Fundoplication technique is described in another chapter (**FIG 8**).
- Intraoperative endoscopy should be performed at the conclusion of the case to confirm wrap positioning and location of the GE junction in the abdomen.



A



B

FIG 8 ● Line drawing **(A)** and intraoperative photo **(B)** of full fundoplication.

PEARLS AND PITFALLS

Indications	■ Only symptomatic (GERD associated) sliding hernias should be repaired. ■ All PEHs (types II to IV) can be considered for repair given the risks of volvulus and obstruction.
Patient selection	■ In elderly or infirm patients, consider gastropexy as an alternative to PEH repair. ■ In morbidly obese patients, consider laparoscopic sleeve gastrectomy or gastric bypass as an alternative operation.[3]
Dissection	■ Full dissection around the sac must be accomplished. Divide the sac off of the crus and then maintain an areolar plane in the mediastinum
Esophageal mobilization	■ Must be carried superiorly into the mediastinum to ensure adequate intraabdominal esophageal length (3 cm).
Mesh placement	■ After primary repair of a large hiatal defect, mesh reinforcement may be used. Biologic mesh has fewer potential complications[4] but may have a higher recurrence rate.[5]

POSTOPERATIVE CARE

- The patient generally has an overnight stay in the hospital.
- Patients should be given an incentive spirometer, have chemical deep vein thrombosis (DVT) prophylaxis, and prompt Foley catheter removal.
- Patients can be given clear liquids on the night of surgery and the diet can be advanced the following day. They should be discharged on a pureed diet and should progress to soft diet over the next month. Pills should be crushed or converted to elixirs for 1 month.
- Patients should anticipate at least 2 more weeks of recovery at home, depending on their age and comorbidities.
- Activity is largely unrestricted, but heavy lifting or other Valsalva maneuvers should be avoided to keep the intraabdominal pressure down and avoid early hernia recurrence.

OUTCOMES

- A recent randomized controlled trial of laparoscopic PEH repair with and without biologic mesh demonstrated a lower recurrence rate at 6 months with biologic mesh.[5]
- This difference in outcomes did not persist when patients were reexamined with upper GI series at a median follow-up time of 5 years.[6]
- At that time, the recurrence rate was found to be the same between the two groups; there was a 50% radiographic recurrence rate.
- Most of these recurrences were small and did not correlate with patient symptoms except a mildly increased rate of heartburn.[7]
- Despite the high rate of radiographic recurrence, all symptoms were improved at long-term follow-up.
- Only 3% of patients in this trial ultimately required reoperation for hernia recurrences.

COMPLICATIONS

- As with any major abdominal surgery, complications can include bleeding, infection (either at the surgical site or elsewhere), or thromboembolic events.
- Complications that are particular to PEH repair can include postoperative respiratory compromise.
  - Changing pulmonary physiology after reduction of the herniated stomach, general anesthesia, and postoperative abdominal pain can lead to increased dyspnea and oxygen requirement during the immediate postoperative period.
  - This generally stabilizes enough for discharge within 1 to 2 days or the patient can be discharged on a short course of home oxygen.
- Pneumothorax can occur intraoperatively during mediastinal dissection. The pleura should be repaired to prevent further insufflation of the pleural cavity with CO_2. Once the pleura is closed and the abdomen is desufflated, the CO_2 is reabsorbed quickly and decompression is not generally required.
- Following fundoplication, there can be some dysphagia during the early postoperative period. This can generally be managed with dietary modification. Bloating can also be a complaint early on.
- Hernia recurrence is a potential complication. Recurrence was covered in the "Outcomes" section.

Chapter 24 | Redo Fundoplication

C. Daniel Smith

DEFINITION

- A variety of fundoplication procedures are used today (Table 1), primarily to treat gastroesophageal reflux disease (GERD).
- The 360-degree fundoplication (Nissen fundoplication) is the most popular of the various fundoplication techniques.
- Although fundoplication, when done by an experienced surgeon, results in control of GERD and significant improvement in quality of life in the majority of patients, this operation does fail, necessitating further surgery or a redo fundoplication.[1–3]
- Broadly speaking, there are three reasons that an operation will fail to control a patient's symptoms and/or GERD.
  - Errors in workup or patient selection
  - Errors in operative management
  - Natural history of the particular antireflux operation or condition being treated

DIFFERENTIAL DIAGNOSIS

- Fundoplication failure is defined as either recurrence of the condition or symptoms that necessitated the fundoplication (e.g., recurrent GERD or recurrent hiatal hernia) or the development of new symptoms not present preoperatively (e.g., dysphagia, nausea, or regurgitation).
- One typically sees failure of a fundoplication in a few distinct patterns.[4–6] These are outlined in Table 2 and **FIGS 1** and **2**.
- When considering these reasons for failure, hiatal hernia is the most common cause (44% of cases). Wrap disruption or breakdown is the next leading cause, accounting for 16% of failures. Slipped wraps account for 11.7% of failure, and finally, wraps improperly positioned at the time of their initial construction is found in 3.9% of cases.[7]
- Wrap or crural stenosis is a rare cause of failure and often times hard to determine as a primary etiology of failure.
- If mesh was used at the initial operation, a distinctly different pattern of failure and management strategy is needed.[8]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Common symptoms of failure of fundoplication are outlined in Table 3.
- Recurrent GERD is the most common (59%) and dysphagia (31%) the next most common. Although these symptoms can occur with any or all of the patterns of failure, there are patterns of symptoms that correlate highly with a given mechanism of failure (**FIG 3**).

Table 1: Fundoplication Procedures

360-degree fundoplication (Nissen fundoplication)
180-degree posterior fundoplication (Toupet fundoplication)
180-degree anterior fundoplication (Dor fundoplication)
Posterior gastropexy (Hill procedure)
Transthoracic posterior plication (Belsey procedure)

Table 2: Patterns of Fundoplication Failure

Wrap disruption or loosening
Wrap migration or slip
Hiatal herniation or reherniation
Wrap or crural stenosis
Wrap too loose or misplaced at the initial operation

- Gross anatomic abnormalities such as hiatal hernia or severe wrap/crural stenosis are more likely to present with symptoms related to poor esophageal transit and emptying. These symptoms commonly include dysphagia, chest pain, and regurgitation.
- The wrap that has loosened or come undone more commonly presents with recurrent GERD symptoms, often identical to those being experienced before the first antireflux procedure. Commonly, this includes typical symptoms such as heartburn, regurgitation, and chest pain but can also be more atypical symptoms such as cough, laryngitis, or asthma. Again, the relationship and similarity of symptoms to those before the initial operation is strongly predictive of wrap disruption or loosening.
- A slipped wrap will often have a broad constellation of symptoms with more prevalence of nausea and epigastric pain than the other presentations.
- A favorable response to antisecretories and postural regurgitation predicts wrap loosening or incompetence, whereas poor tolerance of heavy dense foods or weight loss predicts hiatal herniation or esophageal outlet issues. Improvement

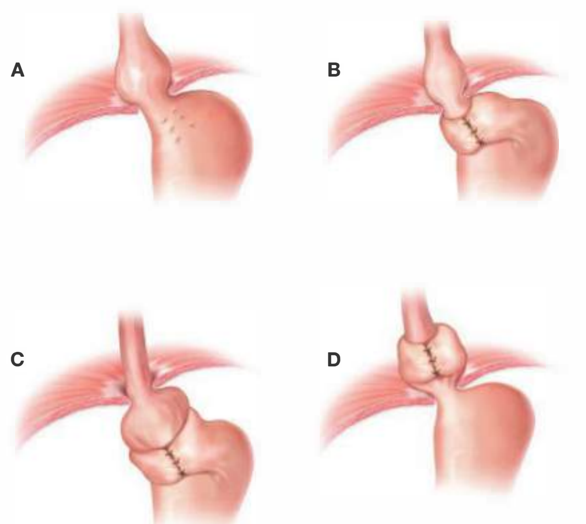

FIG 1 ● Common anatomic patterns of antireflux surgery failure: **(A)** fundoplication disruption, **(B)** tight fundoplication or crural stenosis, **(C)** slipped fundoplication, and **(D)** hiatal herniation.

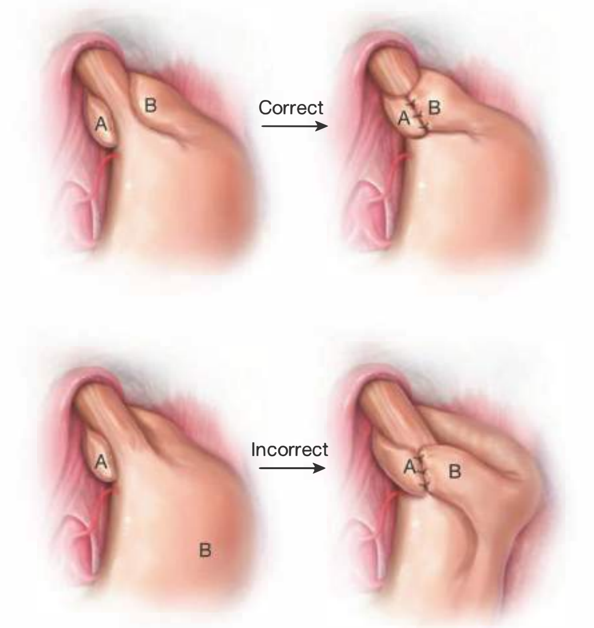

FIG 2 ● Illustration of incorrectly created fundoplication compared to correct creation.

with dilation supports esophageal outlet restriction. Failure of symptoms to respond to any intervention is more likely with wrap slippage.

- A confusing presentation is the patient with early postprandial bloating or meal-induced diarrhea. With this symptom constellation, one should be suspicious of vagal nerve injury or inflammation (dysfunctional gastric emptying). This symptom complex in the absence of an obvious anatomic abnormality or a positive pH test should lead one to pursue further workup rather than a redo antireflux operation.

Table 3: Common Symptoms of Fundoplication Failure

Heartburn
Chest pain
Regurgitation
Dysphagia
Nausea
Bloating
Shortness of breath (SOB)
Aspiration

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Testing for suspected fundoplication failure falls into testing to secure a diagnosis or reason for failure and testing for operative planning. An algorithm for the workup of patients suspected to have failed a prior fundoplication is shown in **FIG 4**.

Establishing the Diagnosis

- In pursuit of a diagnosis of failure, the workup should start with an anatomic assessment. This usually includes an upper endoscopy (esophagogastroduodenoscopy [EGD]) and contrast esophagram.
- Often, a contrast esophagram is all that is needed to identify the pattern of failure. **FIG 5** depicts the esophagram findings corresponding to the various patterns of failure.
- Alternatively, an EGD may clearly show an anatomic abnormality. The common endoscopic findings of failure are outlined in Table 4.
- In many cases, if the presenting symptoms correlate with findings on an esophagram or EGD, this is all that is needed to diagnose failure and the need for reoperation.
- If recurrent GERD is the dominant presentation, then pH testing should be obtained.

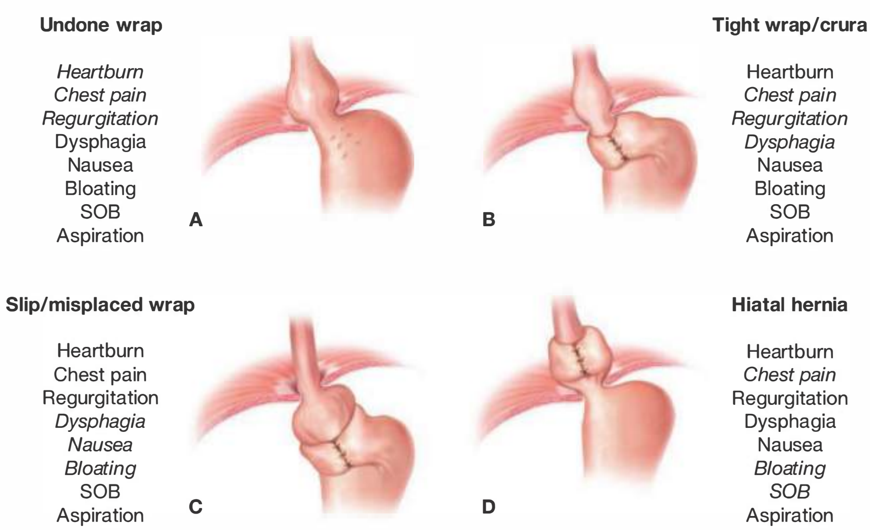

FIG 3 ● **A–D.** Symptoms of antireflux surgery failure correlated with anatomic pattern of failure. SOB, shortness of breath.

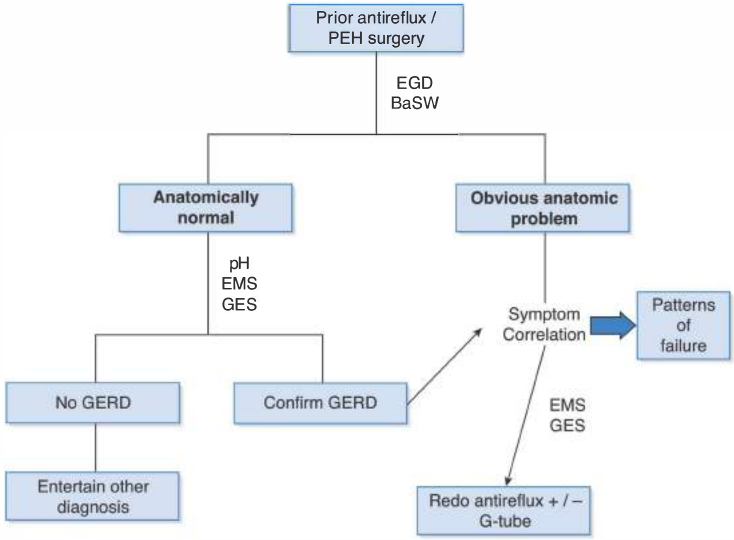

FIG 4 ● Flowchart of workup for possible antireflux surgery failure. *PEH*, paraesophageal hernia; *EMS*, esophageal motility study; *GES*, gastric emptying study.

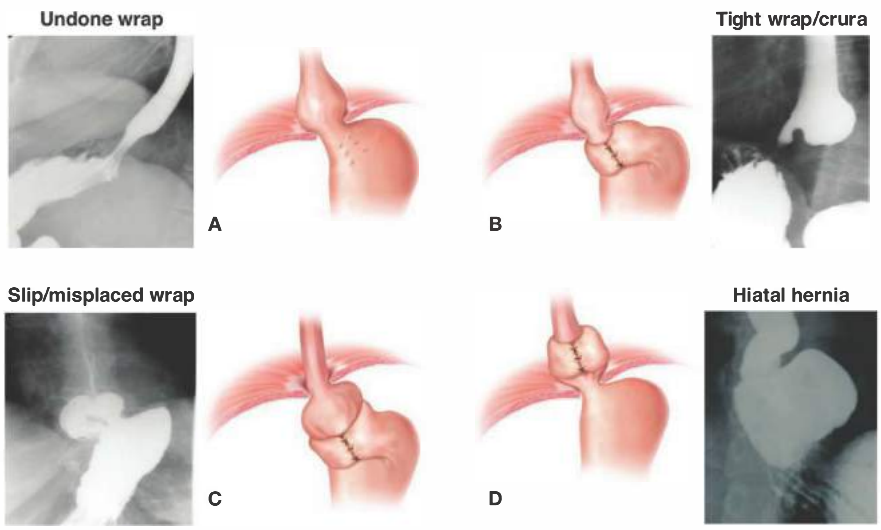

FIG 5 ● **A–D.** Contrast swallow examples for each common anatomic pattern of failure.

Table 4: Endoscopic Findings of Failed Fundoplication

Viewing Location	Findings (Pattern of Failure)
Retroflex view of distal esophagus	Gastric folds extending into wrap (slipped/misplaced fundoplication) Esophagogastric junction does not hug scope (loose or undone fundoplication) Gastric mucosa extending above hiatal indentation (hiatal hernia)
Forward view of distal esophagus	Narrowing that does not accept scope (tight wrap or crural stenosis) Esophagitis/esophageal ulcers (loose or undone fundoplication) Constriction on proximal stomach below constriction of wrap (hiatal hernia) Constriction of wrap distal to esophagogastric junction (slipped or misplaced wrap)

Planning for Operative Management

- With a diagnosis of fundoplication failure secured, further testing may be indicated to help plan the most effective reoperative strategy.
- The most common conditions associated with failure that need to be investigated are esophageal motility problems and impairment in gastric emptying. All patients should undergo an esophageal motility study and a gastric emptying study before redo surgery.
- Impairment in esophageal motility may indicate the need for a partial 270-degree fundoplication rather than a 360-degree fundoplication. Classically, a partial fundoplication should be considered if normal esophageal peristalsis is present in less than 70% of swallows or esophageal body pressure is less than 30 mmHg.
- Delayed gastric emptying may require the addition of a gastrostomy tube to provide gastric decompression in the early postoperative period, thereby preventing gastric distension–induced crural or wrap disruption.

SURGICAL MANAGEMENT

- Redo fundoplication can be both rewarding and challenging. Although the right diagnosis and proper preparation are important, they are no substitute for experience with all manner of foregut surgery. Redo fundoplication should not be undertaken by a general surgeon who occasionally performs elective fundoplication.

Preoperative Planning

- For a skilled laparoscopic surgeon, almost all redos can be approached laparoscopically. Early conversion to an open approach is more likely in the following situations:
  - Multiple prior foregut procedures, especially prior open repairs
  - Hiatal hernia with a significant amount of the stomach incarcerated in the chest, especially if mesh was used
  - Prior operations that were complicated by postoperative leak, fistula, or early reoperation
- In these situations where one may predict a higher likelihood of conversion, it is prudent to be prepared for not only an open approach but also a thoracoabdominal approach.
- EGD should be available intraoperatively for all redos, and an EGD performed by the surgeon before scrubbing provides valuable firsthand anatomic information that is useful intraoperatively. Leaving the scope in the stomach allows intraoperative identification of key anatomic structures such as the squamocolumnar junction or the location of the fundoplication.

Positioning

- A split-leg approach is used in nearly all cases (**FIG 6**). If conversion to an open approach is anticipated, one arm should be tucked so that a table-mounted retraction system can be secured at the patient's shoulder, well away from the surgeons' standing position at the patient's side for open access.

FIG 6 • Patient positioning for reoperative antireflux operation.

GAINING ABDOMINAL ACCESS AND PORT PLACEMENT

- If the prior fundoplication was performed laparoscopically, it is reasonable to attempt abdominal access by passing a Veress needle through an area in the upper abdomen free of prior incisions. The safest means of access is a visualized access using an open technique.
- A five-trocar technique as depicted in **FIG 7** is used.

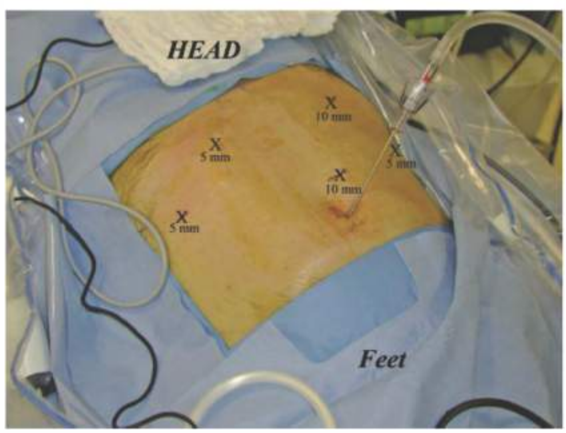

FIG 7 • Illustration or photo of trocar placement on abdomen.

IDENTIFY AND EXPOSE HIATAL ANATOMY

- The dissection commences by approaching the esophageal hiatus from the left. The greater curve of the stomach is found and followed upward toward the angle of His while using a tissue-sealing device to divide any remaining short gastric vessels or vascularized scar tissue (Table 5).
- Once the base of the left crus is found, the left crus is cleared of adhesions up to and around the crural arch as far as possible (**FIG 8**). Often, the left lobe of the liver is fused to the fundus starting along the crural arch limiting how much crural arch can be exposed at this point in the operation.
- The mediastinum is entered from the left as far posterior as possible. Usually, this opens a plane just anterior to the aorta and behind the esophagus (**FIG 9**). This plane is often very friendly allowing the posterior mediastinum to be cleared proximally and to the right, over the top of the aorta toward the spine. A ½-in Penrose drain cut 6-in long can be left in the posterior mediastinum (**FIG 10**) to be found later when the mediastinum is entered from the right posteriorly.
- With at least ½ of the esophageal hiatus exposed from the left, the more complicated dissection of the right crus can be undertaken more safely with some awareness of the esophageal hiatus relationship to the scar plate that tends to envelop the right side of the hiatus.
- Starting distal along the lesser curve of the stomach and well below the adhesions of the left lobe of the liver to the anterior surface of the stomach will often reveal a friendly dissection plane leading under the caudate lobe of the liver and to the base of the right crus (**FIG 11**).

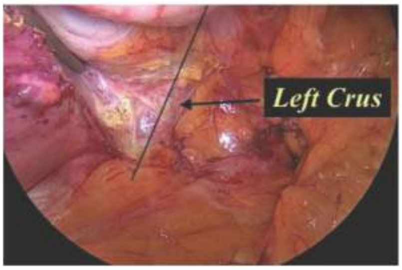

FIG 8 ● Photo of left crus exposure.

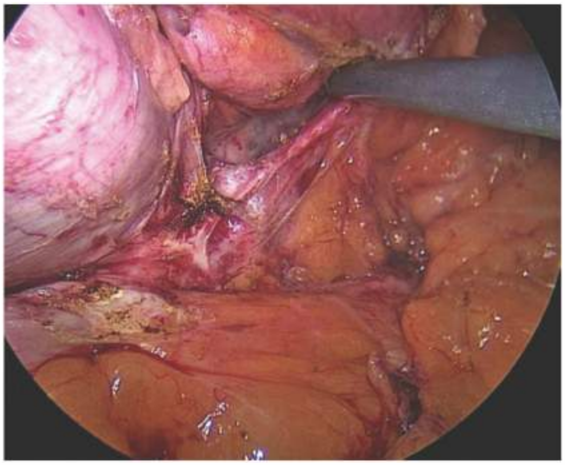

FIG 9 ● Posterior mediastinum opened from left.

Table 5: Sequence for Successful Hiatal Dissection

- Start along greater curve of stomach.
- Divide any remaining short gastric vessels (ideally none are encountered).
- Expose left crus from base through arch.
- Enter mediastinum from left and posterior to hiatal content.
- Dissect further proximal into mediastinum and from left to right along plane anterior to aorta until over spine
- Leave left side of hiatus and develop plane between anterior surface of stomach and undersurface of liver to find caudate lobe of liver.
- Following lower edge of caudate lobe of liver, expose right crus from base to arch (often need to free wrap adhesions to right crus).
- Enter mediastinum from right and complete retroesophageal window.
- Encircle esophagus with Penrose drain to manipulate and control esophagus during rest of mediastinal dissection and esophageal mobilization.
- After hiatus completely dissected and esophagus mobilized, take down prior wrap by releasing anterior fusion/sutures and dissect wrap from esophagus
- Intraoperative endoscopy to identify location of squamocolumnar junction (adequate esophageal length) and wrap has been completely taken down (retroflexed view)

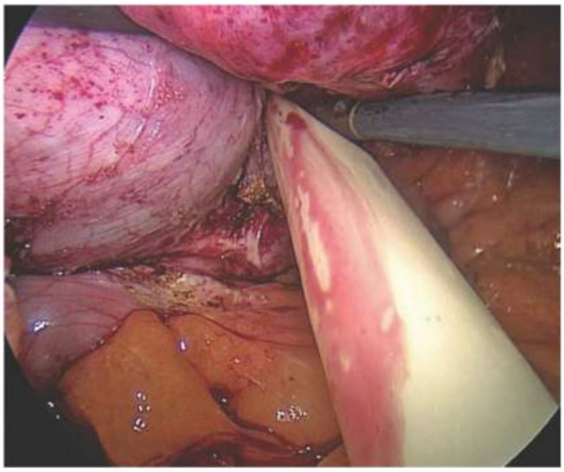

FIG 10 ● Penrose drain left in mediastinum from left.

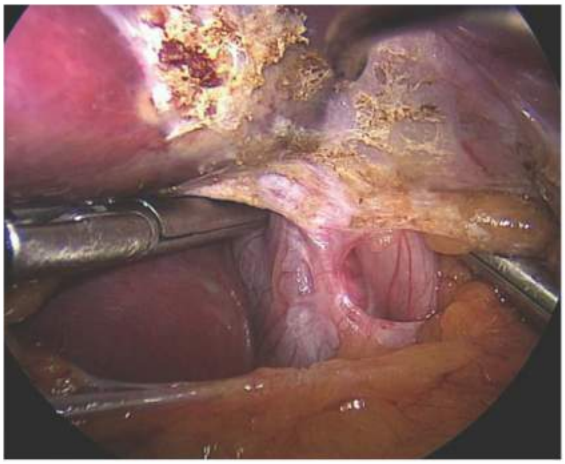

FIG 11 ● Approaching the base of right crus along caudate lobe of liver.

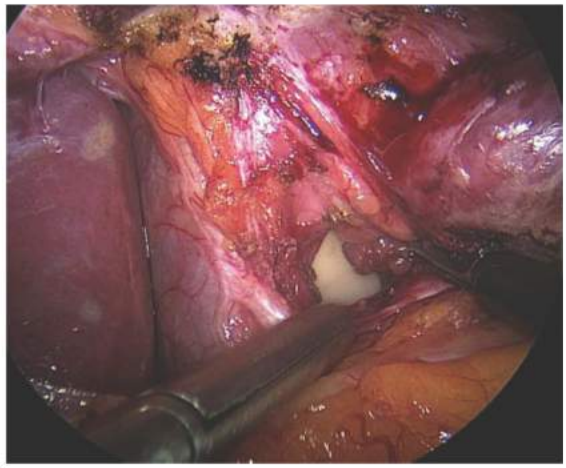

FIG 12 ● Penrose drain retrieved from right.

- Once the base of the right crus is exposed, the mediastinum is entered from the right and the Penrose drain left in the mediastinum from the right is retrieved (**FIG 12**). At this point, the Penrose drain can be brought around the entire hiatal contents and used as a retractor to facilitate the remainder of the hiatal dissection.
- This technique of starting on the left and using the crura as the edges of dissection assures safe isolation of hiatal content thereby minimizing the risk of esophagogastric perforation or vagal nerve injury (**FIG 13**).
- At this point, an EGD is useful to confirm anatomy, assess for any unsuspected perforation, and help localize the fundoplication in preparation for undoing the fundoplication.

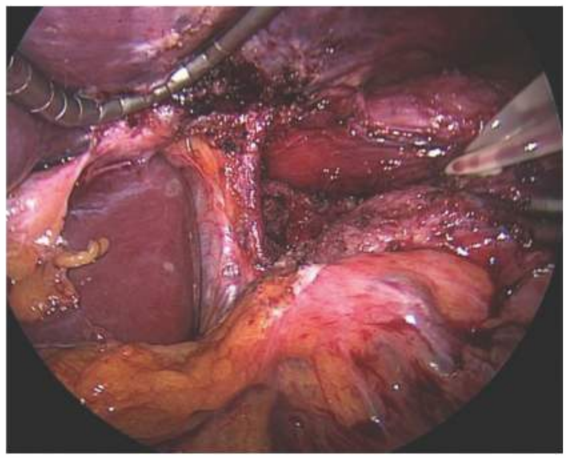

FIG 13 ● Completed hiatal dissection.

UNDO PREVIOUS FUNDOPLICATION

- Finding the inferior edges of the fundoplication where it drapes over the proximal stomach, especially on the left side of the gastric cardia, allows the edge to be traced toward the anterior fusion of a 360-degree fundoplication. A similar exposure on the left can also be accomplished, but the left lower edge of the fundoplication tends to be more fused along the neurovascular bundles of the lesser curve.
- Once the anterior fusion of the fundoplication is found, it can be isolated and either released with the aid of electrocautery or separated by firing a linear cutting stapler between the two limbs (**FIG 14**).

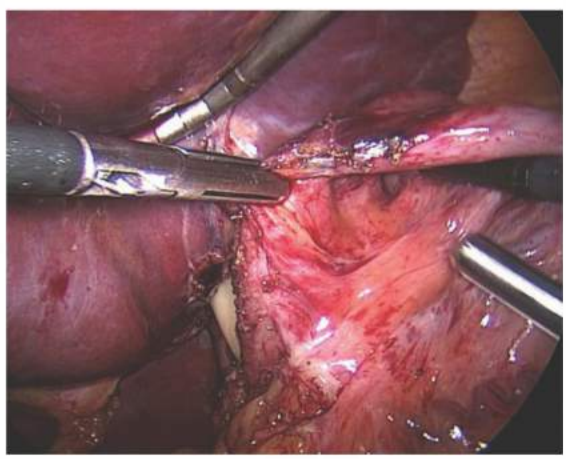

FIG 14 ● Exposed anterior fusion of wrap.

- With the anterior portion of the fundoplication released, the right limb is dissected away from the lesser curve of the stomach and right side of the esophagus and returned to its normal location in the left upper quadrant (FIG 15). As the fundoplication is dissected away posteriorly, the posterior vagus nerve should be sought and protected.
- With the fundoplication completely undone, an EGD is again performed to assure that the wrap is completely mobilized and assess for any perforation. This is done by submerging the area of the gastroesophageal junction (GEJ) under saline while inflating the lumen of the esophagus and stomach with air and looking for an air leak externally.

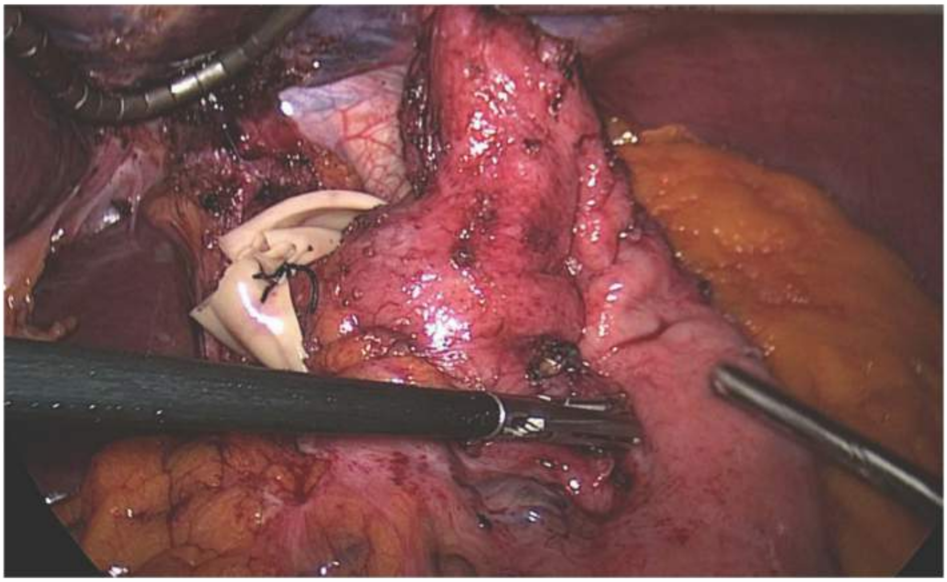

FIG 15 ● Gastric fundus returned to normal location.

RECONSTRUCT ESOPHAGEAL HIATUS

- The esophageal hiatus is reconstructed using permanent sutures to approximate the crura posteriorly. Pledgets can be used to limit the sawing effect of the suture over time (FIG 16).
- If the hiatal defect is large, the intraabdominal pressure is decreased to 10 to 12 mmHg, thereby unloading the pressure on the diaphragm and crural repair.
- Several anterior crural sutures may be needed if the defect is large and the posterior-only closure is creating an angle at the GEJ.
- The crural reconstruction should result in the crura effacing the esophagus circumferentially without impinging.

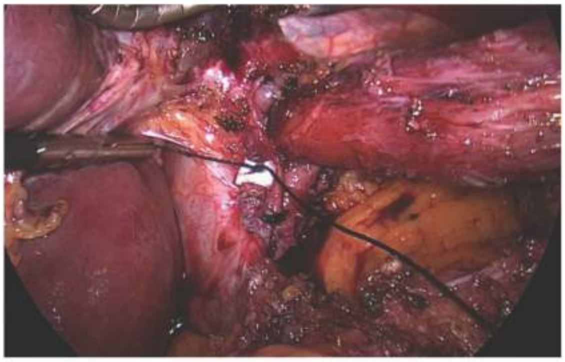

FIG 16 ● Hiatal reconstruction.

TECHNIQUES

REDO FUNDOPLICATION

- A standard technique for fundoplication can be used.[9,10] This entails a 360-degree fundoplication if there is adequate fundus and the preoperative esophageal motility is adequate (peristalsis in 70% or more of swallows or esophageal body pressure of 30 mmHg or greater).

Table 6: Options for Redo Fundoplication

Reconstruction Option	Uses
360-degree fundoplication	Adequate fundus and normal esophageal motility
270-degree fundoplication	Poor esophageal motility or inadequate fundus for 360-degree fundoplication
No fundoplication	Tight wrap or hiatal stenosis with inadequate fundus for any fundoplication
Proximal divided gastroplasty/gastrectomy with Roux-en-Y gastrojejunostomy	Recurrent GERD following multiple prior antireflux operations and/or no fundus for redo fundoplication with/without injury to gastric cardia/fundus during redo
Esophagogastric myotomy with/without partial fundoplication	Pseudoachalasia
Esophagectomy with gastric pull-up or colon interposition	Severe pseudoachalasia with massive esophageal dilation
Roux-en-Y esophagojejunostomy	Recurrent GERD following multiple prior antireflux operations and injury to gastric cardia or distal esophagus during redo

GERD, gastroesophageal reflux disease.

A 270-degree fundoplication should be used if these criteria are not met (Table 6).

- Fundoplication should be calibrated by completing the wrap around a 56- to 60-Fr dilator placed across the GEJ (**FIG 17**). It is best if the fundus is positioned for the fundoplication before this dilator is placed; otherwise, the wrap can be very difficult to bring around the esophagus posteriorly with the dilator in place.
- Two to three permanent sutures that include the anterior esophagus are placed to produce a 2-cm long fundoplication.

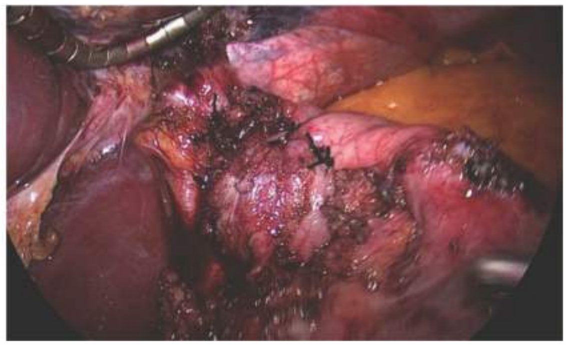

FIG 17 ● Completed redo fundoplication.

ASSESS FOR POTENTIAL COMPLICATIONS

- One final EGD is recommended to assess the location of the wrap and look for any potential complications. A retroflex view is very helpful to assure that the wrap is on the distal esophagus and not the proximal stomach (the appearance of gastric folds extending up and into the wrap suggests a wrap that is too low).

CONSIDER ADJUNCTS

- If the hiatal dissection or undoing the wrap was particularly difficult, a gastrostomy tube can be used to allow gastric decompression and possible gastric feeds while waiting for proximal gastrointestinal (GI) function to return and normalize.

PEARLS AND PITFALLS

Indications for surgery and diagnosis of failure	■ Functional reasons for symptoms after fundoplication (e.g., misdiagnosed GERD, other GI problems, vagal nerve injury) *cannot* be corrected with surgery. ■ Without evidence of an obvious anatomic failure or confirmation of recurrent GERD by pH testing, surgery should be avoided.
Preoperative testing	■ Preoperative tests are intended to assure that correct redo technique is performed (e.g., total vs. partial fundoplication). ■ Skipping testing may compromise redo success.

Identify and expose hiatal anatomy	■ Injury to the liver, lesser curve of the stomach, the wrap, and the esophagus is more likely if dissection is started on the right. ■ Starting on the left allows exposure of the hiatus before working in the more anatomically congested right side.
Intraoperative testing	■ Liberal use of intraoperative endoscopy to guide dissection by frequently assessing anatomy ■ Assess for potential luminal injury penetration.
Surgical technique	■ A standardized technique adhering to key technical principles will help assure successful outcomes (Table 7).
Postoperative care	■ Managing nausea to prevent retching starts in the operating and recovery room and is critical to minimizing trauma early postoperative that could disrupt the redo. ■ Gastric decompression avoids gastric distension that could disrupt a wrap or cruroplasty. ■ Tube access to the stomach may allow nonoperative management of a small leak found postoperatively.

POSTOPERATIVE CARE

- Postoperative management after reoperative antireflux surgery mirrors the care of any foregut surgery patient. A one- to two-night stay is pretty typical if the redo is laparoscopic, extra days if open. Key aspects of postoperative care are oral intake and return to activity.
- A preventable cause of antireflux surgery failure is early postoperative retching. The two most common reasons for early postoperative retching are nausea and dietary indiscretion.
- Patients should receive preemptive nausea control and antiemetics and be counseled carefully about maintaining a liquid and soft food diet for at least 1 month after surgery.
- Instructing patients to ingest only pourable liquids for the first week after surgery provides a simple rule to follow, and then providing a detailed menu of acceptable soft foods for another 3 weeks will help effect compliance with the postoperative diet.
- Too rapid advancement to activity that will result in increased intraabdominal pressure can put sutures and the reconstructed anatomy at risk. A full 30 days of limiting lifting to no more than 30 lb and no vigorous exercise during this time provides simple guidelines for patients to follow.
- Setting appropriate expectations for patients with regard to their overall recovery, diet progression, and resolution of preoperative symptoms is important. Dysphagia may linger for more than 4 weeks after a redo and preparing patients for this likelihood will allow them to accept this more readily.
- Early dilation may improve the dysphagia, but it also increases the risk of recurrent GERD and therefore should be avoided if possible. We reserve dilation within the first 3 months after any antireflux operation for only those patients whose difficulty swallowing makes it hard to handle their own saliva or maintain hydration.

Table 7: Standard Technique for Redo Fundoplication Success

- Full hiatal dissection (reduce and resect any hiatal hernia sac)
- Adequate esophageal mobilization—3–4 cm of esophagus below diaphragm
- Divide all short gastric vessels (be sure to mobilize fundus posteriorly to find and divide any high posterior vessel[s]).
- Resect any epiphrenic fat (careful to not undermine the anterior vagus).
- Determine esophageal length and location of EGJ (use endoscopy if unsure).
- Careful handling of crura during dissection and closure
- Decrease pneumoperitoneum to unload the diaphragm during closure.
- Anterior crural stitch if large hiatal defect
- Calibrate wrap (assure the fundus is in contact with the esophagus circumferentially—you can make a wrap too loose).
- Use gastrostomy tube for gastric decompression if large hiatal hernia or excessive manipulation of stomach/area of vagal nerves.
- Avoid postoperative nausea (use preemptive antiemetics).

EGJ, esophagogastric junction.

OUTCOMES

- The outcomes of redo fundoplication can be comparable to primary antireflux surgery, and in patients suffering with significant and debilitating symptoms, the operations can return patients to a nearly normal quality of life with low morbidity and virtually no mortality[11] (Table 8).
- The patient requiring multiple reoperations for failed fundoplication is a special situation that deserves special mention. When undertaking a fourth redo, the failure rate jumps from around 7% to over 17%.[7] We will rarely simply undertake a redo after three prior attempts. A divided gastroplasty and Roux-en-Y reconstruction for recurrent severe GERD, an esophagogastric myotomy for pseudoachalasia or esophagectomy for severe pseudoachalasia with massively dilated esophagus, or an esophagojejunostomy for poor esophageal emptying with severe GEJ distortion is instead advised.

COMPLICATIONS

- Complications can best be understood, identified, and managed considering their occurrence.

Intraoperative

- Bleeding
- Liver injury
- Esophagogastric perforation
- Pneumothorax
- Vagal nerve injury

Postoperative

- Pneumonia
- Esophageal obstruction (edema) with inability to swallow
- Delayed gastric emptying
- Atelectasis and hypoxemia

Chapter 25

Laparoscopic Partial Fundoplication for Gastroesophageal Reflux Disease

Marco E. Allaix Marco G. Patti

DEFINITION

- Gastroesophageal reflux disease (GERD) is a chronic condition resulting from the reflux of gastric contents into the esophagus and is associated with a spectrum of symptoms, with or without tissue injury.[1,2]

DIFFERENTIAL DIAGNOSIS

- Several conditions, including irritable bowel syndrome, achalasia, gallbladder disease, coronary artery disease, or psychiatric disorders can present with heartburn as the main symptom.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Heartburn, regurgitation, and dysphagia are considered *typical* symptoms of GERD.
- GERD can also cause *atypical* symptoms such as cough, wheezing, chest pain, hoarseness, and dental erosions.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Clinical history, based on *symptoms* only, has a low diagnostic accuracy of GERD in about 30% of patients.[3]
- *Upper endoscopy* is often the first test performed to confirm the diagnosis of GERD. However, about 50% of patients with clinical symptoms of GERD do not have endoscopic sign of esophagitis.[3] In addition, endoscopic evaluation is highly operator dependent, especially in the assessment of low-grade esophagitis.[4] Therefore, the major role of endoscopy is to detect Barrett's esophagus (usually present in 1% to 5% of patients with GERD) and to exclude gastric and duodenal pathology.
- *Barium swallow* is useful for detecting and characterizing the type and size of a hiatal hernia; for determining the location and size of a stricture; and for evaluating length, diameter, and function of the esophagus. This test, however, is not diagnostic of GERD as a hiatal hernia or reflux of barium can be present in the absence of abnormal reflux or absent in the presence of clinically significant GERD.
- *Esophageal manometry* provides information about the lower esophageal sphincter (LES) in terms of resting pressure, length, and relaxation and the amplitude and propagation of esophageal peristaltic waves. In addition, manometry is essential for proper placement of the pH probe for ambulatory pH monitoring (5 cm above the upper border of the LES).
- *24-hour ambulatory pH monitoring* is considered the gold standard for the diagnosis of GERD (**FIG 1**). Its role is key in the workup as it determines the presence and amount of abnormal reflux and it establishes a temporal correlation between symptoms and episodes of reflux (particularly important when cough or chest pain are present).[5] An abnormal score not only confirms the diagnosis but also is an independent predictor for the successful outcome of antireflux surgery.[6] Finally, pH monitoring is mandatory for the proper evaluation of patients who have recurrent symptoms after antireflux surgery.[7]
- *Combined multichannel intraluminal impedance and pH testing* (MII-pH) detects episodes of reflux, regardless of the pH of the refluxate, by identifying changes inducted by the presence of liquids and gas in the esophagus. The episodes are classified as acid, weakly acid, or nonacid on the basis of concomitant pH monitoring. This test is useful in identifying bile reflux and does not require cessation of proton pump inhibitors for testing.

SURGICAL MANAGEMENT

- A laparoscopic fundoplication is currently considered the procedure of choice for the treatment of GERD.
- Even though several eponyms are used to describe different antireflux procedures, we believe that it is more important to focus on the technical elements that make a fundoplication effective and long lasting.
- The type of fundoplication (total vs. partial) is tailored to the quality of esophageal peristalsis as documented by the preoperative manometry. In the United States, a partial fundoplication is proposed only to patients with very impaired or absent esophageal peristalsis in order to reduce the risk of postoperative dysphagia (**FIG 2**).

Preoperative Planning

- A careful symptomatic evaluation testing is performed in every patient before surgical intervention.

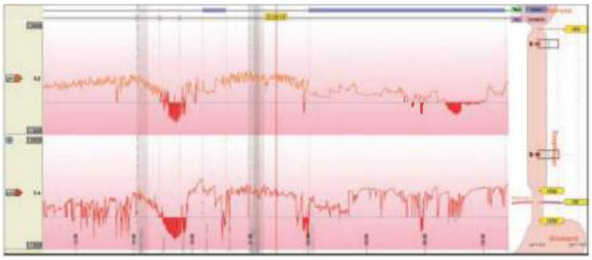

FIG 1 • Ambulatory 24-hour pH monitoring.

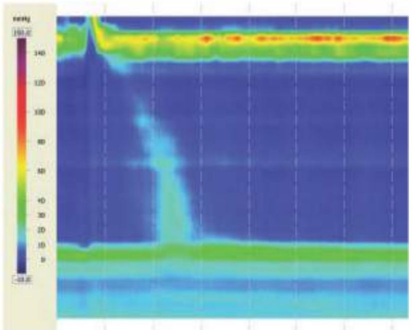

FIG 2 ● High-resolution esophageal manometry: ineffective esophageal motility.

Positioning

- After induction of general endotracheal anesthesia, the patient is positioned in low lithotomy position with the lower extremities extended on stirrups with knees flexed 20 to 30 degrees. Alternatively, a split-leg table may be used.
- To avoid sliding as a consequence of the steep reverse Trendelenburg position used during the entire procedure, a beanbag is inflated to create a "saddle" under the perineum.
- Because increased abdominal pressure from pneumoperitoneum and the steep reverse Trendelenburg position decrease venous return, pneumatic compression stockings are always used as prophylaxis against deep venous thrombosis.
- An orogastric tube is placed to keep the stomach decompressed during the procedure.
- A Foley catheter is inserted at the beginning of the operation and removed at the end.
- The surgeon stands between the patient's legs. The first and second assistants stand on the right and left side of operative table (**FIG 3**).

FIG 3 ● Position of the patient and surgical team in the operating room.

PLACEMENT OF PORTS

- Five 10-mm trocars are used for the procedure (**FIG 4**).
  - The first incision is made in the midline 14 cm distal to the xiphoid process and a Veress needle is introduced into the peritoneal cavity. The peritoneal cavity is initially insufflated to a pressure of 15 mmHg. Subsequently, under direct vision, an optical port with a 0-degree scope (**port 1**) is placed. Once this port is placed, the 0-degree scope is replaced with a 30-degree scope and the other trocars are inserted under laparoscopic vision.
- **Port 2** is placed in the left midclavicular line at the same level of port 1. It is used by the assistant for

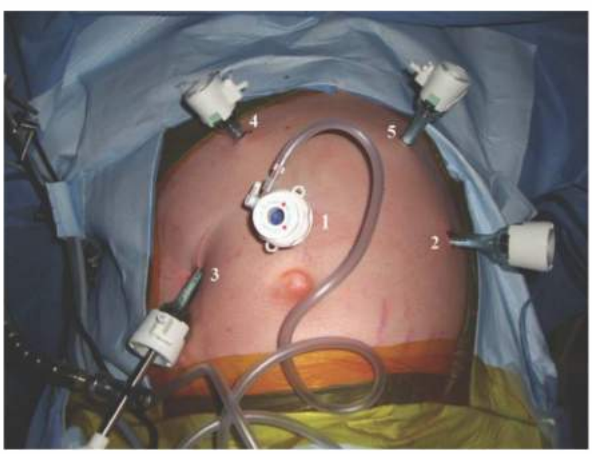

FIG 4 ● Placement of the ports *(1–5)*.

traction on the gastroesophageal junction and to take down the short gastric vessels.
  - **Port 3** is placed in the right midclavicular line at the same level of the other two ports. A retractor is used through this port to lift the left lateral segment of the liver to expose the gastroesophageal junction. The retractor is held in place by a self-retaining system fixed to the operating table.
  - **Ports 4** and **5** are placed under the right and left costal margins so that their axes and the camera form an angle of about 120 degrees. These ports are used by the operating surgeon for the insertion of graspers, scissors, and dissecting and suturing instruments.
- The instrumentation necessary for laparoscopic partial fundoplication is reported in Table 1.

Table 1: Instrumentation for Laparoscopic Partial Fundoplication

Five 10-mm ports
0- and 30-degree scope
Graspers and needle holder
Babcock clamp
L-shaped hook cautery with suction–irrigation capacity
Scissors
Laparoscopic clip applier
Electrothermal bipolar vessel-sealing system
Liver retractor
Suturing device
2-0 silk sutures
Penrose drain
56-Fr esophageal bougie

DISSECTION

- The gastrohepatic ligament is divided, beginning the dissection above the caudate lobe of the liver, where the ligament is thinner, and continuing toward the diaphragm until the right pillar of the crus is identified (**FIG 5**).
- The right pillar of the crus is separated from the esophagus by blunt dissection until the left crus is recognized and the posterior vagus nerve is identified (**FIG 6**).
- Subsequently, the peritoneum and the phrenoesophageal membrane overlying the esophagus are divided, and the anterior vagus nerve is identified.
- The left pillar of the crus is then separated from the esophagus and dissected toward the junction with the right pillar of the crus (**FIG 7**).

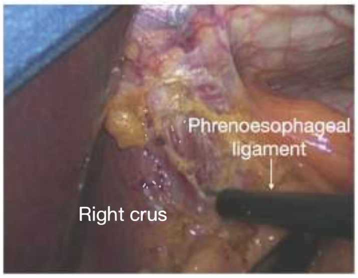

FIG 6 ● Dissection of the right pillar of the crus.

FIG 7 ● Dissection of the left pillar of the crus.

FIG 5 ● Gastrohepatic ligament division.

DIVISION OF THE SHORT GASTRIC VESSELS

- The short gastric vessels are taken down all the way to the left pillar of the crus, starting from a point midway along the greater curvature of the stomach (**FIG 8**).[8]

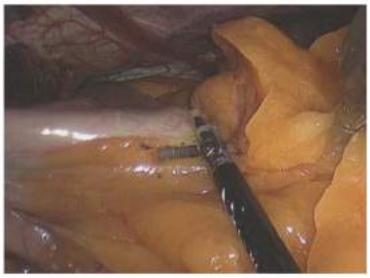

FIG 8 ● Division of short gastric vessels.

CREATION OF A WINDOW AND PLACEMENT OF A PENROSE DRAIN AROUND THE ESOPHAGUS

- The esophagus is retracted upward with a Babcock clamp applied at the level of the esophagogastric junction.
- A window is opened by a blunt and sharp dissection under the esophagus, between the gastric fundus, the esophagus, and the left pillar of the crus (**FIG 9**).
- The window is enlarged, and a Penrose drain is passed around the esophagus.
- Any hiatal hernia is completely reduced and a minimum of 3 cm of intraabdominal esophageal length is achieved.

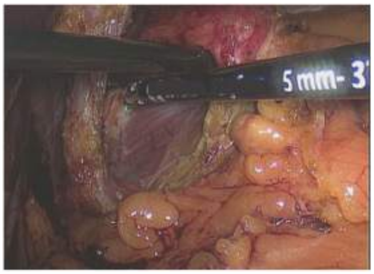

FIG 9 ● Creation of a window between the gastric fundus, the esophagus, and the left pillar of the crus.

CLOSURE OF THE CRURA

- Interrupted 2-0 silk sutures that are tied intracorporeally with an Endo Stitch device (Covidien, Norwalk, CT) are used to close the diaphragmatic crura (**FIG 10a**).
- Retraction of the esophagus upward and toward the patient's left with the Penrose drain provides proper exposure.
- The first stitch should be placed just above the junction of the two pillars.
- Additional stitches are placed 1 cm apart, and a space of about 1 cm is left between the uppermost stitch and the esophagus.

FIG 10 ● Crura closure *(a)*; posterior partial fundoplication *(b)*; two coronal stitches placed between the top of the wrap, the esophagus, and the right or left pillar of the crus *(c)*; and one additional stitch placed between the right side of the wrap and the closed crura *(d)*.

INSERTION OF THE BOUGIE INTO THE ESOPHAGUS AND THROUGH THE ESOPHAGEAL JUNCTION

- The orogastric tube is removed, and a 56-Fr bougie down the esophagus through the esophagogastric junction is inserted.[9]
- The crura must be snug around the esophagus but not too tight: A closed grasper should slide easily between the esophagus and the crura.

PARTIAL FUNDOPLICATION

- *Partial posterior fundoplication*
  - The gastric fundus is gently pulled under the esophagus with two graspers.
  - The right and left sides of the wrap are separately sutured to the esophagus, leaving 80 to 120 degrees of the anterior esophageal wall uncovered.
  - Three 2-0 silk sutures are placed on each side between the muscular layers of the esophageal wall and the gastric fundus (**FIG 10b**).
  - Two coronal stitches are then placed between the top of the wrap, the esophagus, and the right or left pillar of the crus (**FIG 10c**).
  - One additional stitch is placed between the right side of the wrap and the closed crura (**FIG 10d**).

- The resulting wrap measures about 240 to 280 degrees.
- *Partial anterior fundoplication (See Part 1, Chapter 16 for more details.)*
  - It is a 180-degree anterior fundoplication.
  - Two rows of sutures (2-0 silk) are used. The first row is on the left side of the esophagus and has three stitches. The top stitch incorporates the fundus of the stomach, the muscular layer of the left side of the esophagus, and the left pillar of the crus.
  - The second and third stitches incorporate the gastric fundus and the muscular layer of the left side of the esophagus.
  - The fundus is then folded over the esophagus so that the greater curvature of the stomach is next to the right pillar of the crus.
  - The second row of sutures on the right side of the esophagus consists of three stitches between the fundus and the right pillar of the crus.
  - Finally, two additional stitches are placed between the fundus and the rim of the esophageal hiatus to eliminate any tension from the fundoplication.

PEARLS AND PITFALLS

Indications	■ A careful evaluation, including manometry, 24-hour pH monitoring, upper endoscopy, and barium swallow must be done.
Placement of ports	■ Extreme care must be taken when positioning port 1, because the site of insertion is just above the aorta. ■ We recommend using an optical trocar with a 0-degree scope to obtain access. ■ If port 3 is too low, the left lateral segment of the liver will not be properly retracted, resulting in inadequate exposure of the esophagogastric junction. ■ If port 2 is too low, the esophagogastric junction or the upper short gastric vessels will be difficult to reach. ■ If ports 4 and 5 are too low, the dissection at the beginning of the procedure and the suturing at the end will be challenging. ■ If port 3 is too medial, the liver retractor may interfere with the instrument used through port 4.
Dissection	■ An accessory left hepatic artery originating from the left gastric artery is frequently present in the gastrohepatic ligament. If this vessel limits the exposure, it may be safely divided. ■ The electrocautery should be used with extreme caution. Because of the lateral spread of the monopolar current, vagus nerves may be damaged even without direct contact. A bipolar instrument represents a safer alternative.
Short gastric vessels division	■ Bleeding, either from the short gastric vessels or from the spleen, and damage to the gastric wall are possible complications. ■ Excessive traction and division of a vessel not completely coagulated are usually the main causes of bleeding. ■ A burn caused during dissection of the short gastric vessels or traction applied with the graspers or the Babcock clamp are the most common mechanisms of damage to the gastric wall.
Creation of a window and placement of a Penrose drain around the esophagus	■ Left pneumothorax and perforation of the gastric fundus are two main complications that can occur during this step of the procedure. ■ Left pneumothorax is usually created when the dissection is performed in the mediastinum above the left pillar of the crus rather than between the crus and the gastric fundus. ■ Proper identification and dissection of the left pillar of the crus are crucial. ■ Perforation of the gastric fundus is usually caused by pushing a blunt instrument under the esophagus or by using monopolar electrocautery for dissection.
Closure of the crura	■ The bougie is not placed inside the esophagus during this step of the procedure in order to have a proper exposure for suturing.
Insertion of the bougie into esophagus and through esophageal junction	■ The most serious complication during this step is an esophageal perforation. ■ Lubrication of the bougie and instruction to the anesthesiologist to advance the bougie slowly and to stop if any resistance is encountered help to prevent this complication. ■ All instruments must be removed from the esophagogastric junction and the Penrose drain must be opened. In this way, the creation of an angle between the stomach and the esophagus, which increases the risk of perforation, is prevented.
Partial fundoplication	■ Atraumatic graspers must be used to reduce the risk of injury to the gastric wall.

POSTOPERATIVE CARE

- Patients are usually discharged after 23 to 48 hours.
- Patients start clear liquids and then a soft diet the morning after surgery.
- They are instructed to avoid meat, bread, and carbonated beverages for the following 2 weeks.
- The time to full recovery ranges between 2 and 3 weeks.

OUTCOMES

- Long-term studies conducted in United States have reported a less effective control of GERD with a partial fundoplication rather than a total fundoplication.[10–12]
- At 5-year follow-up, recurrence of GERD confirmed by pH monitoring is reported in more than 50% of patients after partial fundoplication.[10]

COMPLICATIONS

- Esophageal or gastric perforation can be caused either by traction or by an inadvertent electrocautery burn during any step of the dissection.
- A leak usually manifests itself during the first 48 hours.
- Peritoneal signs will be present if the spillage is limited to the abdomen; shortness of breath and a pleural effusion will be noted if spillage also occurs in the chest.
- The site of the leak must always be confirmed by a contrast study using a water-soluble contrast agent.
- Optimal management consists of a reoperation and direct repair. An esophagectomy may be indicated in case of a too extensive damage or when the extent of the inflammatory reaction makes the direct repair impossible. Wide drainage, feeding jejunostomy tube, and use of a covered esophageal stent may also assist in healing the injury when it cannot be directly repaired.
- Gastroesophageal junction and wrap slippage into the chest rarely occurs when coronal suture is placed and the crura are closed.[8] The main symptoms of recurrence are dysphagia and regurgitation. A barium swallow confirms the diagnosis.
- The incidence of paraesophageal hernia may be increased if the closure of the crura is not performed or if it is too loose.[8]

Chapter 26

The Minimally Invasive Surgical Approach to Gastroesophageal Reflux Disease

W. Scott Melvin   Luke M. Funk

DEFINITION

- Endoscopic therapies for gastroesophageal reflux disease (GERD) include transoral incisionless fundoplication (TIF) and the application of radiofrequency energy to the lower esophageal sphincter (LES). Minimally invasive LES augmentation surgery involves the placement of a magnetic band across the LES. All three therapies are designed to reduce GERD symptoms by minimizing the reflux of gastric contents into the esophagus and are alternatives to traditional surgical fundoplication techniques.

DIFFERENTIAL DIAGNOSIS

- Typical GERD symptoms
  - Achalasia
  - Biliary colic/cholecystitis
  - Delayed gastric emptying
  - Esophageal cancer, esophagitis, esophageal motility disorders
  - Gastritis
  - Hiatal hernia
  - *Helicobacter pylori* infection
  - Irritable bowel syndrome
- Atypical GERD symptoms
  - Coronary artery disease
  - Asthma
  - Bronchogenic carcinoma

PATIENT HISTORY AND PHYSICAL FINDINGS

- History taking should focus on identifying both typical and atypical symptoms associated with GERD.
  - Typical symptoms include heartburn, regurgitation, water brash (salty taste related to salivary secretion), and dysphagia.
  - Atypical symptoms include dyspnea, cough, wheezing, chest pain, recurrent pneumonias, hoarseness, and dental erosions.
- Response to antireflux medications, such as proton pump inhibitors and H_2 blockers is important to illicit, as the majority of patients with typical GERD symptoms will respond to these medications. Failure to respond to these medications should heighten the surgeon's concern that the patient's symptoms may be unrelated to GERD.
- Once the diagnosis of GERD is confirmed with objective testing, several key points should be discussed with the patient:
  - Medical therapy, including lifestyle modifications (i.e., diet modification, weight loss, smoking cessation) and antireflux medications, should control typical GERD symptoms for most patients. Surgical intervention is indicated for GERD patients who (1) cannot take antireflux medications due to side effects, (2) would prefer not to take antireflux medications due to cost or lifestyle impact, or (3) continue to experience symptoms despite antireflux medications.
  - Laparoscopic gastric fundoplication (i.e., Nissen fundoplication) is considered to be the gold standard surgical therapy for the treatment of GERD. Endoscopic therapies and laparoscopic LES augmentation surgery should probably be reserved for GERD patients who are candidates for surgical intervention and (1) would prefer a less invasive option than laparoscopic fundoplication surgery or (2) would be considered too high risk for laparoscopic fundoplication due to comorbidities or previous abdominal surgery, including prior laparoscopic fundoplication.
- Of the three procedures discussed in this chapter, laparoscopic LES augmentation surgery is the only one that requires general anesthesia, although TIF also involves general anesthesia in the vast majority of cases. Conscious sedation is usually adequate for radiofrequency therapy. Thus, poor candidates for general anesthesia (i.e., those with cardiopulmonary conditions such as severe chronic obstructive pulmonary disease [COPD] or congestive heart failure [CHF]) may be better candidates for radiofrequency therapy. The presence of these comorbid conditions should be sought out in the history. Additional contraindications for these procedures are listed in Table 1.
- Because there are few physical exam findings associated with GERD, the physical exam should focus on conditions that might suggest an alternative explanation for the

Table 1: Contraindications for Undergoing Treatment

For all three procedures
Barrett's esophagus
Dysphagia (i.e., multiple times per week)
Esophageal dysmotility, strictures, varices
Esophagitis (grade C or D esophagitis according to the Los Angeles classification)
Hiatal hernia (>2–3 cm)
Obesity (BMI >35)
Specific to transoral incisionless fundoplication
Inability to tolerate general anesthesia
Specific to laparoscopic LES augmentation surgery
Inability to tolerate general anesthesia
Titanium, stainless steel, nickel, or ferrous allergy
Patients who may need to undergo an MRI (LINX considered not safe for MRI)

BMI, body mass index; LES, lower esophageal sphincter; MRI, magnetic resonance imaging.

patient's symptoms. These include recent weight loss or progressive inability to tolerate solids and liquids (malignancy), atypical symptoms associated with exertion (coronary artery disease or asthma), or diarrhea (irritable bowel syndrome).

- The presence of abdominal surgical scars or abdominal wall hernias is important to identify if laparoscopic LES augmentation surgery is being considered as they may make access to the peritoneal cavity and the gastroesophageal (GE) junction challenging.
- Laparoscopic LES augmentation surgery, which involves placement of a magnetic device around the GE junction, is considered not safe for magnetic resonance imaging (MRI). Patients should be aware of this contraindication prior to surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Establishing GERD as the etiology of the patient's symptoms is critical before proceeding with any intervention. Patients may have subjective complaints of heartburn or dysphagia that are unrelated to their reflux disease. The four diagnostic tests that are most commonly used to establish a diagnosis are upper endoscopy, barium esophagram, pH testing, and manometry.
- Upper endoscopy (esophagogastroduodenoscopy [EGD])
  - All patients undergoing an antireflux procedure should have an EGD.
  - EGDs can identify the presence of hiatal hernias and rule out other pathology, which may be contributing to the patient's symptoms, such as peptic ulcer disease or malignancy.
  - GERD-related complications such as esophagitis, Barrett's esophagus, and esophageal strictures can also be identified (**FIG 1**).
- Ambulatory pH testing
  - This is considered to be the gold standard test for diagnosing the presence of symptomatic GERD.
  - Patients should typically not be taking their antireflux medications when the study is performed.
  - pH testing can be performed via catheter-based systems (i.e., 24-hour pH probe testing) or wireless systems (i.e., 48-hour Bravo testing).
  - Both catheter-based and wireless systems allow for the quantification of six variables including total/upright/supine time that the pH is less than 4, number of reflux episodes, number of episodes longer than 5 minutes, and longest episode. These variables can be combined to calculate the "DeMeester score," which is used by many surgeons as definitive evidence for the presence of GERD.[1]
- Barium esophagram
  - This is a dynamic fluoroscopic study that characterizes both anatomic and functional aspects of the esophagus. It involves multiple swallows of barium and barium-coated solid food.
  - The two most important things to characterize with a barium esophagram are the position of the GE junction relative to the diaphragmatic hiatus and overall esophageal motility. The presence of a large hiatal hernia (**FIG 2**) or significant esophageal dysmotility is a contraindication for any of the three procedures.[2]
  - Esophagrams can also identify the presence of reflux that is characterized by the spontaneous reflux of barium back into the esophagus. However, they are less sensitive than pH studies and thus a negative finding here does not rule out GERD.
  - Video recording of this study is crucial because it allows the surgeon to actively assess esophageal peristalsis and the functional significance of hiatal hernias.
- Manometry
  - Esophageal manometry uses pressure transducers within a transnasal catheter to provide data regarding the LES resting pressure, LES abdominal and total length, and adequacy of LES relaxation. It also characterizes esophageal motility by quantifying the amplitude, duration, and propagation of each contraction.
  - The presence of significant esophageal dysmotility is a contraindication for all three procedures.
- Multichannel impedance testing and gastric emptying studies are also used on occasion to identify nonacidic GERD and assess gastric functionality, respectively.

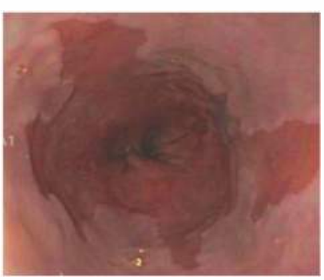

FIG 1 ● The presence of Barrett's esophagus is a contraindication to TIF, radiofrequency energy application, and laparoscopic LES augmentation surgery.

FIG 2 ● A lateral view of a barium esophagram. A large hiatal hernia is present with a significant portion of the stomach herniated into the chest. A small distal esophageal diverticulum is seen. All three procedures would be contraindicated in the presence of this hernia.

TRANSORAL INCISIONLESS FUNDOPLICATION

- Approved by the U.S. Food and Drug Administration (FDA) in 2007, the only TIF device that is currently available for use in the United States is the EsophyX device (EndoGastric Solutions, Redmond, WA).
- EsophyX re-creates the LES by plicating the distal esophagus and the gastric cardia together, thus creating an antireflux valve similar to that of a laparoscopic Nissen fundoplication.
- The device consists of a handle, an 18-mm diameter shaft, a tissue invaginator composed of holes in the side of the device (which are connected to a suction device), an articulating arm, which approximates gastric and esophageal tissue and deploys the tissue fasteners, a helical screw, two stylets, and 20 polypropylene H-fasteners (10 plication sets) (**FIG 3**).

Preoperative Planning

- At our institution, general anesthesia is administered and the procedure is performed in the operating room.
- Nasotracheal intubation is performed so the oropharynx can be used entirely for the EsophyX device. A bite block is placed to protect the teeth from the device and scope.
- Two physicians perform the procedure. One manipulates the endoscope while the other controls the device.

Positioning

- After intubation, the patient is placed into the left lateral decubitus position with the head elevated slightly (**FIG 4**).

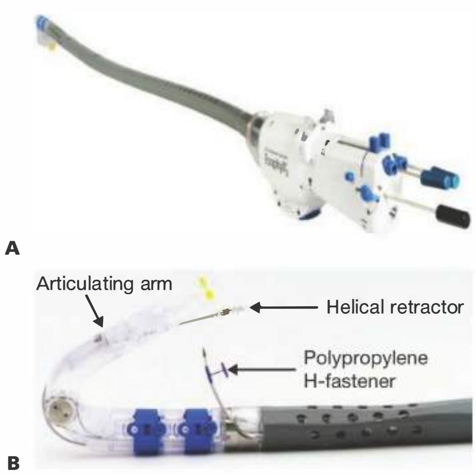

FIG 3 ● **A.** EsophyX device with the articulating arm fully extended. **B.** Articulating arm is flexed with the H fasteners visible between the shaft and the distal end of the articulating arm. The helical retractor is visible as well (images © 2015 EndoGastric Solutions, Inc).

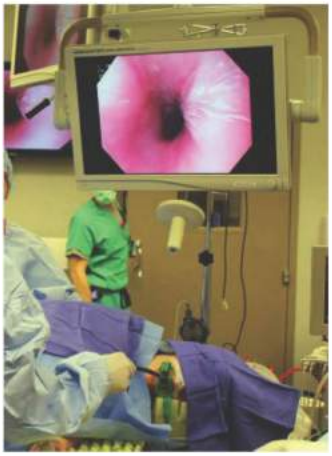

FIG 4 ● With the patient in the left lateral decubitus position and a nasotracheal tube present, a bite block is placed to facilitate passage of the endoscope and subsequently the EsophyX device.

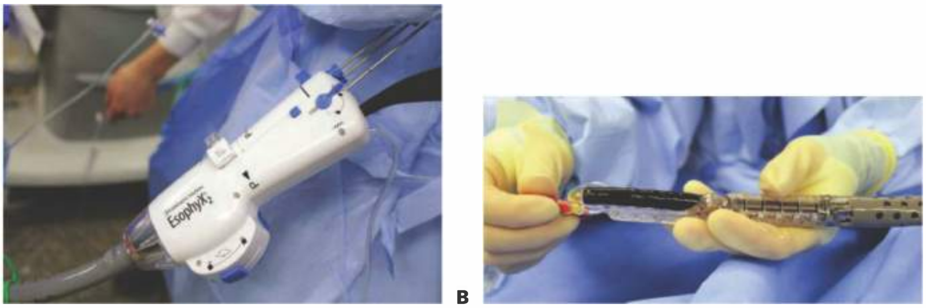
- Prophylactic antibiotics are administered before the procedure begins because transluminal fasteners are placed, which may increase the risk of postoperative infections.

Placement of the Transoral Incisionless Fundoplication Device into the Stomach

- Preprocedure endoscopy is performed to verify anatomic landmarks.
- A 56-Fr bougie is inserted into the esophagus and then removed to facilitate subsequent passage of the EsophyX device (**FIG 5**).
- The EsophyX device is lubricated and a standard endoscope is threaded through the device (**FIG 6**). Both are placed through a bite block and advanced through the esophagus into the stomach.
- The scope is advanced into the gastric lumen and then retroflexed to examine the GE junction. Using a standard, high-flow insufflator, the stomach is insufflated with

FIG 5 ● Passage of a large Bougie after diagnostic endoscopy facilitates advancement of the EsophyX device into the stomach and minimizes the likelihood of esophageal injury during passage of the device.



A B

FIG 6 ● **A.** The endoscope is passed through the handle of the EsophyX device and can be seen exiting the distal end of the device **(B)**. The articulating arm is fully extended in this image. Once the scope and device are advanced into the stomach, the scope is withdrawn into the body of the device and the articulating arm is flexed. The scope is advanced back into the stomach and retroflexed to obtain a view of the GE junction.

carbon dioxide to a pressure of 15 mmHg via the working channel of the endoscope. Once the articulating arm is visualized within the stomach, the scope is withdrawn into the device, the articulating arm is flexed, and the scope is then advanced back into the retroflexed position within the gastric lumen (**FIG 7**).

- Using the retroflexed view, the GE junction is envisioned as a clock face with the 12 o'clock position located at the lesser curvature, the 6 o'clock position at the greater curvature, and the 9 o'clock position located along the posterior gastric wall (**FIG 8**).[3]

Anterior Rotational Plication Fasteners

- The closed articulating arm is placed at the 12 o'clock position (**FIG 9A**). The helix retractor portion of the device is also at the 12 o'clock position and advanced into the squamocolumnar junction (**FIG 9B**). The entire device is then advanced distally a couple of centimeters and rotated clockwise on the screen. This allows the articulating arm to be opened and the helical retractor disengaged from the articulating arm.
- The articulating arm is then rotated back to the 6 o'clock position, partially closed, and pulled back 1 to 2 cm (**FIG 9C**). The GE junction is advanced caudally by applying tension to the helical retractor.
- The stomach is then desufflated and the articulating arm is rotated toward the 1 o'clock position. This maneuver rotates the fundus anteriorly around the esophagus thereby initiating the fundoplication. Externally, the handle of the device is rotated approximately 180 degrees (**FIG 10**). This has been described in the literature as the "Bell Roll maneuver."[3]
- The helical retractor and articulating arm are secured in place and the suction is applied.

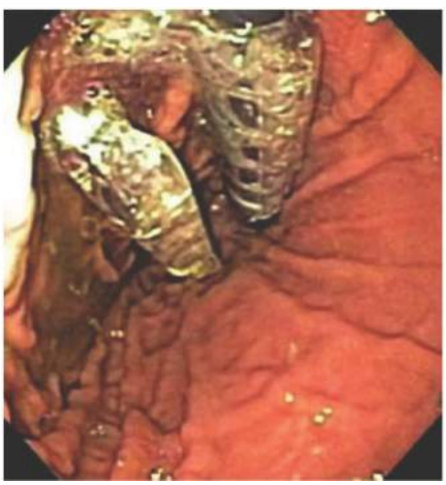


FIG 7 ● The articulating arm of the device is flexed within the gastric lumen. The arm will subsequently be rotated into the 12 o'clock position at the lesser curve to facilitate placement of the helix retractor.

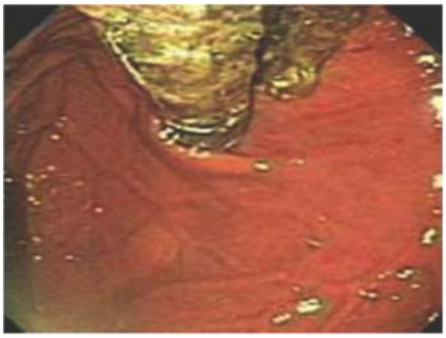
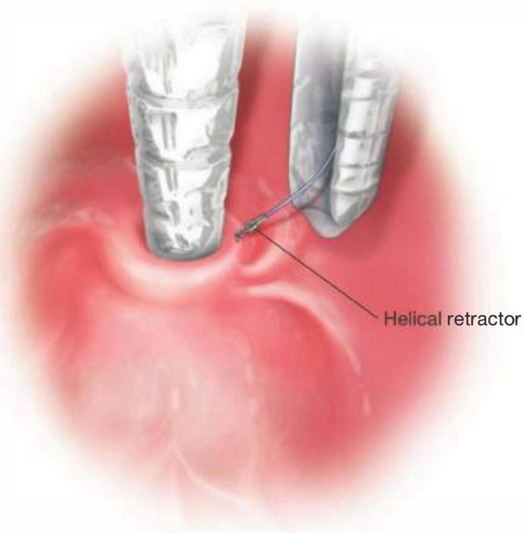
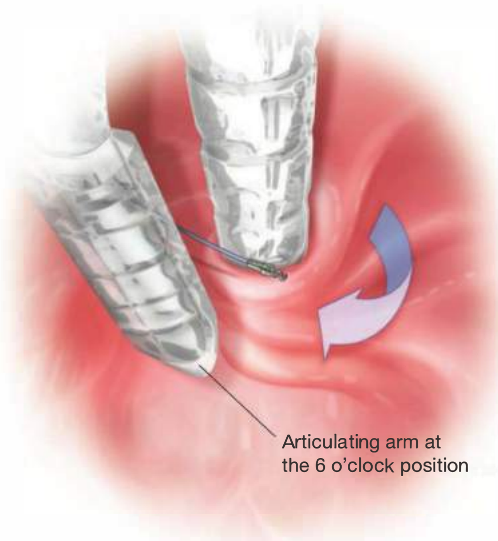
FIG 8 ● Using a clock face to describe the anatomy of the GE junction in a retroflexed view, the lesser curvature is at 12 o'clock while the greater curvature is a 6 o'clock.



A



B



C

FIG 9 ● **A.** With the articulating arm at 12 o'clock, the helix retractor is placed into the squamocolumnar junction. **B.** The helix retractor can be seen as a thin, horizontally oriented wire entering the gastric lumen. The device is then advanced distally into the stomach and rotated clockwise on the screen so that the articulating arm is at 6 o'clock **(C)**.

FIG 10 ● The articulating arm is rotated counterclockwise back toward the 1 o'clock position (the tip is thus not visible in this view). The fundus is thus anteriorly rotated around the esophagus. This completes the anterior portion of the fundoplication.

- The first H-fastener set is then deployed.
- The stomach is then reinsufflated to visualize deployment of a pair of H fasteners. Two sets of additional H fasteners are subsequently placed at varying distances from the GE junction.
- This will result in the placement of six fasteners 1 to 3 cm above the squamocolumnar junction.

Posterior Rotational Plication Fasteners

- The helix retractor portion of the device is maintained at the 12 o'clock position.
- The articulating arm is rotated counterclockwise through the lesser curve to the 8 o'clock position, partially closed, and pulled back 1 to 2 cm. The GE junction is advanced caudally by applying tension to the helical retractor.
- The "Bell Roll" maneuver is again performed, but this time in the clockwise direction (clockwise on the screen).

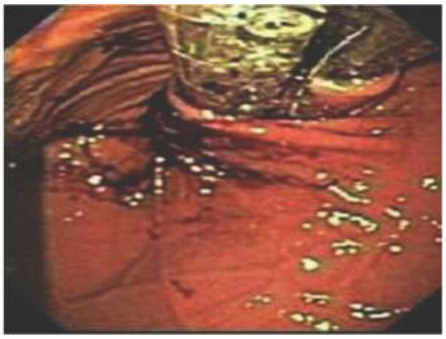


FIG 11 ● To perform the posterior component of the fundoplication, the articulating arm is rotated clockwise to the 11 o'clock position. This maneuver is a mirror image of the maneuver used to create the anterior component of the fundoplication.

The stomach is desufflated and the articulating arm is rotated clockwise to the 11 o'clock position. This maneuver rotates the fundus posteriorly around the esophagus (FIG 11).

- The first set of posterior rotational plication fasteners is then deployed.
- The process is then repeated to place two additional sets of H fasteners at varying distances from the GE junction.

Anterior Corner Longitudinal Plication

- To address a gap in the anterior component of the plication that is often appreciated only after the anterior and posterior sets have been placed, an anterior corner plication set is often placed.
- The articulating arm is rotated counterclockwise through the lesser curve toward the 1 o'clock position.
- Tension is applied to the helical retractor caudally and the approximating arm is pulled proximally while desufflating the stomach.
- Two additional sets of H-fasteners are deployed around the 1 o'clock position.

Greater Curve Deep Plication

- The purpose of this maneuver is to fixate the greater curvature slightly more proximally on the esophagus. This lengthens the antireflux valve.
- The helix retractor is disengaged from the 12 o'clock position and re-engaged at the squamocolumnar junction at the 6 o'clock position.
- The reticulating arm is moved into the 5 o'clock position and one or two sets of fasteners are 2 to 4 cm proximal to the squamocolumnar junction (FIG 12).
- The newly constructed antireflux valve should be 200 to 300 degrees in circumference.

Inspection of the Newly Created Antireflux Valve

- The device and endoscope are withdrawn together and then endoscope is removed from the EsophyX device.
- The endoscope is then advanced back into the stomach to allow inspection of the antireflux valve and to assess for any bleeding or injuries to the esophagus and stomach. The fasteners are visualized in the distal esophagus (FIG 13).
- The fundoplication created by the EsophyX device should have a similar endoscopic appearance as one created by a laparoscopic Nissen fundoplication.

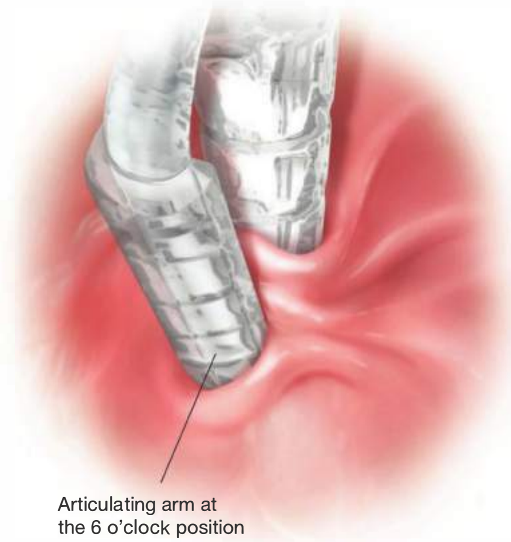

FIG 12 ● The shaft of the device has been pulled back into the esophagus 3 to 4 cm. This allows placement of the greater curve plication sutures with the articulating arm near the 6 o'clock position. This move adds length to the antireflux valve.

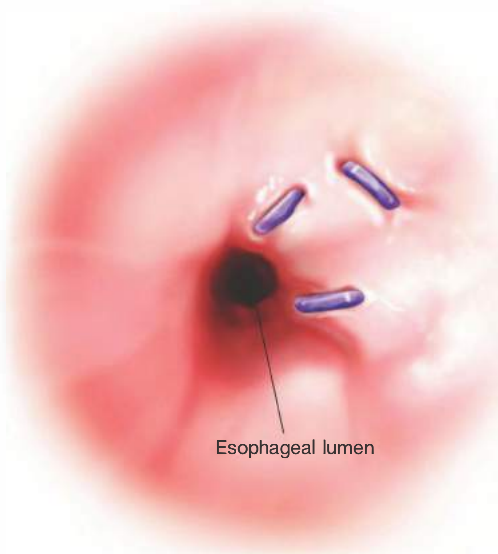

FIG 13 ● Multiple purple polypropylene fasteners are visualized with the distal esophagus after TIF is completed. These fasteners are not typically seen when retroflexing from within the stomach.

RADIOFREQUENCY ENERGY APPLICATION TO THE LOWER ESOPHAGEAL SPHINCTER

- Approved by the FDA in 2000, the Stretta system (Mederi Therapeutics Inc, Greenwich, CT) is currently the only device on the market that uses radiofrequency energy for the treatment of GERD.[4]
- The application of radiofrequency energy to the GE junction results in thermal injury and subsequent scarring, which reduces LES compliance, decreases the number of transient LES relaxations, and thereby decreases the incidence of reflux symptoms.
- The Stretta system is composed of two main components: a radiofrequency generator and a catheter system that connects to the generator. The catheter system is composed of an outer sheath, a 30-Fr bougie tip, and four nickel-titanium 22-gauge needle electrodes surrounding a balloon. The system also includes a channel for suction and another for irrigation (**FIG 14**).

A

B

FIG 14 ● **A.** Schematic representation of the Stretta catheter system. The distal end is composed of a 30-Fr bougie tip. The nickel-titanium needle electrodes can be seen pointing outward surrounding the balloon. **B.** Radiofrequency generator (images © 2015 Mederi Therapeutics Inc).

Preoperative Planning

- Conscious sedation is usually adequate for use of the Stretta system. At our institution, Stretta is usually performed in the endoscopy suite as opposed to the operating room.
- Only one physician is typically needed to perform the procedure.

Positioning

- After administration of conscious sedation medications, the patient is placed into the left lateral decubitus position and a bite block is placed.

Placement of the Stretta Device into the Distal Esophagus

- A standard endoscope is advanced down to the GE junction. The distance from the patient's lips to the squamocolumnar junction is measured.
- A guidewire is inserted through the working channel of the endoscope and the endoscope is removed.
- Under fluoroscopic guidance, the catheter system is then passed over the guidewire into the stomach. The catheter tip is then positioned 1 cm above the squamocolumnar junction based on measurements obtained from the endoscopic evaluation.

Application of Radiofrequency Energy

- The balloon is inflated to a pressure of 2 lb/in^2.
- The electrodes are then deployed through the mucosa and into the muscularis propria. Suction and irrigation are initiated through their respective working channels.
- The generator is activated and radiofrequency energy is applied for approximately 90 seconds per application. During this process, the muscularis propria is heated to a temperature of 85°C, whereas the esophageal mucosa is maintained below 50°C via cold water that is instilled through the catheter system. This creates four ablation sites that are distributed 90 degrees apart from each other.
- After the 90-second interval is complete, the catheter system is rotated 45 degrees and another cycle of radiofrequency energy is delivered for 90 seconds. Following this cycle, eight lesions approximately 45 degrees apart are created in a circumferential fashion at that level.
- The catheter system is advanced approximately 5 mm and the process is repeated to create another 8 sites of ablation. In total, this process is performed at six levels (from 1 cm proximal to the squamocolumnar junction to the proximal gastric cardia), creating 48 ablation sites (**FIG 15**).
- The Stretta system is then removed.

Inspection of the Gastroesophageal Junction

- The endoscope is advanced back down to the GE junction to allow inspection of the radiofrequency energy application site (**FIG 16**).

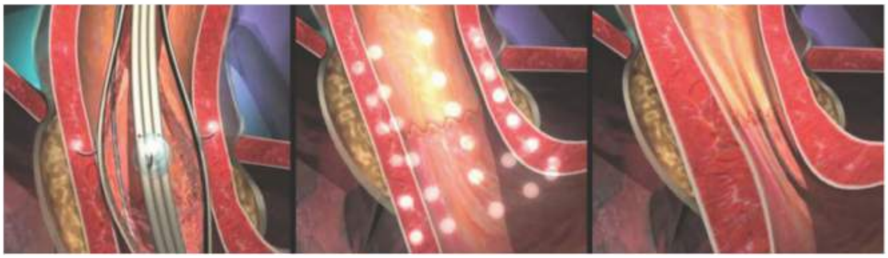

FIG 15 ● Coronal section through the esophagus with the electrodes positioned 1 cm proximal to the squamocolumnar junction. Two electrodes can be seen entering the muscularis propria. After the tissue has been ablated at six levels (indicated by white), the GE junction will eventually scar down as a result of the thermal injury (images © 2015 Mederi Therapeutics Inc).

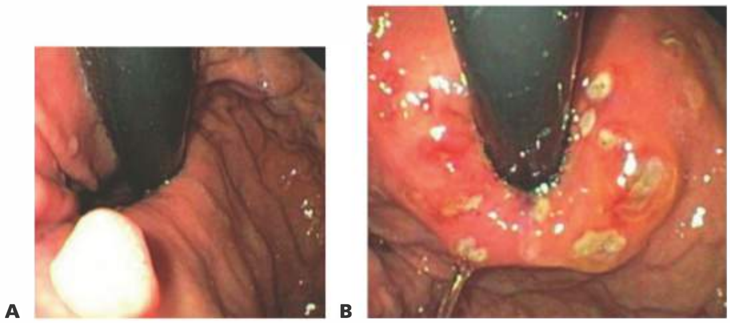

FIG 16 ● Retroflexed views of the GE junction immediately before **(A)** and after **(B)** use of the Stretta device.

LOWER ESOPHAGEAL SPHINCTER AUGMENTATION SURGERY

- The only commercially available laparoscopic LES augmentation device in the United States is the LINX Reflux Management System (Torax Medical, St. Paul, MN). The LINX system is designed to decrease reflux of gastric contents into the distal esophagus via placement of a flexible, expandable device consisting of multiple interlinked titanium beads with a magnetic core (**FIG 17**).
- When placed around the GE junction, it enhances the ability of the LES to resist opening and prevent reflux into the esophagus.
- With the device in place, once a patient swallows and esophageal peristalsis reaches the GE junction, the pressure of the peristalsis overcomes the magnetic field within the LINX device thereby allowing the device to open and food to enter into the stomach. The magnetic beads can also separate when intragastric pressure exceeds the magnetic strength of the beads, which allows the patient to belch or vomit if/when necessary.

Preoperative Planning

- General anesthesia is necessary.
- Preoperative prophylactic antibiotics are administered prior to incision to reduce the chance of infection.

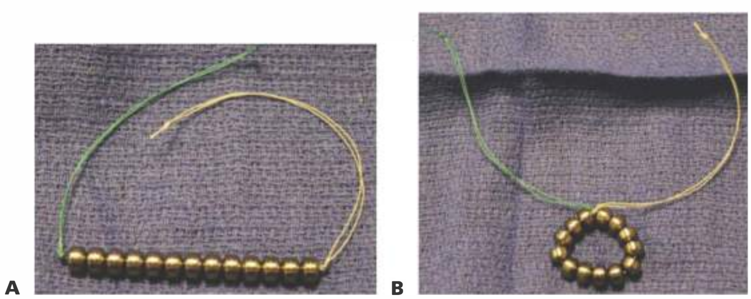

FIG 17 ● **A.** LINX device fully open with sutures at each end. **B.** Magnetic beads at each end are brought together. This is the configuration that the device is in when placed around the GE junction.

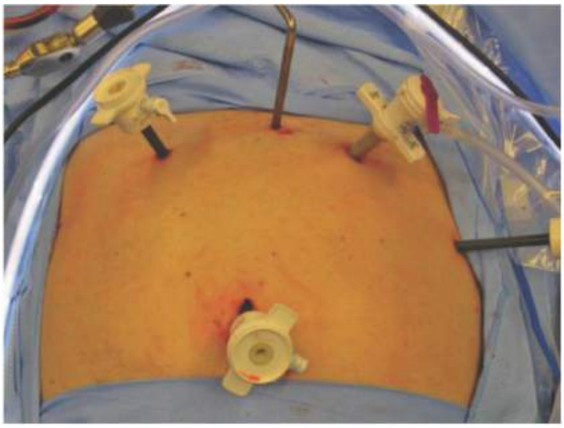

FIG 18 ● A 5-mm supraumbilical port, 8-mm left upper quadrant port, 5-mm left upper outer quadrant port, and 5-mm right upper quadrant port are placed. A bladed 5-mm subxiphoid port is temporarily placed to facilitate insertion of a liver retractor. The surgeon stands between the patient's legs and uses the 5-mm right upper quadrant port and 8-mm port. The assistant on the patient's left controls the camera and retracts the stomach inferiorly via the 5-mm right upper outer quadrant port.

Positioning

- The patient can be placed into either the supine or split-leg position on the operating room table.

Port Placement and Initial Dissection

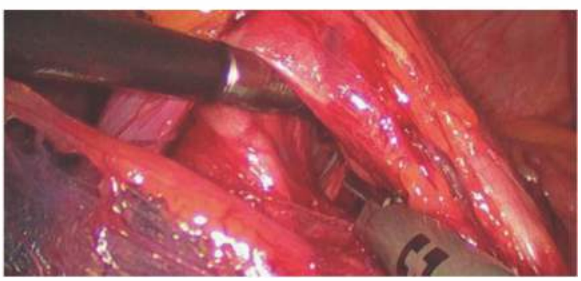
- Our technique involves initial placement of a Veress needle in the left upper quadrant. Four ports are subsequently placed including a 5-mm supraumbilical port, 8-mm left upper quadrant port, 5-mm left upper outer quadrant port, and 5-mm right upper quadrant port. A 5-mm port is temporarily placed in the subxiphoid position to facilitate placement of a liver retractor (**FIG 18**).
- A 5-mm camera is inserted through the supraumbilical port, which is operated by an assistant surgeon standing on the patient's left. The operating surgeon stands between the patient's legs and uses the 5-mm right upper quadrant port and the 8-mm port. The operating surgeon uses a blunt grasper (left hand) and an ultrasonic dissector (right hand) to enter the lesser sac via the pars flaccida. The left upper outer 5-mm port is used by the assistant surgeon to retract the stomach downward and laterally toward the spleen to facilitate dissection of the GE junction.

Dissection of Gastroesophageal Junction

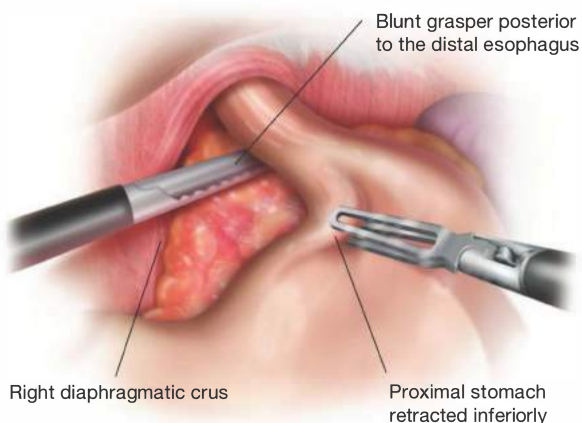
- The medial border of the right crus of the diaphragm is identified to facilitate the dissection of the retroesophageal space (**FIG 19**). The posterior vagal trunk is identified and preserved. The medial border of the left crus is then identified from the patient's left to further open the retroesophageal space.
- The blunt grasper in the surgeon's left hand is then passed through the retroesophageal plane between the posterior esophageal wall and the posterior vagal trunk, which is preserved. The tip of the grasper exits the retroesophageal tunnel anterior to the left crus of the diaphragm and is maintained in that location.

Device Selection and Placement

- A Penrose is placed into the upper abdomen and pulled through the retroesophageal tunnel. This serves as a tract for smooth passage of the sizer.
- The sizing instrument is placed into the abdomen through the 5-mm port (surgeon's left hand) and advanced through the retroesophageal plane from the patient's right to left.
- The white portion of the sizing instrument is then tightened around the GE junction cephalad to the hepatic branches of the anterior vagal trunk. As the circumference



A



B

FIG 19 ● **A,B.** A blunt grasper in the surgeon's left hand retracts the medial border of the right crus laterally to open up the retroesophageal plane while the proximal stomach is retracted inferiorly and laterally. The vagus nerve has been mobilized away from the esophagus to open up the plane for the sizer to be introduced. (Photo courtesy of Dr. Kyle Perry, The Ohio State University Wexner Medical Center.)

of the sizer approaches that of the GE junction, the appropriate LINX device size will be indicated on the sizing device (**FIG 20**).

- The sizing instrument is removed and the LINX device is inserted through the same plane that the sizer was placed through. The LINX device is then wrapped around the GE junction anteriorly. The sutures at each end of the device are then secured with a Ti-Knot device or securing the magnetic clasp depending on the version of the device employed (**FIG 21**).
- The abdomen is desufflated, the ports are removed, and the skin incisions are sutured closed.

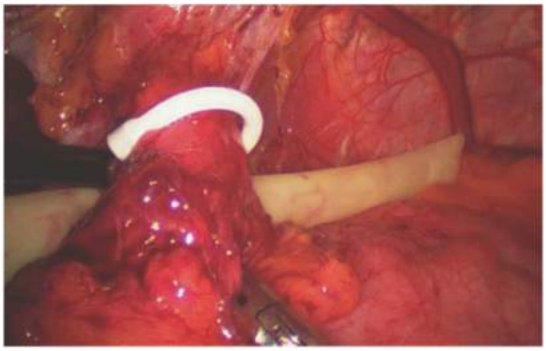


FIG 20 ● With the sizer gently wrapped around the GE junction anteriorly, the appropriate length of the LINX device is estimated and the LINX device is modified so that the length of the device matches this distance. (Photo courtesy of Dr. Kyle Perry, The Ohio State University Wexner Medical Center.)

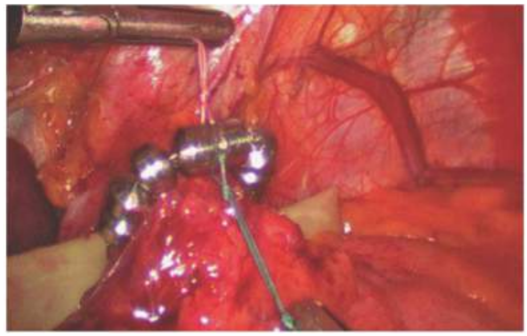

FIG 21 ● The LINX device is in place around the GE junction. The sutures at each are retracted superiorly and inferiorly to illustrate ideal positioning of the device. (Photo courtesy of Dr. Kyle Perry, The Ohio State University Wexner Medical Center.)

PEARLS AND PITFALLS

Pitfall	Pearl
Transoral incisionless fundoplication	
■ Cervical esophageal injury during placement of the device given the relatively large size of the device	■ Dilation of the esophagus with a large bougie (i.e., 56 Fr) and generous application of lubricant to the device will minimize the likelihood of esophageal injury. ■ Nasotracheal intubation will help clear the oropharynx for EsophyX device insertion.
■ Postoperative bleeding due to helix retractor placement or during fastener placement, particularly along the lesser curve of the stomach	■ Minimize the number of times that the helix retractor is deployed (once at the 12 o'clock position and once at the 6 o'clock position should be enough). ■ Minimize fastener placement along the lesser curvature. ■ Postprocedural EGD will identify early bleeding that may occur during these steps; if identified, endoclips can be placed.
■ Gastric or esophageal perforation related to fastener placement	■ Avoid placement of the fasteners through the diaphragmatic crura by ensuring that the fasteners are deployed below the point where the crura cross the esophageal wall. ■ Administer antiemetics aggressively to avoid significant postoperative retching which may pull on the fasteners.
Radiofrequency energy application	
■ Imprecise radiofrequency energy application due to patient movement during the procedure	■ Adequate amounts of anxiolytic and narcotic medications will help minimize patient movement; if necessary, general anesthesia can be administered.
■ Overdistention of the stomach from excess irrigation fluid	■ Monitor the suction return closely to prevent the stomach from filling up with irrigant; there should be essentially a 1:1 correlation between irrigation and suction fluid.
■ Uneven energy application via the four-needle electrodes due to asymmetry of the GE junction (i.e., if a small hiatal hernia is present)	■ More than two device rotations per level may be necessary to ensure that the radiofrequency energy is applied at numerous points throughout the circumference of the esophagus.

Lower esophageal augmentation surgery	
■ Esophageal injury while developing the retroesophageal plane.	■ Minimize the use of the ultrasonic dissector near the esophagus. ■ To minimize bleeding near the posterior vagal trunk, which may obscure the retroesophageal plane, carefully and bluntly dissect with a Maryland or blunt grasper.
■ Postoperative dysphagia due to excessive restriction from the device	■ Ensure that there is no tension on the sizer when measuring the circumference around the GE junction.
■ Device migration	■ When developing the retroesophageal plane, minimize the amount of dissection posterior to the GE junction. The dissection only needs to be wide enough to permit passage of the sizer.

POSTOPERATIVE CARE

- TIF—Patients are admitted postoperatively for overnight observation. A liquid diet is initiated following the procedure and advanced to a soft solid diet within the next several weeks. Antiemetics are administered liberally to minimize postoperative retching. Routine postoperative imaging is not obtained.
- Radiofrequency energy application—Patients are discharged home on the day of the procedure. They are kept on a liquid diet for the first several weeks and are subsequently advanced to a soft solid diet. Routine postoperative imaging is not obtained.
- LES augmentation surgery—Patients are admitted to the hospital overnight. During our early experience, as part of a clinical trial, all patients underwent a routine chest x-ray and barium esophagram to verify correct position of the device. Routine imaging is not currently obtained. The patient may resume a normal diet immediately after the procedure.

OUTCOMES

- TIF—With the earliest case series being published in 2008,[5] truly long-term data regarding TIF are lacking. In 2012, Trad and colleagues[6] published their data which involved 28 patients and a median follow-up of 14 months. Eighty-two percent of patients remained off their daily antireflux medications, whereas 68% were satisfied with the results of the procedure.[6] Heartburn and regurgitation symptoms were eliminated in 65% and 80% of patients, respectively.
- Radiofrequency energy application—In the earliest multicenter trial conducted in the United States (involving 47 patients), 87% of patients had discontinued their antireflux medications at 6 months while quality of life improved and esophageal exposure to acid (pH <4.0) decreased by over 50% (11.7% to 4.8% of the total time).[7] Four-year follow-up data from a study published in 2007 found that, along with sustained improvements in quality of life scores, 85% of patients remained off proton pump inhibitors or had decreased their use by half.[8]
- Lower esophageal augmentation surgery—In February 2013, the results of a nonrandomized multicenter trial were published in the *New England Journal of Medicine*.[9] Sixty-four percent of patients had either normalized or significantly reduced their esophageal acid exposure at 1 year. Ninety-three percent of patients had significantly reduced their antireflux medication regimen, whereas 92% experienced a substantial improvement in quality of life.

COMPLICATIONS

- TIF
  - Esophageal laceration/perforation
  - Postoperative bleeding
  - Gastric leak, mediastinal abscess
  - Early fundoplication failure
- Radiofrequency energy application
  - Bloating, dyspepsia
  - Esophageal ulceration/bleeding
  - Esophageal perforation
- LES augmentation surgery
  - Bloating, dysphagia
  - Device migration and/or erosion into the GI tract (to date, none have been reported or published in the literature)
  - Allergic reaction to the device (patients with titanium, stainless steel, nickel, or ferrous allergies)

Chapter 27

Radiofrequency Ablation of Barrett's Esophagus

Shajan Peter C. Mel Wilcox Klaus Mönkemüller

DEFINITION

- Barrett's esophagus (BE) is an acquired condition due to a change in the normal esophageal squamous epithelium to columnar epithelium containing goblet cells. This metaplastic change can progress to low-grade dysplasia (LGD) and high-grade dysplasia (HGD), with the latter having a 5% to 10% risk of developing into esophageal adenocarcinoma.[1,2]
- Radiofrequency ablation (RFA) is a safe and effective endoscopic treatment modality for BE whereby squamous tissue replaces the ablated metaplastic or dysplastic epithelium. RFA uses a bipolar electrode array to generate thermal energy to result in tissue dissipation.[3]

PATIENT HISTORY AND PHYSICAL FINDINGS

- It might be difficult to distinguish symptoms of BE from gastroesophageal reflux disease (GERD) clinically, although increased duration, severity, and early age of onset for reflux symptoms as well as obesity predispose to BE occurrence.[4]
- Age older than 55 years, male gender, white ethnicity, or smokers are predisposing factors for BE development and progression to dysplasia. Genetic influences may play a role, although only a small proportion (7%) of patients with BE have a documented family history of BE or esophageal cancer.[5]
- Selection of patients for endoscopic treatment of BE requires a multidisciplinary approach consisting of the endoscopist, pathologist, and the surgeon.
- Confirmation of dysplasia (high or low grade) on biopsies or endoscopic mucosal resection (EMR) specimens is done by a dedicated gastrointestinal (GI) pathologist.[6]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Detailed endoscopic examination with high-definition white light of the BE segment is essential for management.
- The extent of the BE segment should be defined using the Prague C & M classification including the length of the circumferential segment (C) and the maximal extent of the BE segment (M)[7] (**FIG 1**).

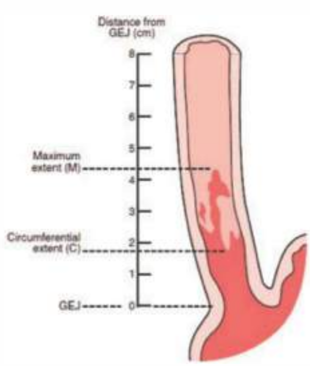

FIG 1 ● Prague C & M classification.

- Other imaging modalities that might help in delineating BE are narrow band imaging (NBI), chromoendoscopy, autofluorescence imaging, and confocal laser endoscopy. These adjuncts aid in directed biopsies.
- Any visible lesions in the Barrett's segment should be described using the Paris classification.[8]
- Targeted biopsies are obtained from visible abnormalities, followed by four-quadrant biopsies of every 1 to 2 cm of the BE segment (Seattle protocol) and these should be reviewed by a dedicated GI pathologist.[9] Nodular lesions are best staged by an EMR as described in Part 1, Chapter 28.

ENDOSCOPIC MANAGEMENT

Preoperative Planning

- Patients are given standard esophagogastroduodenoscopy (EGD) preprocedure preparation instructions with specific attention to factors that increase risk of sedation including morbidly obese patients; anatomic variants such as short neck, cervical osteophytes, cricopharyngeal hypertrophy; and prior history of surgery involving the GI tract, radiation, or documentation of previous strictures.
- No antibiotics are required and it is desirable to minimize or stop antiplatelet/anticoagulation prior to the procedure.
- Equipment lists for circumferential and focal ablation can be found in Tables 1 and 2.

Positioning

- The patient is placed in the left lateral decubitus position and prepared as for a routine upper endoscopy.

Table 1: Circumferential Ablation Equipment List

CIRCUMFERENTIAL ABLATION

Endoscopy with Inspection and Recording the Landmarks

- Measurements are taken to map the extent of the BE showing (1) top of intestinal metaplasia (TIM), (2) proximal contiguous area of BE (M), (3) proximal level at which the BE is circumferential, (4) and the top of the gastric folds (TGF) (**FIG 2**).
- Careful inspection should be made to rule out prior ulceration, strictures, previous scarring from EMR or residual nodularity as these may compromise any balloon circumferential ablation. Dilatations should be performed prior to ablation.
- Mucosa is washed with N-acetylcysteine to clear any excess mucus and prepare the tissue for further ablation.
- After adequate inspection and recording landmarks, a guidewire is passed into the gastric antrum and then the endoscope removed.

Sizing

- The sizing balloon is attached to the control unit and then calibrated externally also to rule out any leaks. It is then introduced over the guidewire into the body of the esophagus, placing it 3 cm proximal to the TIM measurement.
- Serial measurements are taken at 1-cm intervals, starting proximally and proceeding distally by inflating the device on the pedal provided. The displayed measurements on the console are then recorded by a technician or nurse. The smallest diameter treatment balloon suggested throughout the sizing is chosen as appropriate ablation catheter.

Selecting Appropriate Ablation Device

- After sizing, the catheter is then removed, keeping the guidewire in place.
- The smallest diameter treatment balloon suggested throughout the sizing is chosen as appropriate ablation catheter and attached to the generator.

First Ablation Pass

- The Barrx™ 360 RFA Balloon Catheter (Covidien, Mansfield, MA) (**FIG 3**), consisting of a 3-cm electrode array encircling a 4-cm long balloon, is then passed over the guidewire into the esophagus (**FIG 4A**). The endoscope is intubated alongside the catheter to visualize the proximal end of the balloon, which is then positioned 1 cm proximal to the TIM.
- The balloon is automatically inflated first and then energy delivered by using the foot pedals attached to the control unit. The uniform energy has a density of 12 J/cm^2 and power of 40 W/cm^2 ablating to a depth of 700 to 1,000 μm over 3 cm of array (**FIG 4B**).
- After a second of ablation, the balloon automatically deflates and the circumferential burn is visible.
- Depending on the length of the segment, an additional 3 cm of circumferential ablation is performed such that there is minimal overlap with the previously ablated segment (**FIG 4C**).

Cleaning Procedure

- The balloon catheter is then removed along with the endoscope, leaving the guidewire in place. Outside the patient, it is inflated and cleaned using damp gauze, removing adherent ablated tissue.
- The treated area is then cleaned of the coagulum using a HALO cap attached to the tip of the endoscope (**FIG 5**). After reintroduction of the endoscope, the coagulum is gently removed using the edge of the cap, debriding proximal to distal in a circumferential manner and thereafter cleaning with saline lavage. The endoscope is removed and then the cap discarded.

Second Ablation Pass

- The cleaned ablation catheter device is then introduced over the guidewire with the endoscope and a second set of ablation is performed as described previously, retreating the area and further coagulating any superficial blood vessels preventing bleeding.

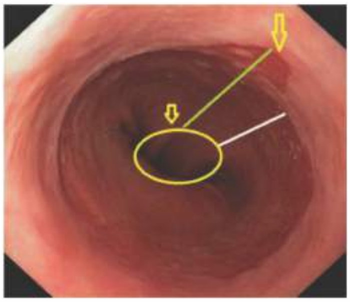

FIG 2 ● Endoscopic appearance of BE. *Yellow oval* indicates top of gastric folds, *green line* to *yellow arrows* indicates maximum length of BE, and *white line* denotes length of circumferential BE.

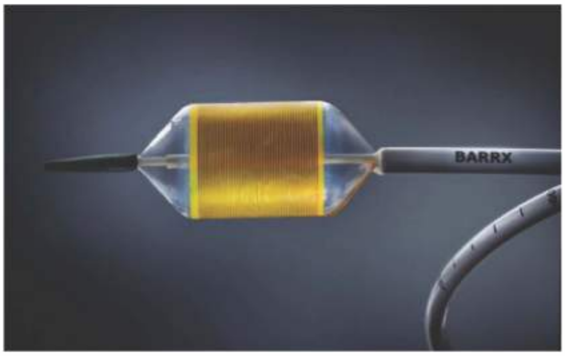

FIG 3 ● Barrx™ 360 RFA Balloon Catheter (© 2014 Covidien).

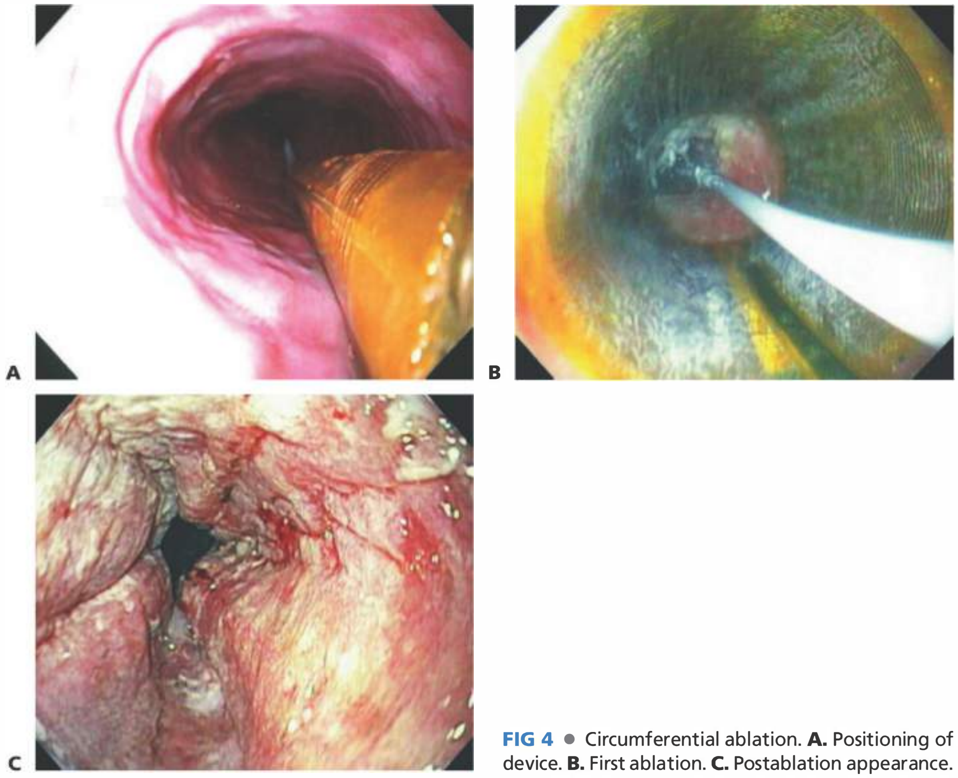

FIG 4 ● Circumferential ablation. **A.** Positioning of device. **B.** First ablation. **C.** Postablation appearance.

Focal Ablation

- The focal ablation is performed for treating shorter segments, tongues and islands of BE, and during follow-up after an initial circumferential RFA. It may also be of special use in treating areas adjacent to the squamous-columnar junction.

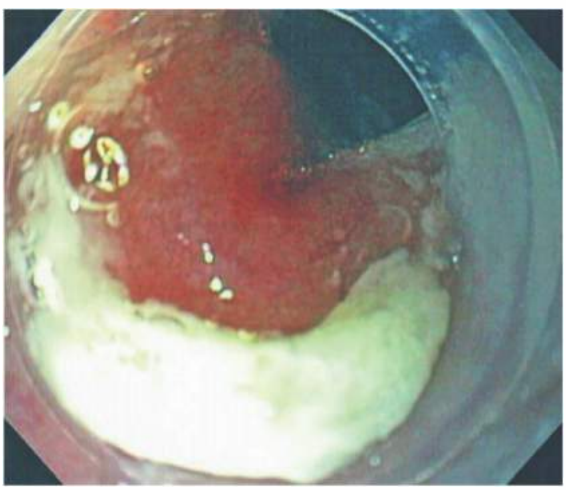

FIG 5 ● Cleaning using HALO cap.

- After careful endoscopic examination, the areas are recorded and endoscope removed while externally, the HALO^{90} device (array measuring 13 × 20 mm) is attached to the tip of the scope. It is positioned such that the back of the thumb-shaped array is located at 12 o'clock position on the endoscopic field of view and can be pivoted easily. It is reintroduced into esophagus after careful intubation.
- The esophagus is washed with N-acetylcysteine solution. The targeted area of BE is identified and the endoscope is angulated such that the ablation device is tightly opposed to the mucosa (FIG 6A).
- After maintaining optimal contact, the energy is delivered using the foot pedal using the similar energy settings previously described. Maintaining the same position, a second pulse of energy is given. The device is then moved to the next treatment area and previously mentioned steps repeated, treating all visualized BE (FIG 6B).
- The coagulum of desiccated mucosa is then removed using either a HALO cap as previously described or even the tip of the ablation device could be used to scrape the tissue. After gentle debridement, the device is then externally cleaned using damp gauze, reintroduced while mounted on the scope and a second round of two applications per area are performed in an identical manner such that eventually each targeted area receives a total of four energy ablations.

A 
B 
FIG 6 ● Focal ablation. **A.** Positioning of device. **B.** Ablation.

FOLLOW-UP

- Endoscopic evaluation of the ablated area is performed 2 months following the procedure, and complete healing should have occurred by this time (**FIG 7**).

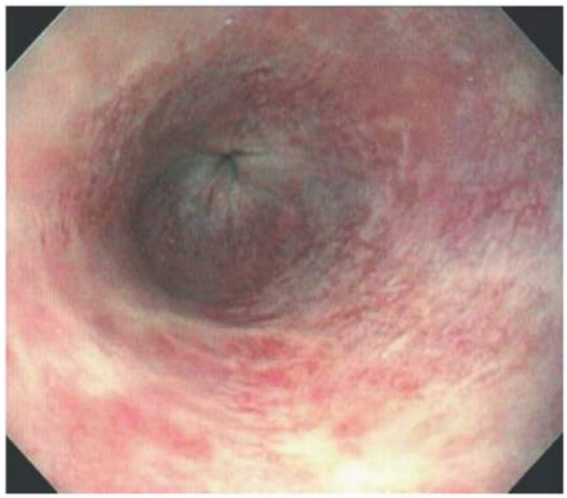

FIG 7 ● Follow-up showing healing.

PEARLS AND PITFALLS

Indications	■ Careful history, endoscopic findings, and pathologic review of records should be done prior to selection of patients for ablation.
Selection of ablation method	■ Long-segment circumferential areas should be targeted using the circumferential HALO[360] device. ■ Short segment and subsequent sessions or "touch up" of BE can be treated using the focal HALO[90] device.
Circumferential ablation	■ Endoscopic identification of landmarks and length on segment based on Prague classification ■ Sizing of device and selection of balloon ablating catheter ■ Careful positioning and endoscopic visualization of the catheter and performing the first ablation pass ■ Cleaning of device externally while performing debridement of tissue using the endoscope and cap ■ Performing the second ablation pass
Focal ablation	■ Endoscopic identification of landmarks ■ Attachment of device to endoscope such that it is in 12 o'clock endoscopic view ■ Optimal opposition to targeted mucosa and energy delivered using "dual technique" with continued ablation of all areas ■ Debridement of tissue, cleaning of device, and second pass of ablation for all areas
Follow-up	■ Immediate postprocedure instructions are given regarding food intake, pain management, and antireflux medications. ■ Follow-up after 2 months for repeat endoscopy, further ablation, or biopsies.

POSTOPERATIVE CARE

- After RFA treatment, patients may experience chest pain and dysphagia for 3 to 4 days thereafter.
- Postoperative care includes a pain management with viscous lidocaine or liquid acetaminophen with narcotic. A liquid diet is advised for 24 hours after treatment and then to slowly return to normal diet.
- A maintenance dose of proton pump inhibitor (PPI) such as esomeprazole 40 mg twice a day during the entire treatment period for adequate acid suppression is required to promote healing. In addition, sucralfate 1 g four times a day for 2 weeks is prescribed.
- Patients are usually discharged home on the same day as the procedure. On occasion, severe chest pain may require admission for observation and optimizing pain management.
- They are instructed to be followed up for 2 months after the initial ablation when they are reassessed for further treatment or biopsies if neo-squamous epithelium is seen. Approximately 3.5 treatment sessions may be necessary to clear all dysplastic BE and this will depend on the length of segment.

OUTCOMES

- RFA is effective for treatment of HGD and LGD.[3]
- In a randomized sham-controlled trial, complete eradication for HGD was noted in 81.0% compared to 19.0% in controls. Similarly, disease progression was lower in the ablation group (3.6% vs. 16.3%).[10] Patients with LGD achieved eradication in 90.5% of the ablation group as compared to 22.7% of control group at the end of 12 months. Durability of RFA demonstrated eradication of dysplasia in 98% and 91% of metaplasia at the end of 3 years since ablation therapy.[11]

COMPLICATIONS

- RFA has a low complication rate with low adverse events. Chest pain and dysphagia are commonly associated symptoms lasting for a period of 3 to 4 days posttreatment and resolves spontaneously to baseline.[12,13]
- Strictures can occur on follow-up and the rate varies between 0% and 8%, with longer segments and preceding EMR to be higher risk factors for developing them. They can, however, be managed by endoscopic dilatation.
- Bleeding is rare (<1%) and encountered especially in patients on antiplatelet or anticoagulation therapy.
- No perforations or RFA-related deaths have been reported after RFA. Fever is also a rare complication and can be managed using antipyretics.
- Buried intestinal metaplasia or glands has been of concern postablation and may not be visible endoscopically. It is less frequently reported after RFA (0.9%) and highlights the need for deep endoscopic biopsies, which need to be carefully reviewed by the pathologist.[14]

Chapter 28 Endoscopic Mucosal Resection for Barrett Neoplasia

Shajan Peter C. Mel Wilcox Klaus Mönkemüller

DEFINITION

- Barrett esophagus (BE) is a strong risk factor for esophageal adenocarcinoma.[1]
- The annual risk of BE progression to adenocarcinoma ranges from 01.12% to 0.61%.[1,2]
- The traditional treatment of choice for "resectable" esophageal adenocarcinoma is esophagectomy.
- However, surgical resection is still associated with significant mortality and morbidity, even in high-volume centers and especially in elderly or poor surgical candidates.[3]
- Thus, during the last two decades, patients with early cancer or those with high-grade dysplasia have been successfully treated with endoscopic resection methods.[4,5]
- The most common method used is endoscopic mucosal resection (EMR) or "mucosectomy."[4,5]

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of mucosal neoplasia of the distal esophagus is narrow. The most common malignant neoplasia of the distal esophagus is adenocarcinoma, followed by squamous cell cancer.[4,5]
- Proximal stomach cancer such as cardiac or fundic adenocarcinoma extending into the esophagus may be difficult to differentiate from distal esophageal adenocarcinoma.
- Submucosal tumors such as gastrointestinal (GI) tumors, spindle cell tumors, lipoma, and leiomyoma are easily differentiated from mucosal lesions as these tumors generally have a normal overlying mucosa.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with Barrett's neoplasia do not have any specific symptoms and BE is discovered incidentally during an upper GI endoscopy performed for the evaluation of gastroesophageal reflux symptoms, dyspepsia, or abdominal pain.[6]
- However, Barrett's neoplasia is more common in patients with the following characteristics: male, central obesity, Caucasian, age older than 50 years, tobacco use, and chronic gastroesophageal reflux disease (GERD).[6]
- Although reflux of acid is a common occurrence in BE, a high proportion of BE patients deny a history of reflux symptoms.[7]
- Therefore, any patient undergoing upper endoscopy should be carefully investigated for columnar-lined epithelium and intestinal metaplasia of the distal esophagus, with special attention to patients with the risk factors mentioned earlier.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiologic studies do not play a role in the evaluation of BE unless there is a stricture present (benign or malignant). In this instance, a barium esophagogram can be helpful to determine the length and characteristics of the stenosis.
- Although computed axial tomography is useful to evaluate for lung metastasis and mediastinal and perigastric lymph node involvement in esophageal adenocarcinoma, its role in patients with early Barrett neoplasia is negligible, as most of these patients have local disease, which does not extend beyond the submucosa of the esophagus.
- Patients with Barrett's cancer invading the submucosa (sm1) have a very low risk of lymph node metastasis and thus are ideal candidates for EMR.[4–6]
- In the past, endoscopic ultrasound (EUS) was used to determine the depth of GI layers involvement in early Barrett neoplasia.[8]
- However, the sensitivity and specificity of EUS for early Barrett neoplasia are low and the results can be misleading.[8]
- The mainstay of diagnosis of BE is with light endoscopy, ideally using high-definition endoscopes and equipment.[9]
- It is very important to measure the proximal distance of extension of cylindrical-type epithelium into the esophagus. The extent of BE segment should be defined using the Prague C & M classification including the length of the circumferential segment (C) and the maximal extent of the BE segment (M).[10]
- The use of various staining agents and dyes (chromoendoscopy) such as methylene blue (**FIG 1**) and indigo carmine or agents such as acetic acid (**FIG 2**) enhances the mucosal pit pattern analysis (see the following text) and thus facilitates the detection high-grade dysplasia and carcinoma.[9]

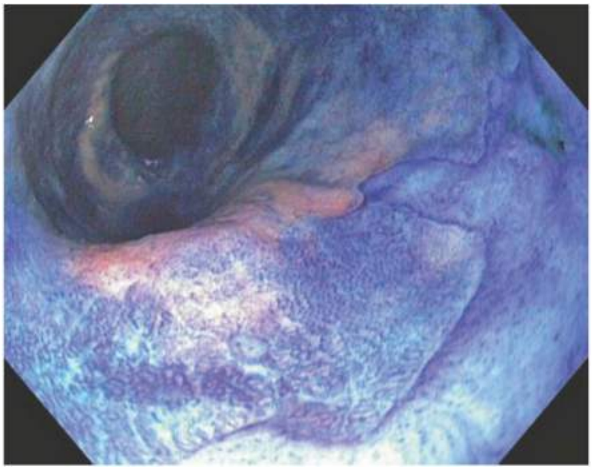

FIG 1 ● Chromoendoscopy with methylene blue allows for a better definition of the pit pattern and the detection of areas of dysplasia and carcinoma. The absence of colorant points to a suspicious area of dysplastic cells. This image shows a pit pattern type IIIS.

FIG 2 ● Acetic acid is another useful adjunct to define the mucosal pit pattern. Careful analysis of the pit pattern of Barrett's epithelium is mandatory to define its type and discover areas of dysplastic cells. This sample shows a type II pit pattern.

- Other imaging modalities that might help in delineating BE are narrow band imaging (NBI) (**FIG 3**), autofluorescence imaging, and confocal laser endoscopy.
- Magnification endoscopy is also important to characterize the mucosal surface and pit pattern (**FIG 4**).
- The most widespread classification used to categorize the pit pattern in BE is the Endo classification (adapted from S. E. Kudo).[11]
- This classification categorizes the opening of the pits into round (I), stellar or asteroid (II) (see **FIG 2**), tubular elongated (IIIL), tubular short or round (IIIS) (see **FIG 1**), gyrus or sulcus branched (IV) (see **FIG 4**), and irregular or amorphous (V) (**FIG 5**).
- Types I, II, and III pit patterns are "benign," whereas pit pattern types IV and V are more commonly present in advanced neoplasia or carcinoma.
- Chromoendoscopy is performed to aid in obtaining directed (i.e., targeted) biopsies prior to mucosectomy to define the precise extent of neoplastic involvement.
- Targeted biopsies are obtained from visible abnormalities, followed by four-quadrant biopsies of every 1 to 2 cm of the BE segment (Seattle protocol; see Part 1, Chapter 27) and these should be reviewed by a dedicated GI pathologist.

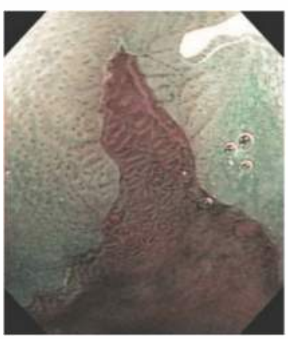

FIG 3 ● NBI is one of the many "virtual" chromoendoscopy techniques to evaluate the mucosal and submucosal surface. This sample shows a pit pattern type IIIL.

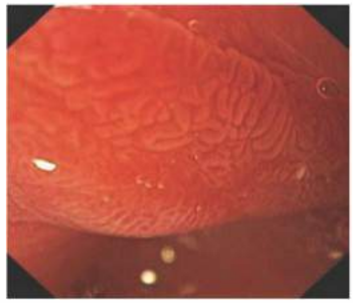

FIG 4 ● Magnification endoscopy permits the close examination of the mucosa. The pit pattern in this case is mixed (IIIL and IV).

ENDOSCOPIC MANAGEMENT

- The two most important indications for EMR of Barrett's neoplasia are diagnostic and therapeutic.[5,6,12]
- EMR can be generally attempted if the lesions are smaller than 20 mm in diameter.
- Endoscopic submucosal dissection (ESD) should be reserved for larger lesions.
- However, ESD is a technique that has been mainly used for early squamous cell cancer of the esophagus. The results of ESD for Barrett neoplasia are still suboptimal.

Preoperative Planning

- All patients should undergo a thorough history and physical examination and be classified based on the American Society of Anesthesiologists (ASA) score.
- Interventions in patients with ASA score greater than or equal to 4 are not deemed beneficial, as the risk of harm outweighs the potential benefits.
- Obtaining routine laboratory data such as white blood cell and platelet count, bleeding studies (partial thromboplastin time [PTT]/international normalized ratio [INR]), and creatinine and electrolytes is mainly indicated in multimorbid patients or those taking medications that specifically affect any organ or system (e.g., anticoagulant, diuretics).
- Management of anticoagulants preoperatively should be based on the guidelines established by the American Society for Gastrointestinal Endoscopy.[13]

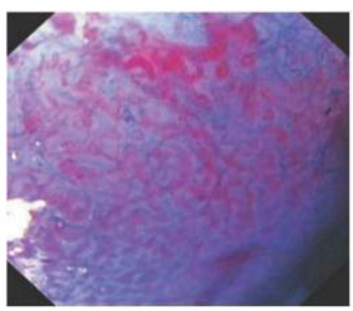

FIG 5 ● The abnormal and amorphous pit pattern (type V) with the presence of tortuous or irregular vessels is suggestive of dysplasia and malignancy.

- In patients with high-risk cardiovascular conditions on warfarin, it is important to bridge this period with the use of low-molecular or fractionated heparins.[13]
- Prophylactic antibiotics are not recommended before EMR.[14]
- The standard of care is the administration of conscious sedation.[4,5,12,15]
- Exceptions include patients who ingest narcotics or benzodiazepines, multimorbid patients, or heavy alcohol drinkers. For these groups of patients, we prefer monitored anesthesia care (MAC), use of nurse-assisted propofol sedation (NAPS), or general anesthesia (GA).
- We want to emphasize that a carefully performed EMR in expert hands should take less than 15 minutes.
- When performing an EMR, the bulk of time is usually in recognizing and characterizing the lesion. The resection per se is a focused procedure that should be targeted, efficient and efficacious.

Positioning

- The patient is placed in the left lateral decubitus position and prepared as for a routine upper endoscopy.

ENDOSCOPIC MUCOSAL RESECTION TECHNIQUES

- Several EMR techniques have been described for removal of focal and diffuse lesions in BE.[4,5,12,15]
- Table 1 lists the essential equipment needed for EMR.

Table 1: Endoscopic Mucosal Resection Equipment List

Endoscope with high-definition white light capabilities
Spray catheter (or biliary cannula) to apply dye for chromoendoscopy
Indigo carmine or methylene blue solution for chromoendoscopy
Duette® EMR kit or esophageal varices banding device
Snares (hexagonal and oval)
Injection needle
Roth Net to retrieve resected specimen
Cork or Styrofoam plates and pins to pin down the specimen
Electrosurgical unit

EMR, endoscopic mucosal resection.

SNARE TECHNIQUE

- This is the most "simple" technique to remove a lesion.[4,5,15]
  - It entails using an oval or hexagonal electrocautery snare.
- However, simple refers mainly to the commonly used instruments to perform an EMR, as it requires high-level skills and experience to be able to grasp the target lesion and resect it entirely by just using a snare.
- It is important to always remove all the air before snaring the lesion. This allows for ensnaring more tissue.
- The assistant holding the snare should carefully close it while the endoscopist aspirates the air and advances the snare catheter toward the lesion.
- The electrocautery used for performing EMR should be predominantly cut or blended.
- Coagulation currents tend to produce deep injury and are associated with high risk of perforation.

SUBMUCOSAL INJECTION AND SNARE

- A modification of the snare technique is the use of a submucosal cushion below the tissue to be removed.[4,5,12]
- This "safety" cushion may theoretically decrease the risks of perforation.
- By iatrogenically swelling up the mucosa with the injection of substances, it will be harder for the pathologist to determine the depth of tumor invasion (if present).
- We also caution against the use of epinephrine in the solution used to create the submucosal cushion as the venous irrigation from the distal esophagus returns to the right heart without first-pass metabolism through the liver via the azygous vein, thus increasing the chance of systemic effects and side effects, including cardiac ischemia.

USE OF A TRANSPARENT CAP ("SUCK-AND-CUT" OR INOUE TECHNIQUE)

- A transparent cap is attached to the tip of the scope.
- The cap is placed perpendicularly against the mucosa, preferentially in the greater curvature of the stomach. A snare is advanced, opened, and placed around the inner ring of the cap (**FIG 6**).
- Once the snare is partially opened, completely inside the inner part of the cap, the scope is pulled back into the esophagus and directed toward the lesion of interest.
- The lesion is then aspirated inside of the cap and the snare is closed snuggly around the base of the lesion (**FIG 7**).
- Once the lesion has been caught with the snare, electrosurgical currents are applied and the lesion is resected (**FIG 8**).

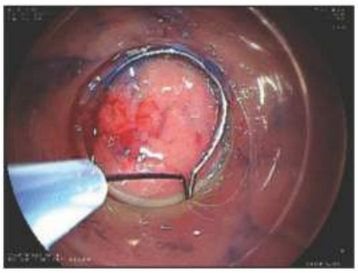

FIG 6 ● A snare is advanced, opened, and placed around the inner ring of the cap.

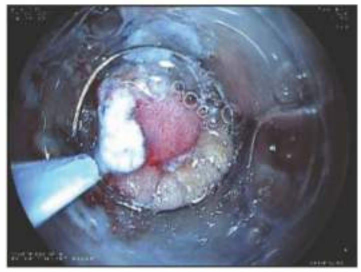

FIG 7 ● Once the lesion has been sucked inside the cap and caught with the snare, electrosurgical currents are applied and the lesion is resected.

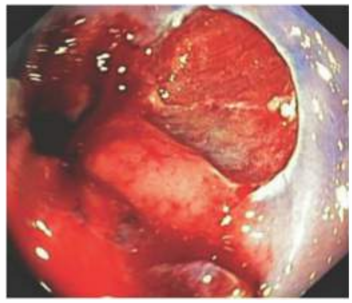

FIG 8 ● Successful EMR. The resected site shows the muscularis propria demonstrating an effective resection of mucosa and submucosa. The aim of any EMR should be an in toto and R0 resection.

USE OF CAP WITH LIGATURE DEVICE ("SUCK-LIGATE-AND-CUT" TECHNIQUE)

- With this method, both the mucosa and submucosa are aspirated or "sucked" into a transparent cap loaded with elastic ligature bands or rings (**FIG 9**).
- This device is essentially the same as the one to perform esophageal variceal ligation.
- Whereas some experts use a "multiband" ligator (MBL), using a single-band ligation device is also possible.
- After placing the bands, the scope is retrieved, the cap is removed, and the scope is reinserted to perform the EMR.
- By aspirating ("sucking") the tissue into the cap and releasing the ring on its base, a pseudopolyp is created (**FIG 10**).
- The main advantage of the Duette®-MBL (Cook Medical, Winston Salem, NC) is that a 5-Fr polypectomy snare can be passed through both the ligator handle and channel of the scope, thus permitting ligation and subsequent resection using the snare without removal of the endoscope (**FIG 11**).

FIG 9 ● The mucosa and submucosa are sucked into a transparent cap loaded with elastic ligature bands or rings.

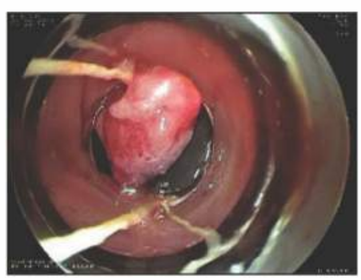

FIG 10 ● By aspirating (sucking) the tissue into the cap and releasing the ring on its base, a pseudopolyp is created.

FIG 11 ● The main advantage of the Duette®-MBL (Cook, Winston Salem, NC) is that a 5-Fr polypectomy snare can be passed through both the ligator handle and channel of the scope, thus permitting ligation and subsequent resection using the snare without removal of the endoscope.

- The "pseudopolyp" is then snared off.
- An advantage of using an MBL method is the creation of one or multiple pseudopolyps.
- The MBL methods is a great option for (1) removing lesions located in various sites, (2) piecemeal EMR of a larger lesion, and/or (3) to perform hemi- or full circumferential resection of the distal esophageal mucosa.[15]
- Resected specimens are collected using the snare Roth Net (US Endoscopy, Mentor, OH) or aspirated into the inside of the cap of the scope and retrieved out of the esophagus or stomach.
- The piece(s) should be fixed onto a piece of cork or Styrofoam before being immersed in 4% formalin solution and sent for histopathologic assessment.

PEARLS AND PITFALLS

Patient evaluation	■ Careful history, endoscopic findings, and pathologic review of records should be done prior to selection of patients for EMR.
Indication	■ EMR is only indicated for lesions less than 20 mm.
Endoscopy	■ Endoscopic identification of landmarks and length on segment should be based on the Prague classification. ■ Knowledge of chromoendoscopy and advanced endoscopic methods is essential for a successful EMR. ■ The chromoendoscopy devices should be ready before the procedure gets started. ■ Careful description and documentation of the exact location of the lesion is mandatory. ■ Use a diagram to document findings. ■ Endoscopic photodocumentation is mandatory.
EMR method/technique	■ EMR should be only performed by endoscopists with advanced endoscopic training. ■ Become well-versed in one EMR technique. ■ Remove the air before ensnaring the lesion. ■ Be ready for potential complications (bleeding, perforation) and know how to treat them. ■ Each resected specimen should be pinned down into cork or Styrofoam and placed into distinctly labeled formalin containers. ■ Always have an additional large hexagonal and small oval snare readily available.
Follow-up	■ All patients undergoing EMR should be put on long-term proton pump inhibitors. ■ All EMR cases should be presented at the pathology conference. ■ Follow-up endoscopy is mandatory to ensure complete resection and evaluate for synchronous or metachronous lesions or recurrence. ■ All patients undergoing EMR should be kept in a registry to ensure quality care.

POSTOPERATIVE CARE

- A liquid diet is administered for 24 hours after treatment and then advanced to regular diet.
- All patients undergoing EMR should be on long-term proton pump inhibitors.
- The dosage is doubled after EMR and kept at this level for 4 weeks.
- Patients are usually discharged home on the same day of the procedure.
- Follow-up endoscopy is based on the type and histology of lesion resected.
- Long-term follow-up is based on the recommendations of the American College of Gastroenterology and American Society for Gastrointestinal Endoscopy.

OUTCOMES

- EMR is efficacious method to treat BE with high-grade dysplasia and early cancer as long as the lesions are less than 20 mm.[4,5,12,15]
- In expert hands, complete remissions of more than 95% can be achieved.[4,5,12,15]
- A favorable outcome is dependent on the following "low-risk" criteria: invasion not beyond sm1, absence of infiltration into lymph vessels and/or veins, histologic grade G1/2, and macroscopic type I/II.
- Recurrence or metachronous neoplasia are seen in up to 20% to 30% of patients.
- Repeat endoscopic treatment can be performed in almost all patients presenting with metachronous or recurrent disease.

- Ablative therapy using radiofrequency ablation of the residual or recurrent Barrett segment is possible, feasible, and effective.

COMPLICATIONS

- EMR has low complication rates in expert hands.
- *Early* complications include perforation (<0.5%) and bleeding (5% to 14%).
- Moderate or severe post-EMR bleeding can be easily controlled by diluted epinephrine injection (1:10,000) and/or metal clip application.
- Esophageal stenosis is more common in patients undergoing resection of more than 50% of the distal esophageal circumference

Chapter **29**

Esophagectomy: Transhiatal and Reconstruction

Robert E. Glasgow

DEFINITION

- Transhiatal esophagectomy (THE) or esophagectomy without thoracotomy is defined as removal of the esophagus and upper stomach using an incision in the left anterior neck for purposes of dissection of the upper third of the esophagus via the thoracic inlet, and an upper midline abdominal incision for purposes of dissection of the stomach and lower two-thirds of the esophagus and creation of a conduit for esophageal reconstruction (stomach, colon).
- Although THE is usually applied for purposes of treating esophageal and gastroesophageal (GE) junction carcinoma, THE may also be used for treatment of benign esophageal conditions including end-stage achalasia and medically/endoscopically recalcitrant esophageal stricture from caustic injection or end-stage reflux disease and acute perforation.
- The remainder of this discussion will focus on the use of THE in the treatment of malignant disease. Most aspects of the diagnostic workup and operative techniques also apply to the evaluation and treatment of benign conditions for which THE is being considered.

DIFFERENTIAL DIAGNOSIS

- THE is most commonly used in treatment of esophageal cancer. In particular, adenocarcinomas of lower third of the esophagus and Siewert types I and II GE junction adenocarcinoma (**FIG 1**; Table 1) are optimally suited for this approach.
- Squamous cell carcinomas (SCCs) of the lower third of the esophagus may also be approached via THE, whereas tumors of the middle and upper third of the esophagus usually require transthoracic esophagectomy (TTE) to allow for direct visualization of the dissection of the involved esophagus.

PATIENT HISTORY AND PHYSICAL FINDINGS

- All patients should undergo a comprehensive medical history with emphasis not only on clinical history pertinent to the primary indication for consideration of THE but also the pertinent comorbid conditions that would influence treatment planning. Included in this history is a comprehensive past surgical history. Prior fundoplication will make dissection of the esophageal hiatus more difficult. Patients with a prior history of gastric resection, for example, may not be candidates for use of the stomach as a conduit for reconstruction because of inadequate length or blood supply. Finally, if the colon is to be considered for use for reconstruction, the influence of prior colectomy on anatomy and blood supply should be very carefully considered.

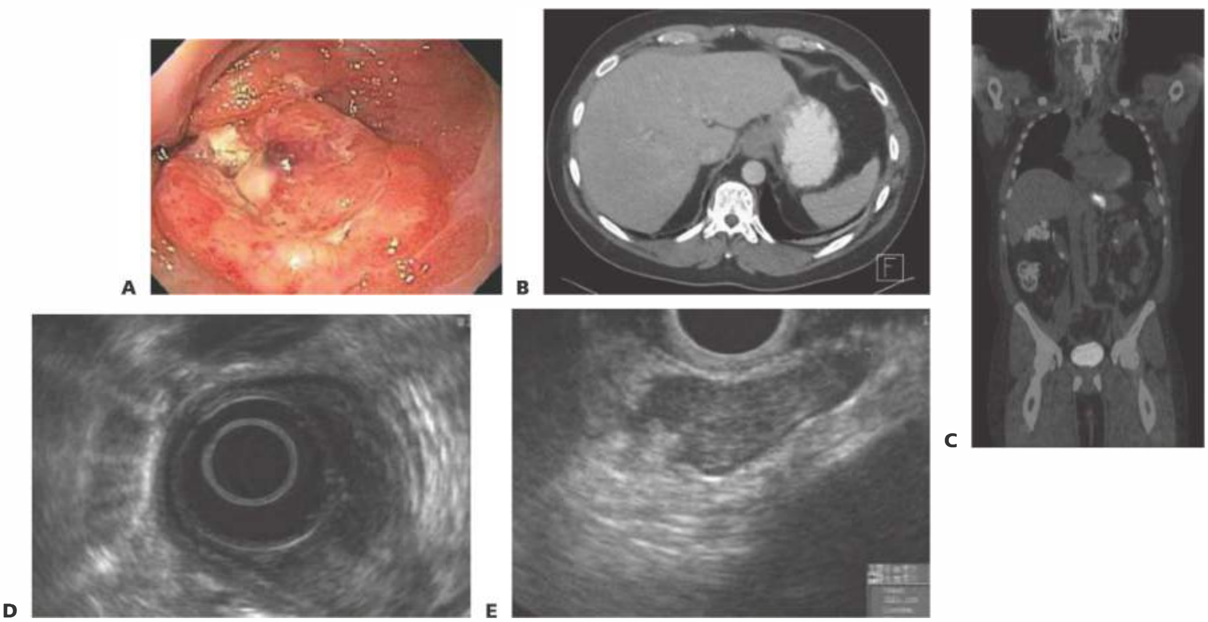

FIG 1 ● Imaging and diagnostic evaluation of a patient with a localized T3, N1, M0 Siewert type 2 GE junction adenocarcinoma undergoing consideration for THE. **A.** Upper endoscopy showing ulcerated mass in the lower third of the esophagus. **B.** CT showing an enlarged mass at the lower third of the esophagus. **C.** PET-CT. **D.** Endoscopic ultrasound showing mucosal-based mass invading into the adventitia of the esophagus. **E.** Endoscopic ultrasound showing enlarged lymph node fine needle aspiration (FNA) biopsy confirming adenocarcinoma.

Table 1: Siewert Classification for Gastroesophageal Junction Adenocarcinoma

Type I: Adenocarcinoma of the lower esophagus with the center located within 1 cm above and 5 cm above the anatomic EGJ.
Type II: True carcinoma of the cardia with the tumor center within 1 cm above and 2 cm below the EGJ.
Type III: Subcardial carcinoma with the tumor center between 2 and 5 cm below EGJ, which infiltrates the EGJ and lower esophagus from below.

EGJ, esophagogastric junction.
From Rüdiger Siewert J, Feith M, Werner M, et al. Adenocarcinoma of the esophagogastric junction: results of surgical therapy based on anatomical/topographic classification in 1,002 consecutive patients. Ann Surg. *2000;232(3):353–361.*

- Whether it be for benign or malignant disease, the principal symptom at the time of presentation for a patient who would undergo THE is dysphagia. Often, these patients have significant nutritional impairment, most notably, weight loss.
- In patients with adenocarcinoma of the esophagus and GE junction, a history of GE reflux disease should be elicited as well as a careful history of prior endoscopic and radiographic evaluations. In patients with SCC, a prior and current history of tobacco and alcohol use should be elicited.
- A comprehensive physical examination should be performed with special attention to the cervical and supraclavicular areas for enlarged lymph nodes, chest exam for possible effusions, and abdominal exam for palpable masses and periumbilical lymph nodes (Sister Mary Joseph nodule).

IMAGING AND OTHER DIAGNOSTIC STUDIES

Upper Endoscopy with Biopsy

- All patients presenting with dysphagia should undergo upper gastrointestinal endoscopy and biopsy with the goal of making a diagnosis and localizing the site of obstruction (**FIG 1**).
  - Multiple biopsies of suspicious areas (nodules, ulceration, stricture, possible Barrett's) should be obtained.
  - Endoscopic mucosal resection (EMR) of focal nodules should be performed to provide accurate T staging and to evaluate degree of differentiation and vascular and/or lymphatic invasion.
  - For cancer, the location of the tumor as measured from the incisors and GE junction and extent of tumor length, circumferential involvement, and degree of obstruction should be documented.

Computed Tomography of Chest and Abdomen

- Once a diagnosis of cancer is made, a computed tomography (CT) of the chest and abdomen with oral and intravenous contrast is done.
- Tumor location, locoregional involvement or invasion, regional and extraregional lymph node involvement, and metastatic disease should be evaluated and recorded.
- If metastasis is suspected, biopsy of concerning lesions should be undertaken to confirm stage and direct palliative treatment.

Positron Emission Tomography–Computed Tomography

- In patients whom a standard CT of the chest and abdomen is unremarkable, a positron emission tomography–computed tomography (PET-CT) should be performed again to confirm primary tumor location and extent, evaluate regional and extraregional nodal involvement, and exclude occult metastases.

Endoscopic Ultrasound

- In patients without metastatic disease (stage 4), an endoscopic ultrasound is done to document depth of invasion of the tumor (T stage) and evaluate mediastinal and perigastric/celiac lymph node involvement (N stage). Biopsy of suspicious lymph nodes is indicated.
- All patients should then be assigned a pretreatment TNM stage to guide treatment planning discussions, preferably under the direction of a multidisciplinary treatment planning conference attended by surgical, medical, and radiation oncology.[1] The National Comprehensive Cancer Network (NCCN) defines optimal treatment planning algorithms.[2]
- In considering options for reconstruction, the two most common conduits are the stomach and colon. Although variations in stomach blood supply are very rare, variations in colonic blood supply are common enough to justify preoperative evaluation of arterial anatomy and collateral circulation by visceral angiography in planning choice of conduit.
  - For purposes of using the stomach as a conduit for esophageal reconstruction, an intact right gastric and, more importantly, right gastroepiploic artery is imperative (**FIG 2**).
  - For purposes of the colon as a conduit for esophageal reconstruction following a THE, an adequate collateral blood supply via an intact marginal artery is required (**FIG 3**). Obviously, a colonoscopy to exclude and/or treat colonic pathology must be done prior to use of the colon.

SURGICAL MANAGEMENT

- As THE is a technically complex operation with a high degree of associated morbidity and mortality, this operation should be done by surgical teams experienced in the perioperative management of these patients.[3–5] This includes experienced operating room personnel and anesthesiologists.

Preoperative Planning

- Patients should undergo preoperative evaluation by the surgical and anesthesia team for purposes of mitigating perioperative risks in the area of cardiac, pulmonary, and renal comorbidities.
- A discussion should be done with the patient as to how pain will be measured and managed following surgery. Regional anesthetics such as an epidural catheter are very

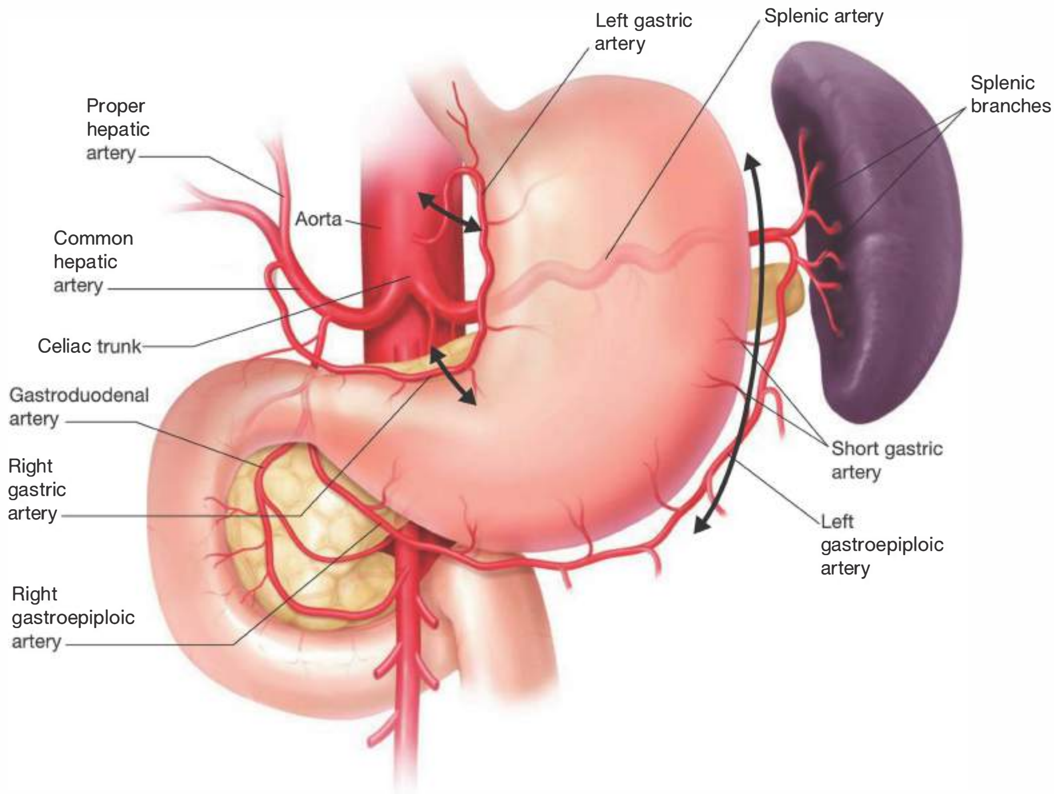

FIG 2 ● Stomach blood supply for purposes of using the stomach as a conduit for reconstruction following THE. *Arrows* show lines of division including the short gastric arteries, left gastroepiploic artery, left gastric artery, and ligation of the right gastric artery at the incisura angularis at the point of origin of the gastric conduit staple line.

helpful in alleviating pain, thereby allowing the patient to be more engaged in early mobilization and physical therapy.

- Perioperative antibiotics should be administered within 60 minutes of skin incision and redosed in a timely manner during the operation. Cefazolin, dosed to weight specifications and redosed every 4 hours, is recommended. Cefoxitin can also be used and redosed every 3 hours. For patients with a beta-lactam allergy, clindamycin or vancomycin and aminoglycoside or aztreonam or fluoroquinolone are used. All prophylactic antibiotics are not necessary beyond surgery completion.[6]
- Perioperative monitoring with an arterial line is helpful especially during blunt mediastinal esophagus dissection where transient hypotension is common because of decreased venous return and compression on the heart. Rarely is a central line indicated.
- Appropriate deep venous thrombosis prophylaxis is required. Intermittent sequential compression devices should be placed prior to induction of anesthesia and continued after surgery. Chemical prophylaxis should be instituted postoperatively once clinically indicated.
- Urinary catheters are placed following induction of anesthesia and discontinued within 24 hours of surgery.

Positioning

- Patients undergoing THE are positioned supine on the operating room table (**FIG 4**).
- Both arms are tucked and pressure points padded to prevent injury during the course of the operation.
- A towel or medium gel roll is placed behind the shoulders to allow for mild extension of the neck. This is of particular importance in obese, short-necked patients.
- The head is rotated 30 degrees to the right to open exposure to the left neck.

Placement of Surgical Incisions

- A midline laparotomy from the xiphoid process to the umbilicus is made (**FIG 4**).
- After verifying the patient to be a candidate for resection and verifying that THE can proceed, a 5-cm incision is made overlying the anterior border of the left sternocleidomastoid muscle with the inferior extent at the head of the clavicle. Contraindications to THE include difficult mediastinal blunt dissection of the esophagus because of tumor or treatment effect, excessive mediastinal bleeding with blunt dissection, and inadequate conduit length for reconstruction.

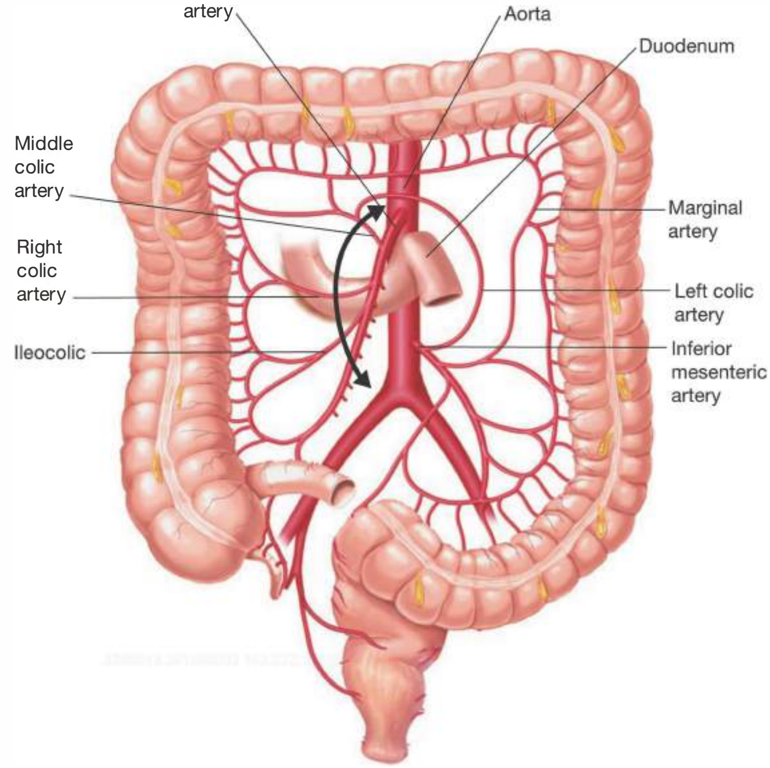

FIG 3 ● Colon blood supply for purposes of using the colon as a conduit for reconstruction following THE.

FIG 4 ● Supine position with location of surgical incisions for THE.

TRANSHIATAL ESOPHAGECTOMY

Abdominal Exploration to Exclude Metastatic Disease

- Upon entering the abdomen, visceral and parietal peritoneal surfaces are palpated to exclude occult peritoneal carcinomatosis. This should include inspection of the lesser sac by opening thru the gastrocolic omentum.
- The liver is palpated for suspicious nodules and biopsy performed. Intraoperative ultrasound can be a useful adjunct in this step. If indeterminate lesions are noted on preoperative imaging, ultrasound-guided biopsy is indicated.
- Metastatic disease is an absolute contraindication to proceeding with surgical resection.

Exploration of the Esophageal Hiatus to Determine Local Resectability

- Prior to proceeding with dissection of the stomach, the esophageal hiatus is explored to make sure the distal esophagus and GE junction can be dissected free of the esophageal hiatus and surrounding abdominal and mediastinal structures. If so, and in the absence of metastatic disease, resection can proceed.

- This dissection and subsequent dissections are facilitated by use of an electrosurgical device such as an ultrasonic or bipolar scalpel.
- The pars flaccida is opened, including division of an accessory or replaced left hepatic artery, if necessary.
- The peritoneum and phrenoesophageal membrane overlying the junction of the right crus of the diaphragm and esophagus is incised allowing the esophagus to be dissected off the right crus.
- The phrenoesophageal membrane just cephalad to the GE fat pad is divided as is the peritoneal reflection overlying the angle of His.
- The esophagus is dissected off the left crus of the diaphragm and esophagus encircled with a 1-in Penrose drain (**FIG 5**).
- The esophagus and GE junction are then dissected free of the crural confluence of the esophageal hiatus, and esophagus with associated periesophageal fatty tissue and lymph nodes dissected free of the esophageal hiatus and underlying aorta.
- If the esophagus and GE junction are free of surrounding structures, resection can proceed. If adherent to or invading the pleura, pericardium, or diaphragm (T4a), resection of these structures can be performed. If adherent to the aorta, vertebral body, or trachea (T4b), resection should be aborted.

Mobilization of the Stomach and Duodenum

- Once it is determined that resection can proceed, the stomach and duodenum are mobilized. Most often, the stomach is used as the conduit for reconstruction following THE. Therefore, mobilization of the stomach for purposes of proceeding with the esophagectomy and for purposes of the creation of the gastric conduit occur simultaneously.
- The right gastroepiploic artery and vein are identified along the greater curvature of the stomach. An adequate pulse in this vessel is imperative if the stomach is to be used for the reconstruction (**FIG 6**). These vessels terminate at the bare area roughly one-half the distance along the greater curvature between the pylorus and GE junction. It is imperative to preserve these vessels as they are the blood supply to and from the conduit.

FIG 5 ● Dissection of the GE junction and encirclement with a Penrose drain to facilitate manipulation.

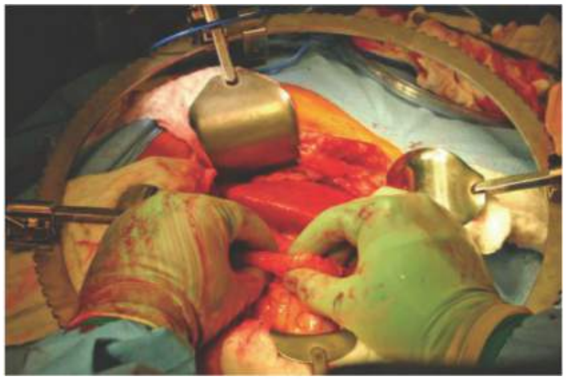

FIG 6 ● Palpation of the right gastroepiploic pedicle along the greater curvature of the stomach to ensure an adequate pulse to permit use of the stomach as a conduit for reconstruction.

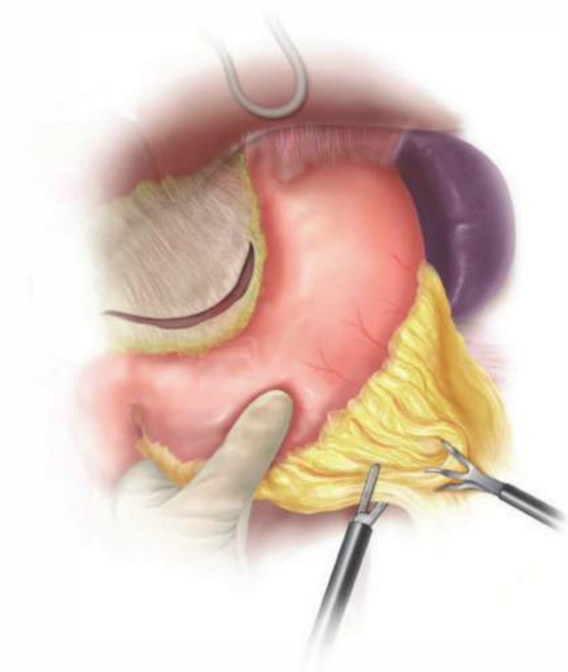
- Once these vessels are identified, the gastrocolic ligament is entered several centimeters from the bare area entering the lesser sac.
- Using an electrosurgery device, the gastrosplenic ligament and short gastric vessels are divided proceeding along the greater curvature toward the esophageal hiatus. Placing a surgical clip on the distal ends of larger vessels, including the left gastroepiploic artery, can ensure ongoing hemostasis of these vessels. The posterior leaflet of the gastrosplenic ligament is likewise divided as are the congenital adhesions of the stomach to the anterior surface of the pancreas. This frees the greater curvature.
- Division of the gastrocolic ligament then proceeds distally, paying careful attention to stay at least a few centimeters away from the right gastroepiploic vessels (**FIG 7**). Careful attention should be paid to not placing traction or trauma to these vessels while freeing the stomach from the colon. This is especially true as one frees the stomach from the anterior surface of the pancreas and approaches the origin of these vessels from under the duodenal bulb. Traction of the vein, in particular, can traumatize these vessels resulting in impaired venous outflow and conduit venous congestion.
- After freeing the stomach from the colon, a Kocher maneuver is performed to permit mobilization of the duodenum. An adequate Kocher maneuver permits mobilization of the pylorus to reach the esophageal hiatus (**FIG 8**).
- At this point, the remainder of the gastrohepatic ligament is divided and left gastric pedicle is identified.
- The lymph nodes along the left gastric pedicle and celiac axis and surrounding aorta are dissected free of the origin of the left gastric artery and included in the surgical specimen. The left gastric artery and vein are then divided with either a vascular load of a surgical stapler or suture ligated.



A

B

FIG 7 ● Mobilization of the greater curvature of the stomach by dividing the gastrosplenic **(A)** and gastrocolic ligament **(B)**, being careful to not injure the gastroepiploic pedicle.

- The stomach is now free of its upper attachments and vasculature. If a colon conduit is preferred, preparation of the colon should proceed. If a gastric conduit is preferred, the gastric conduit is created to avoid trauma to the conduit during retraction of the stomach necessary for the inferior mediastinal dissection. This also allows verification of the adequacy of the blood supply to the apex of the conduit and length of the conduit prior to proceeding with the transhiatal dissection. This will be discussed in the following text. For this discussion, the mediastinal dissection will be described.
- With a Penrose drain around the GE junction for caudal retraction of the stomach and lower esophagus with associated lymphatic tissue is dissected under direct visualization from the lower mediastinum. This dissection is facilitated by a medium handheld malleable retractor and the use of an electrosurgical device. Approximately 5 to 10 cm of mediastinal esophagus can be dissected under direct visualization by this technique. Mobility of the mediastinal esophagus to assure feasibility and safety of a transhiatal blunt dissection is verified.
- After the limits of direct visualization are reached, blunt mediastinal dissection can proceed. To assure proper tactile orientation of the esophagus during blunt dissection, a 44-Fr bougie dilator or equivalent is placed in the esophagus.
- The hand is then first advanced posterior to the esophagus, between the esophagus and aorta. The surgeon's fingers are then advanced up this plane with pressure on the bougie containing esophagus to assure proper tissue plane dissection (FIG 9).
- The same dissection is then performed anterior to the esophagus.
- If vagal nerve sparing is planned, the vagus nerves are elevated off the esophagus by hooking the nerves with the index finger and bluntly dissecting them down and off the esophagus where they are then dissected free from the GE junction and stomach. As this operation is most often performed for malignancy, division of the vagal nerves is required to assure proper oncologic dissection. The nerves are then divided at the level of the hiatus with the electrosurgery device.
- This completes the abdominal stomach and esophagus mobilization.

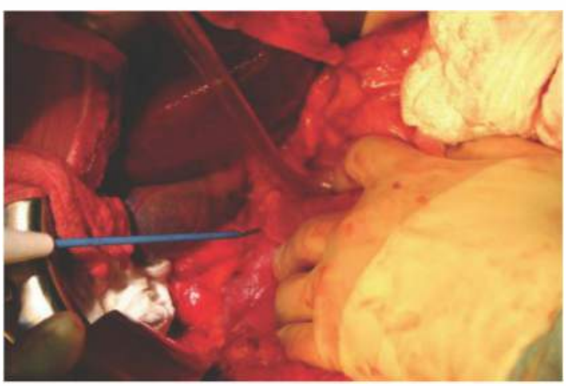


FIG 8 ● Kocher maneuver to ensure adequate mobility of the pylorus. This is assured if the pylorus can freely reach to the hiatus without tension.

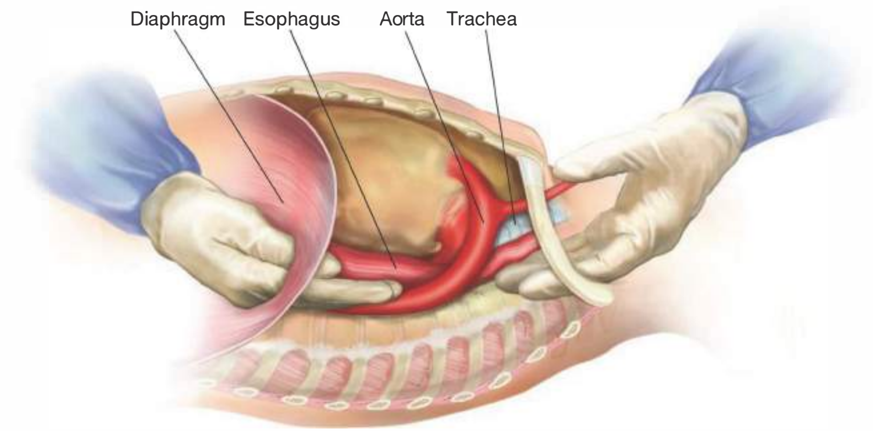

A

B

FIG 9 ● **A,B.** Mediastinal mobilization of the esophagus with a hand placed thru the esophageal hiatus from the abdominal incision and finger placed thru the cervical incision.

Cervical and Upper Mediastinal Esophageal Mobilization

- The cervical esophagus is approached thru a 5-cm incision anterior to the left sternocleidomastoid muscle. The skin, subcutaneous tissues, and platysma are divided with electrocautery (**FIG 10**).
- The thin fascial layer surrounding the anterior border of the sternocleidomastoid muscle is incised with cautery.
- The dissection is carried medial and deep to the sternocleidomastoid muscle. The omohyoid muscle is identified and divided with cautery. The inferior thyroid artery and middle thyroid vein, if identified, are ligated with fine silk or absorbable suture.
- Dissection is carried medial to the carotid sheath with gentle lateral traction on the sternocleidomastoid and carotid sheath and medial traction on the trachea and thyroid. The recurrent laryngeal nerve (RLN)

A

B

FIG 10 ● Cervical skin incision and dissection. **A.** Location of cervical skin incision. **B.** Dissection thru platysma.

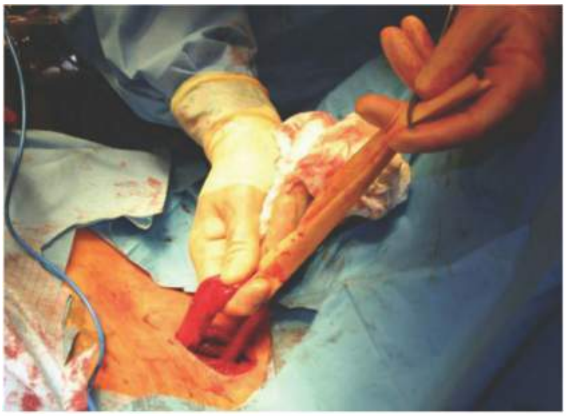

FIG 11 ● Dissection of the cervical esophagus is facilitated by placement of a Penrose drain around the esophagus after sharply dissecting the esophagus free of other vital cervical structures, including the RLN.

is identified and preserved adherent to the tracheoesophageal groove. Dissection is carried down to the prevertebral fascia allowing the surgeon to then pass the index finger between the prevertebral fascia and esophagus.

- The cervical esophagus is then sharply dissected from trachea, being careful to not dissect free nor injure the RLN. Once free of the trachea, a blunt right-angle clamp placed between the trachea and esophagus, rotated and advanced to the prevertebral fascia facilitates placement of a Penrose drain around the esophagus (**FIG 11**).
- Upward traction is placed on the cervical esophagus and blunt mediastinal dissection of the upper and middle third of the esophagus can ensue (**FIG 9**). The surgeon maintains contact between the volar aspect of the first two fingers and the esophagus at all times to the proper tissue plane of dissection. Again, a small-caliber bougie dilator placed in the esophagus facilitates tactile feedback of the esophagus.
- With anterior and upward traction of the cervical esophagus and caudal retraction on the stomach, a hand is inserted thru the hiatus posterior to the esophagus and is met by fingers inserted thru the neck incision down the prevertebral plane. Loose areolar attachments are divided until fingers meet.
- The same dissection is then performed anterior to the esophagus. When performing this dissection, the surgeon must maintain constant pressure on the esophagus to avoid injury to the membranous trachea. Both the anterior and posterior planes can usually be dissected relatively easily.
- Having freed the esophagus from its anterior and posterior attachments, the lateral attachments are then divided. This is often done with a combination of direct downward pressure on these attachments with the index finger from above or by placing the inferior index finger above the attachment pulling down along the insertion of the attachment into the esophagus.
- Alternatively, the bougie can be removed from the esophagus and the lateral attachments divided under direct visualization as the esophagus is retracted anteriorly out the cervical incision. Usually, some sort of bimanual dissection in the posterior mediastinum is required.
- At any point where this dissection proves difficult because of difficult adhesions; fused tissue planes especially in the vicinity of the membranous trachea, carina, and azygous vein; lack of mobility of the esophagus; or excessive bleeding, the blunt dissection should be abandoned and dissection under direct visualization performed via an incision in the right chest.

Removal of the Esophagus

- After complete mobilization of the esophagus, the cervical esophagus is delivered into the next for several centimeters and divided leaving approximately 20 cm of length to the esophagus. The remaining esophagus can subsequently be divided further at the time of anastomosis.
- A 1-in Penrose is affixed to the distal esophagus and the stomach and esophagus drawn down thru the hiatus dragging the Penrose thru the esophageal bed into the abdomen. This will allow the reconstruction conduit to be attached to the Penrose and delivered cephalad up into the cervical incision for subsequent anastomosis to the cervical esophagus (**FIG 12**).

FIG 12 ● Removal of the esophagectomy specimen thru the abdominal incision after attaching a Penrose drain to the cut distal end of the esophagus to guide advancement of the reconstruction conduit back up thru the esophageal bed in the posterior mediastinum.

RECONSTRUCTION: GASTRIC CONDUIT

Creation of Gastric Conduit

- After mobilization of the stomach, the gastric conduit is created. This is best done prior to completion of the mediastinal dissection so as to protect the conduit from trauma due to manipulation of stomach during dissection.
- The goals of creating the gastric conduit are as follows:
  - Create a gastric tube based on the greater curvature blood supply.
  - Create a gastric tube of sufficient length to reach into the cervical incision.
  - Divide the proximal stomach at a point assuring negative surgical margin, usually 5 cm distal to the GE junction along the greater curvature.
  - Resect the lesser curvature of the stomach to include the lesser curvature lymphatic drainage along the distribution of the left gastric artery.
- Six centimeters from the pylorus along the lesser curvature, roughly corresponding to the incisura angularis, the lesser curvature neurovascular pedicle is suture ligated. Careful attention is directed at preserving the integrity of the right gastric artery.
- Using a surgical stapling device, the stomach is divided from this point along the lesser curvature parallel to the greater curvature creating a 5-cm wide gastric tube (**FIG 13**). The division of the stomach is completed 5 cm from the GE junction along the greater curvature (**FIG 14**). For this step, a "thick" load of the stapling device is recommended.
- Length of the conduit is inspected by delivering the conduit over the patient's torso (**FIG 15**). The apex should reach to the sternal notch to be of sufficient length to reach into the cervical incision once brought thru the esophageal bed.
- The conduit should be inspected for viability. If the viability is in question, removal of some of the apex of the stomach may result in insufficient length forcing conversion to a transthoracic approach where gastric conduit length is less of a concern.

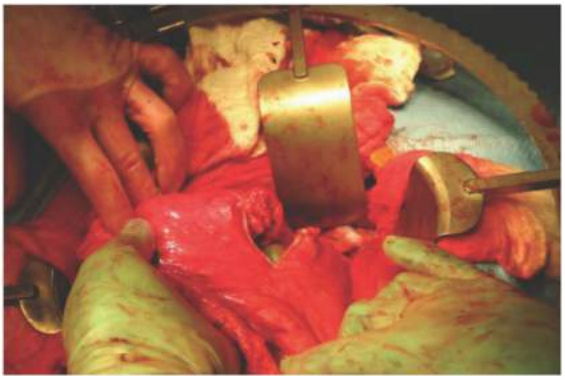

FIG 13 ● The gastric conduit is begun by ligating the lesser curvature neurovascular pedicle then starting the conduit staple line at the incisura angularis.

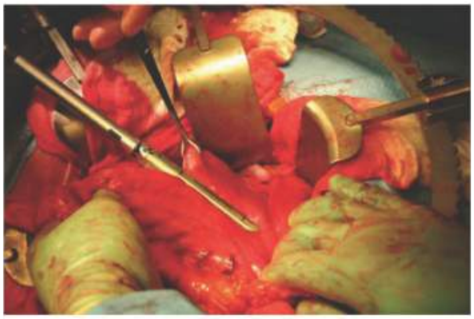
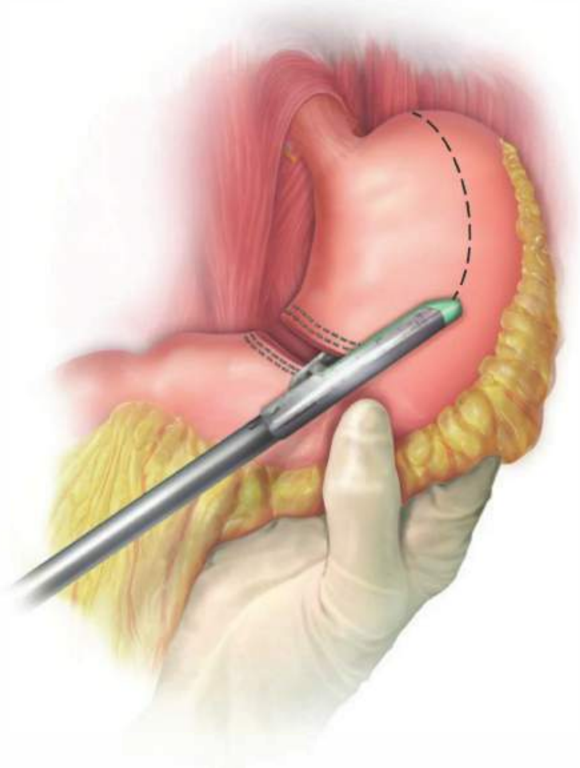


A



B

FIG 14 ● **A,B.** The staple line proceeds cephalad toward the hiatus giving rise to a 5-cm wide gastric conduit while removing the lesser curvature of the stomach and straightening the natural curvature of the stomach to optimize conduit length. The gastric staple line terminates 5 cm from the GE junction along the greater curvature of the stomach.

Gastric Drainage Procedure

- As the vagus nerves will be divided, a gastric drainage is usually necessary either in the form of a pyloromyotomy or pyloroplasty. With tubularization of gastric conduit, some have omitted this step as unnecessary.[7] In these patients, delayed gastric emptying can be managed postoperatively by endoscopic balloon dilation or botulinum toxin injection into the pylorus.

FIG 15 ● The completed gastric conduit.

- For pyloromyotomy, an incision measuring 1.5 cm along the stomach extending 1 cm along the anterior surface of the duodenum across the pylorus is made using the needle tip cautery. With a fine mosquito clamp, the pyloric muscle fibers are divided. An omental patch can be used to patch the exposed submucosa using a Graham patch technique.
- For pyloroplasty, a 4-cm full-thickness longitudinal incision is made beginning 2 cm proximal to the pylorus on the anterior stomach. This full-thickness incision is then closed transversely with interrupted full-thickness 3-0 silk suture (**FIG 16**).

Esophagogastrostomy

- The apex of the gastric conduit is then sutured to the end of the Penrose drain. The Penrose is then drawn up and out the cervical incision delivering the stomach into the neck. Typically, the stomach reaches with excess length permitting trimming of further stomach off the apex of the conduit. Similarly, the esophagus can be further trimmed and both additional specimens marked and sent for final proximal and distal margin analysis.
- The cervical anastomosis can be accomplished either by a hand-sewn or stapled approach.[8,9]
- For hand-sewn, two-layer anastomosis is performed with an outer layer of interrupted 3-0 silk suture in a seromuscular fashion and inner layer of running full-thickness monofilament absorbable suture. Others have described a single-layer anastomosis using monofilament absorbable running suture.
- For a stapled anastomosis, a stay suture of 2-0 silk is placed at the 6 o'clock position of the cervical esophagus. A 2-cm long longitudinal gastrotomy is made on the anterior surface of the gastric conduit close to the greater curvature. The 2-0 silk is then placed at the apex of this gastrostomy and tied to serve as stay suture holding orientation of cervical esophagus and gastric conduit for application of the stapler. A 45-mm stapler is advanced with one arm in the esophagus and the other in the stomach. The stapler is directed toward the right ear with the anastomosis placed along the greater curvature of the stomach. The remaining common enterotomy is closed in two layers with an inner layer of running full-thickness, 3-0 monofilament suture and an outer later of interrupted 3-0 silk suture in a seromuscular fashion (**FIG 17**).

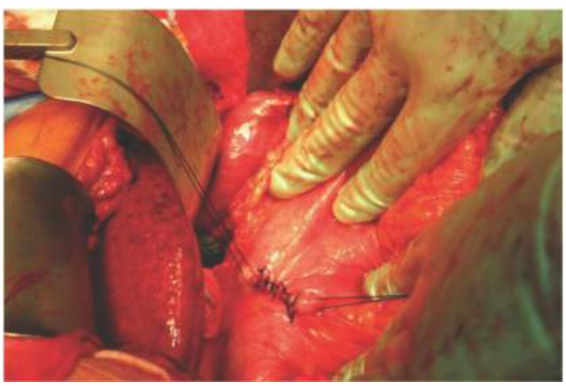


FIG 16 ● A Heineke-Mikulicz pyloroplasty is made by making a 4-cm longitudinal incision centered at the pylorus. This full-thickness incision is closed transversely with interrupted 3-0 silk sutures using a full-thickness bite.

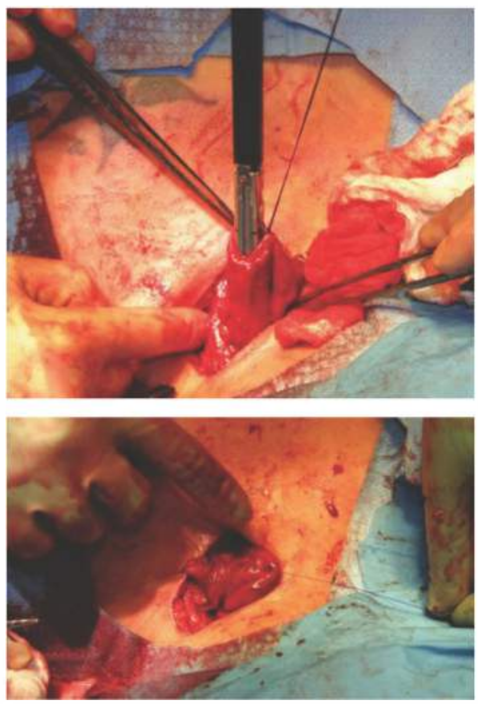

A

B

FIG 17 ● **A.** Linear stapled esophagogastrostomy using a 45-mm line stapler in a side-to-side fashion. **B.** Suture closure of the anterior portion of the anastomosis or common enterotomy of the esophagogastrostomy.

- After completion of the anastomosis, careful caudal traction of the stomach at the hiatus is applied as the anastomosis is delivered back into the neck behind the trachea and excess redundancy of the conduit in the chest is straightened out.
- Either a nasojejunal feeding tube is placed or surgical jejunostomy tube placed for postoperative nutrition.
- The gastric conduit is anchored to the arch of the hiatus with interrupted 3-0 silk suture to prevent herniation.
- The soft closed suction drain is placed thru the thoracic inlet and delivered out onto the chest wall. The neck wound is closed by approximating the platysma muscle with interrupted suture and closing the skin with a running subcuticular suture of 3-0 monofilament absorbable suture. The abdominal wound is closed per routine.

RECONSTRUCTION: COLON CONDUIT

Mobilization of the Colon

- When performing a colon interposition for reconstruction following THE, the stomach is preserved other than the portion removed to assure adequate distal margins. This would include preservation of the left gastric artery. To facilitate use of the colon, however, complete gastric mobilization as discussed earlier is necessary as the preferred route for the colon is retrogastric to decrease tension on the conduit and blood supply.
- Complete colonic mobilization is required including mobilization of both the splenic and hepatic flexures. This often entails extension of the surgical incision below the umbilicus.
- Once mobilization is complete, verification of adequacy of blood supply for the subsequent conduit is needed even in the setting of preoperative angiography. This can be accomplished by serial ligation of the ileocolic artery, then right colic artery, and, if necessary, middle colic arteries with Bulldog clamps (**FIG 3**).
  - Angiographic arterial anatomy requirements for a successful left colic–based colon interposition reconstruction include a patent inferior mesenteric artery, patent ascending branch of the left colic artery, intact marginal artery anastomosis between the left colic (inferior mesenteric) and middle colic (superior mesenteric) arteries, single middle colic trunk prior to bifurcation into a right and left branch, and separate origin of the right colic artery.[10]
- To reach to the neck, a conduit based on the left colic artery branch of the inferior mesenteric artery and, if possible, middle colic arteries is needed. This entails delivering the colon in an isoperistaltic fashion to the neck with the cecum or proximal right colon serving as the proximal end of the colon conduit (**FIG 18**)
- If the blood supply is adequate for a left colic vascular based conduit, the ileocolic artery is ligated as low in the mesentery as possible, as is the right colic artery. The mesentery of the ascending colon is likewise divided to the level of the middle colic arteries.
- The terminal ileum is divided with a surgical stapler.
- The cecum is rotated up to the neck to verify adequate conduit length. If not, the middle colic branches can be divided as well (**FIG 19**).

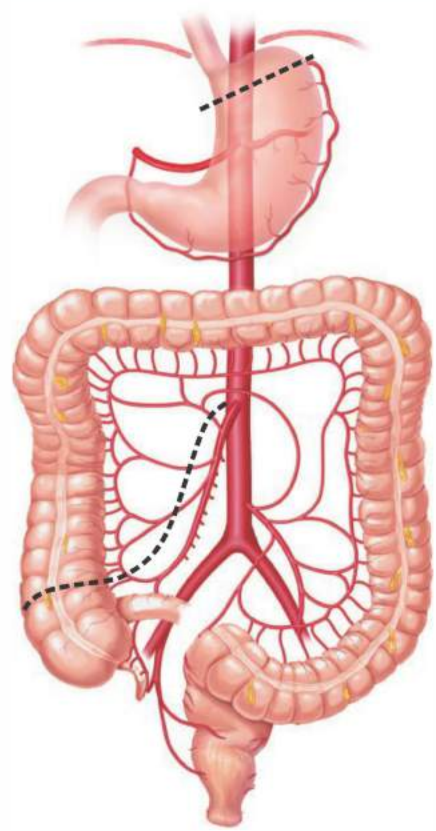

FIG 18 ● Creation of the colon conduit based on the left colic artery.

Delivery of Colon

- Once the colon is mobilized, the colon is delivered thru the hiatus in a fashion similar to the gastric conduit as discussed earlier. To decrease demands on conduit length, it is optimal to deliver the colon to the hiatus behind the stomach in a retrogastric position. Alternatively, the colon can be delivered thru a retrosternal pathway if the posterior mediastinum is no longer a viable option. The disadvantage of this route is increased demand on conduit and blood supply length.
- As there is typically adequate length to the colon conduit, the proximal end of the colon can be amputated back,

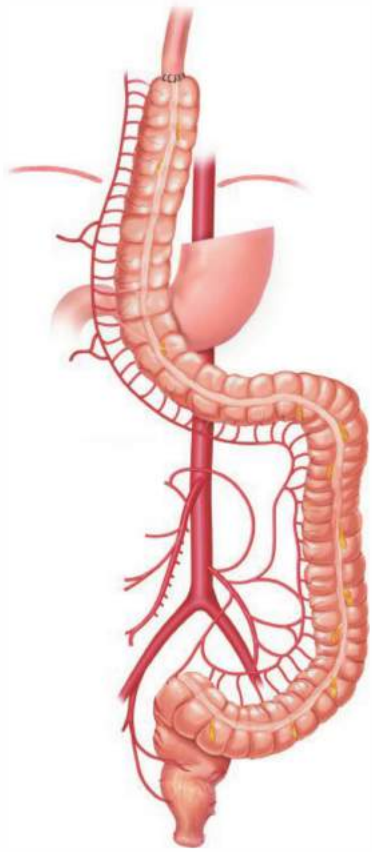

FIG 19 ● Delivery of the colon thru the mediastinum by rotating the cecum up thru the esophageal bed and out the cervical incision.

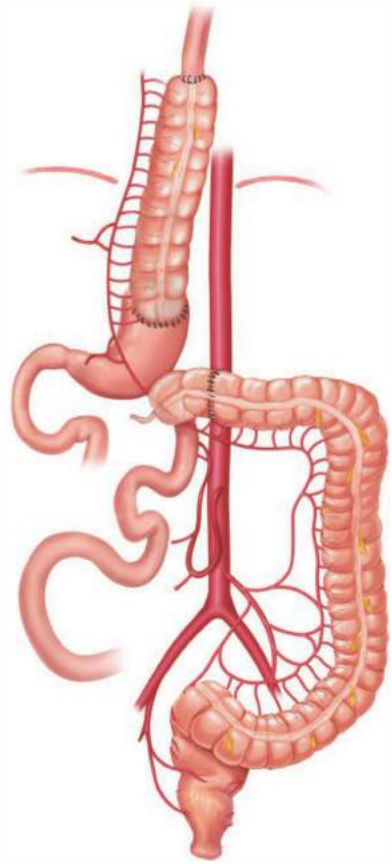

FIG 20 ● The completed reconstruction with both esophageal to colon and colon to stomach anastomoses.

usually removing the cecum. This has the advantage of decreasing the size differential between the cervical esophagus and colon as the colon narrows in luminal diameter and becomes thicker and more muscular. Also, as one moves distally on the colon, the reliance on mesenteric arcades for blood supply decreases.

Anastomoses

- The esophagus-to-colon anastomosis is accomplished in a similar fashion as described in the section on the use of the stomach as a conduit for reconstruction. This can be stapled using a linear stapler or hand sewn in either a one- or two-layer technique. Although circular staplers can be used, conduit length is often inadequate, making this awkward (FIG 20).
- The cervical anastomosis is drawn back in the neck by careful caudal traction on the colon at the hiatus.
- The colon is then divided at a point along the posterior stomach to permit a subsequent colon-to-stomach anastomosis. This is optimally done using a linear stapler joining the colon and stomach in a side-to-side fashion and closing the common enterotomy with an additional stapler load or hand-sewn closure.
- In manipulating the colon for this anastomosis, it is imperative to not disturb the mesentery of the colon out of concern for disrupting the mesenteric vessels.
- Enteric continuity is restored by completing the small bowel-to-colon anastomosis using surgical staplers in a standard fashion.
- A jejunostomy feeding tube is placed for nutritional support as is a cervical closed suction drain.
- A gastric drainage procedure is done if vagotomy was performed during the course of esophageal resection.

PEARLS AND PITFALLS

Indications	■ THE should only be performed for curative intent when treating malignancy. ■ NCCN guidelines should be followed as to preoperative evaluation, staging, and treatment algorithms.
Approach	■ THE should only be considered for patients with appropriate pathology (middle, lower third of the esophagus, and GE junction tumors). ■ In patients with unfavorable prior surgical history (prior gastric surgery rendering the gastric conduit inadequate) or locally advanced tumors that require a direct visualization of mediastinal dissection, a THE is contraindicated in favor of a transthoracic approach.
Gastric mobilization	■ Avoid any traction or direct trauma to the right gastroepiploic and right gastric artery pedicles so as to avoid disrupting these vessels or causing venous injury with resultant thrombosis as this will lead to graft failure. ■ Use of an electrosurgical device greatly improves efficiency and effectiveness of gastric mobilization.
Esophageal dissection	■ If excessive adhesions are encountered secondary to tumor extension or treatment effect or excessive bleeding is encountered with blunt dissection of the esophagus, a TTE should be performed. ■ A small-caliber bougie dilator (44 Fr) in the esophagus facilitates tactile localization of the esophagus during blunt dissection.
Reconstruction	■ Graft failure and anastomotic leak result from ischemia, which is a consequence of inadequate blood supply, venous congestion, tension on the anastomosis, or hypoperfusion in the early postoperative period. These factors should be avoided. ■ Proper orientation of the conduit with prevention of twisting is made easier by drawing parallel lines on the Penrose drain and making sure the drain does not twist as it is pulled out thru the neck delivering the conduit to the cervical incision.
Anastomosis	■ Proper orientation of the cervical anastomotic staple lines should be maintained to maximize perfusion of the gastric wall. This is accomplished by keeping the esophagogastrostomy staple line as far away from the conduit lesser curvature staple line. ■ When placing the anastomosis back in the neck, it should be straightened by reducing redundancy of the conduit by caudal traction on the conduit at the hiatus. Avoid placing tension on the anastomosis.

POSTOPERATIVE CARE

- Patients recover in the intensive care unit until acute cardiac, respiratory, and volume status issues are resolved.
  - As hypoxia and hypotension can lead to hypoperfusion of the reconstruction with anastomotic leak or, in the worst scenario, conduit necrosis, this should be avoided and quickly remedied if clinically encountered.
  - As respiratory failure and pneumonia are the most common complications encountered, aggressive pulmonary care is required. Early ambulation is mandatory.
  - Fluid overload can lead to hypoxia, pulmonary edema, and dysrhythmia (most often atrial fibrillation).
- Enteric nutrition is begun slowly on postoperative day 1.
- Patients should be carefully followed for signs of postoperative complications (see the following text) and evaluation and mitigation strategies employed at the first sign of such issues.
- If the patient is medically stable to consider oral intake, a water-soluble contrast study followed by barium is done on the fourth postoperative day to make sure there is no significant anastomotic leak and the conduit empties adequately into the small intestine.
- If ok, a liquid diet is started and continued for 2 weeks at which time the patient is transitioned to a soft diet for an additional 2 weeks prior to resuming a normal diet. The rationale for this approach is to avoid food impaction during the critical period of anastomotic healing. The surgical drain is removed after a negative study and no evidence of oral fluids in the drain within 48 hours of oral liquid intake.
- The feeding tube is discontinued when the patient is able to take adequate oral intake, usually within the first to second week following surgery.
- Patients should be counseled as to how to optimize their fluid and nutritional intake during this period of transition to regular diet and manage dumping symptoms with dietary and lifestyle modification.
- Patients should be advised as to the early signs of anastomotic stricture and need for esophageal dilation.

OUTCOMES

- THE is a very morbid, high-risk procedure with very high associated operative morbidity and mortality (see the following text).
- Regarding functional outcome, the best data available are reviews from patients who underwent this procedure for benign indications and early stage cancer given the longer survival in these patients compared to patients with cancer.[11,12]
  - Symptoms of physical impairment, including GE reflux, dumping, and dysphagia, are very common after surgery but show gradual improvement toward baseline over the first year, not quite reaching baseline. Long-term physical impairment is less common after THE compared to TTE.
  - Overall health-related quality of life (ability to work, social interaction, daily activities, emotional function, perception of health, energy level, and mental health) decreases after surgery but returns to baseline national norms within 1 year of surgery.

- Regarding cancer-specific outcome, long-term survival is a function of the underlying biology and stage of the tumor rather than surgical approach.[13,14]

COMPLICATIONS

- Perioperative complications occur in 40% to 50% of patients and fall into specific categories depending on the point of time in which they appear following surgery. Reported overall 30-day mortality for THE ranges from 1% in select single center reports to 10% in nonselective administrative database reports.[13,15,16]
- Early postoperative period (0 to 2 days)
  - Technical complications
    - Bleeding
    - RLN injury with resultant hoarseness (unilateral) and airway obstruction (bilateral)
    - Pleural violation with pneumothorax or pleural effusion
    - Conduit necrosis requiring removal of conduit and cervical esophagostomy
  - Medical complications
    - Respiratory complications (respiratory failure, pneumonia)
    - Cardiac complications (dysrhythmia, myocardial infarction, heart failure)
    - Urinary tract complications (renal failure or insufficiency)
- Intermediate postoperative period (2 to 14 days)
  - Technical complications
    - Anastomotic leak manifest as cervical wound infection and drainage or drainage of oral secretions via closed suction drain.
    - Conduit necrosis requiring removal of conduit and cervical esophagostomy
    - Thoracic duct injury with chyle leak, usually manifest by pleural effusion at onset of enteric or oral nutrition.
  - Medical complications
    - Respiratory complications (respiratory failure, pneumonia)
    - Cardiac complications (dysrhythmia, myocardial infarction, heart failure)
    - Urinary tract complications (renal failure/insufficiency, urinary tract infection)
    - Infectious complications, (line infection, organ space infection, wound infection)
- Late postoperative period (after 14 days)
  - Technical complications
    - Anastomotic stricture
    - Delayed gastric emptying
    - Dumping syndrome
  - Medical complications
    - Malnutrition
    - Cancer recurrence

Chapter 30

Ivor Lewis Esophagectomy

Robert E. Merritt

DEFINITION

- An Ivor Lewis esophagectomy is defined as a resection of the esophageal tumor using a laparotomy incision and a right thoracotomy. The esophagogastric anastomosis is performed in the right thoracic cavity. This surgical approach is appropriate for patients with resectable tumors in the middle and distal third of the esophagus as well as the gastroesophageal junction.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients who present with esophageal carcinoma should undergo a complete history and physical examination.
- Patients often complain of dysphagia to solid food and liquids. This symptom is related to esophageal obstruction from a bulky tumor.
- Barrett's intestinal metaplasia or gastroesophageal reflux disease (GERD) may precede the diagnosis of esophageal cancer.
- Significant weight loss is a common symptom of patients with esophageal cancer. The weight loss may be secondary to poor oral intake related to dysphagia or cancer cachexia.
- The cervical lymph nodes and supraclavicular lymph nodes should be thoroughly examined during physical examination. The cervical and supraclavicular lymph nodes are a common site for metastatic spread from esophageal carcinoma.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- An esophagogastroduodenoscopy (EGD) should be performed on every patient with esophageal carcinoma (**FIG 1**). Upper endoscopy allows access to the tumor for diagnosis and determination of the histologic subtype (adenocarcinoma vs. squamous cell carcinoma). The location of the tumor is also important to determine whether an Ivor Lewis esophagectomy would be feasible. Esophageal tumors in the proximal third of the esophagus would require a transhiatal or three-field esophagectomy with a cervical esophagogastrostomy anastomosis.
- Endoscopic ultrasound (EUS) is a critical staging technique for esophageal cancer (**FIG 2**). The EUS determines the depth of invasion of the tumor into the esophageal wall (T stage). Esophageal tumors that penetrate through the esophageal wall are considered locally advanced and have a high propensity to metastasize to locoregional lymph nodes. Periesophageal lymph nodes that are enlarged can be visualized with EUS and fine needle aspiration biopsy can be performed to determine locoregional lymph node involvement. Patients with biopsy-proven lymph node involvement will typically be referred for preoperative chemotherapy or combined chemoradiation.

FIG 1 ● An upper endoscopy demonstrating a large distal esophageal carcinoma. An endoscopic biopsy was consistent with a moderately differentiated adenocarcinoma.

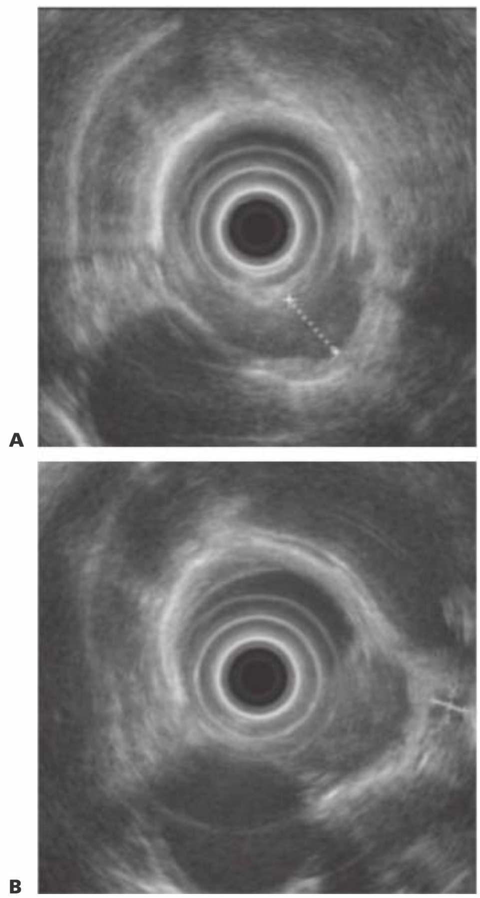

FIG 2 ● **A.** An EUS image demonstrating a T3 esophageal carcinoma with extension into the adventitia. **B.** Demonstration of a peritumoral lymph node.

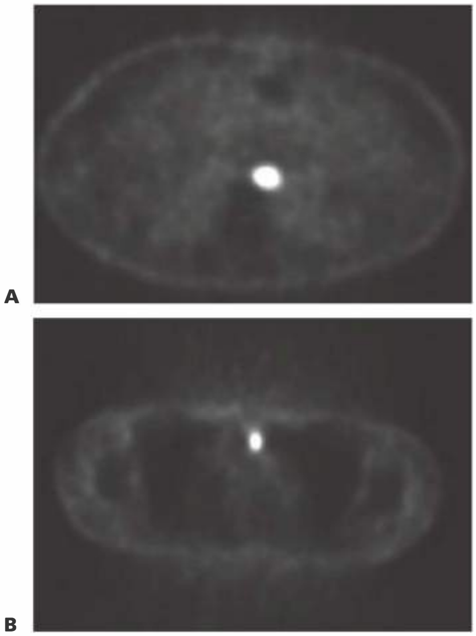

FIG 3 ● **A.** The first PET image demonstrates a hypermetabolic esophageal carcinoma located in the distal third of the esophagus. **B.** The second PET image demonstrates a hypermetabolic cervical lymph node that represents distant metastatic disease.

- All patients who are being considered for esophagectomy should undergo a computed tomography (CT) scan of the chest, abdomen, and pelvis to evaluate the primary tumor in the esophagus and the locoregional lymph nodes. The liver, celiac lymph nodes, bone, and adrenal glands are common sites for metastatic disease secondary to esophageal carcinoma. Positron emission tomography (PET) is an essential staging technique for esophageal carcinoma (**FIG 3**). PET scans can detect occult metastatic disease that was not identified on standard CT scans in about 10% to 15% of cases. This detection of occult metastatic disease will prevent patients with stage IV esophageal carcinoma from undergoing an unnecessary esophageal resection.

SURGICAL MANAGEMENT

Preoperative Planning

- Any patient who is being evaluated for an Ivor Lewis esophagectomy should undergo a complete and thorough cardiopulmonary evaluation prior to the operation. Cardiac disease and respiratory compromise should be identified in the preoperative period to properly access perioperative risk of complications and mortality.
- Pulmonary function tests should be obtained to measure the forced expiratory volume in 1 second (FEV_1) and diffusion capacity. Patients with a history of chronic obstructive pulmonary disease (COPD) will have diminished values for FEV_1 and diffusing capacity of lung for carbon monoxide (DLCO); therefore, they will be at increased risk for perioperative respiratory complications.
- A transthoracic echocardiogram is obtained to assess the left ventricular ejection fraction left ventricular wall motion. A treadmill stress test should be obtained when the echocardiogram findings are abnormal.
- Prior to surgical resection, a patient's nutritional status should be optimized. A preoperative feeding access for enteral nutrition may be necessary in cases of severe malnutrition. A prealbumin level can be measured to further assess the patient's nutritional status.
- Perioperative antibiotics should be given within 30 minutes of the first incision. Compression boots are placed on the lower extremities and subcutaneous unfractionated heparin is given to minimize the risk of postoperative deep venous thrombosis (DVT).
- An arterial line and central venous catheter should be placed for intraoperative hemodynamic monitoring.
- An epidural catheter should be placed for postoperative pain management. Epidural infusion of local anesthetic minimizes postthoracotomy pain and allows patients to participate in pulmonary toilet exercises.

Positioning

- The Ivor Lewis esophagectomy technique uses two incisions. Patients are positioned in the supine position first for the midline laparotomy incision (**FIG 4**). The second portion of the operation is performed through a right posterior lateral thoracotomy (**FIG 5**). Patients are positioned in the left lateral decubitus position. A beanbag is used to help hold patients into position. The operating room bed is flexed to open the rib spaces.

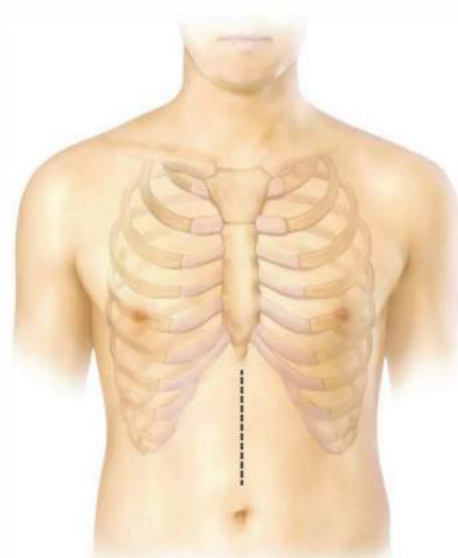

FIG 4 ● A midline laparotomy incision is located between the xiphoid and the umbilicus.

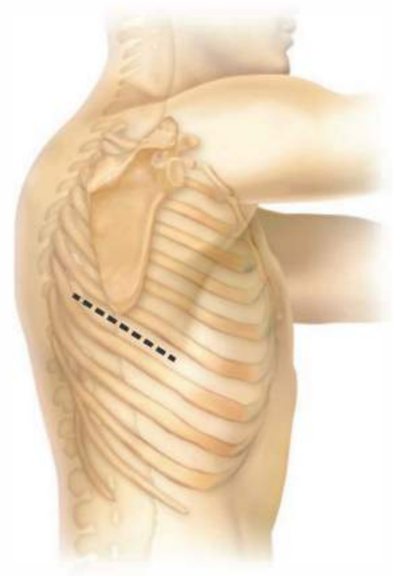

FIG 5 ● A standard posterior lateral thoracotomy incision provides excellent exposure of the intrathoracic esophagus.

MOBILIZATION OF THE GASTRIC CONDUIT

- The patient is positioned supine on the operating table. A double lumen endotracheal tube is placed for single lung isolation. An arterial line, central venous catheter, and epidural catheter are placed by the anesthesia team. Compression boots and subcutaneous heparin are given for DVT prophylaxis.
- A midline laparotomy incision is performed from the xiphoid down to the umbilicus. A full inspection of the abdominal cavity is performed to rule out tumor dissemination on peritoneal surfaces or liver metastasis. A Bookwalter retractor is used to provide exposure. The triangular ligament of the left lobe of the liver is divided and the left lateral segment is retracted cephalad to expose the esophageal hiatus.
- The dissection of the gastric conduit begins by entering the lesser sac along the great curvature of the stomach. The right gastroepiploic artery should be identified and preserved. The greater omentum is divided along the greater curvature of the stomach with an ultrasonic dissector by divided branches of the right gastroepiploic arcade and carefully preserving the gastroepiploic trunk (**FIG 6**).
- The gastrocolic omentum is divided toward the duodenum. The stomach is retracted upward and any adhesions between the stomach and pancreas should be carefully divided (**FIG 7**). The duodenum is then mobilized with the Kocher maneuver.

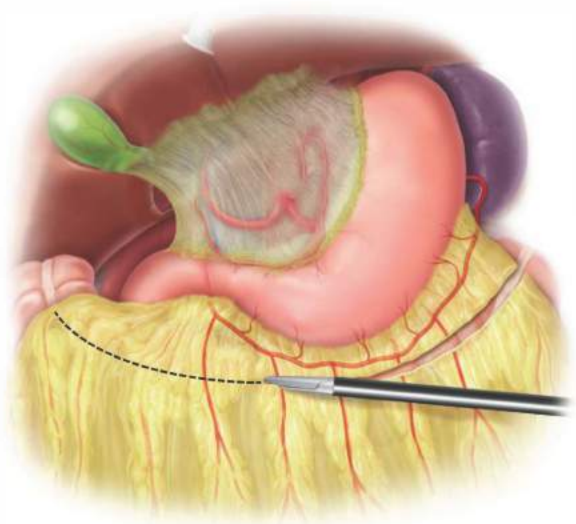

FIG 6 ● The division of the gastrocolic ligament along the great curvature of the stomach. The right gastroepiploic artery is preserved.

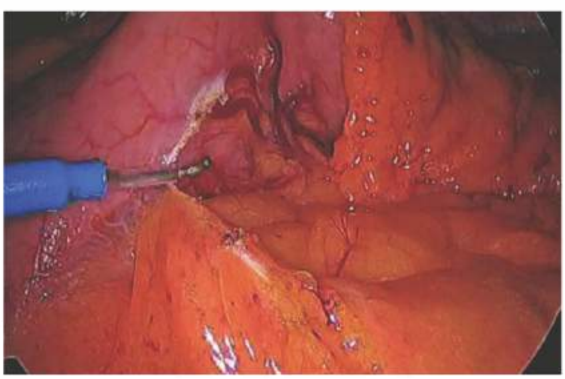

FIG 7 ● Mobilization of stomach.

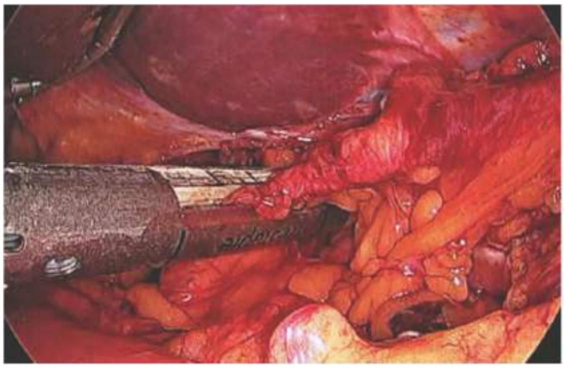

FIG 8 ● Division of left gastric artery.

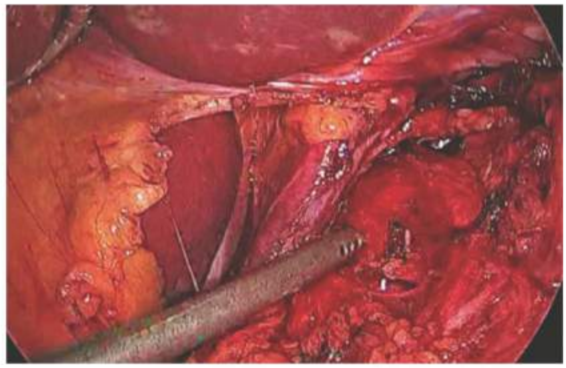

FIG 9 ● Dissection of the hiatus.

- The short gastric vessels are ligated using the ultrasonic dissector. The short gastric vessels should be ligated close to the spleen to avoid thermal injury to the stomach.
- The lesser omentum is then divided toward the esophageal hiatus. A replaced left hepatic artery should be identified and preserved if present. The right gastric artery can be preserved in most cases when the anastomosis is performed in the right thorax.
- The left gastric pedicle is identified along the lesser curvature of the stomach. The left gastric pedicle is divided at the origin from the celiac axis using an Endo GIA linear stapler. The surrounding adipose tissue and lymph nodes should be swept upward prior to ligation of the left gastric pedicle (FIG 8).
- The crura of the diaphragm are identified and the distal esophagus should be visualized. The phrenoesophageal membrane is then divided to facilitate mobilization of the esophagus around the esophageal hiatus (FIG 9). The right crus of the diaphragm are divided if necessary to permit four fingers to fit into the opened esophageal hiatus. This prevents compression of the esophageal conduit and possible ischemia.

FORMATION OF THE GASTRIC CONDUIT

- The Endo GIA linear stapler is used to divide the stomach along the lesser curvature. The staple line is started along the lesser curvature just proximal to the right gastric artery (FIG 10). The staple line should end between the cardia and the fundus. The staple line is oversewn with multiple interrupted 3-0 silk sutures to cover the staple line with serosa. The gastric tube should be 5 to 6 cm in width.
- The gastric tube is secured to the remnant of the gastric cardia with two interrupted 0-silk sutures. This will allow the gastric conduit to be pulled into the chest along with the esophagogastric specimen.

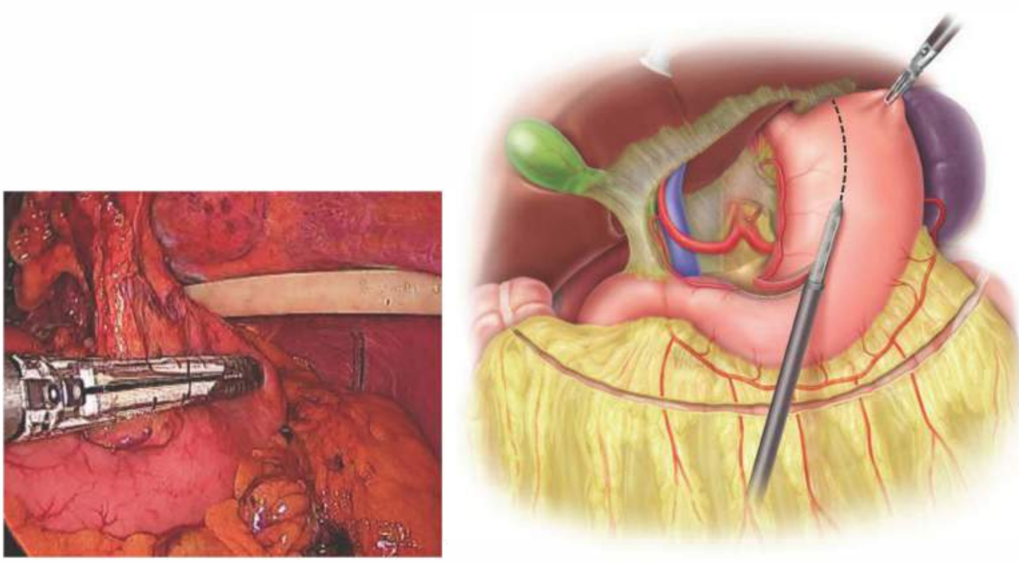

FIG 10 ● **Left and Right:** The formation of the gastric conduit using a linear endoscopic stapler. The gastric conduit should be 5 to 6 cm in diameter.

HEINEKE-MIKULICZ PYLOROPLASTY

- The pylorus muscle is identified with direct palpation at the border of the antrum of the stomach and the first portion of the duodenum. The pylorus muscle is incised longitudinally using the cautery and ultrasonic dissector. The incision is carried through the mucosal layer. The incision is then closed transversely with interrupted 4-0 Vicryl sutures and second layer of 3-0 silk sutures.

JEJUNOSTOMY FEEDING TUBE

- The ligament of Treitz is identified at the root of colon mesentery. The jejunostomy tube is placed in the proximal jejunum about 30 to 40 cm from the ligament of Treitz. A purse-string suture is placed on the serosa of the jejunum using a 4-0 chromic suture. A small enterotomy is created within the purse string. A 10-Fr jejunostomy tube is placed through the abdominal wall and into the jejunum. The purse-string suture is tied and the jejunostomy site is covered with multiple 3-0 silk sutures to imbricate the serosa.
- The jejunostomy insertion site is then secured to the abdominal wall with four interrupted 2-0 silk sutures. The jejunostomy tube site on the abdominal wall should not be twisted to avoid postoperative bowel obstruction or ischemia.

THORACIC MOBILIZATION OF THE ESOPHAGUS

- A right posterior lateral thoracotomy is performed and the right chest is entered through the 5th intercostal space. The serratus anterior muscle is preserved.
- The right lung is isolated with a double lumen chest tube and the right lung is retracted anteriorly.
- The inferior pulmonary ligament is incised with cautery and the level 9 lymph nodes are harvested. The mediastinal pleura along the anterior esophagus is incised with the cautery. The distal esophagus is dissected from the pericardium and the aorta posteriorly (**FIG 11**). The esophagus is then encircled with a 1-in Penrose drain.
- The esophagus is mobilized from the esophageal hiatus to the azygous vein (**FIG 12**). The ultrasonic dissector or LigaSure device can be used to divide small vessels and lymphatics. The thoracic duct should be suture ligated if the structure is injured during the esophageal dissection. The thoracic duct enters the right thorax through the aortic hiatus and is usually located between the azygous vein and the aorta. The thoracic duct crosses over to the left side at T4-T5 and passes behind the aortic arch. The thoracic duct passes posteriorly to the left carotid sheath and drains into the junction of the left jugular and subclavian vein.
- The azygous vein is routinely dissected and divided with an Endo GIA linear stapler. The esophagogastric anastomosis is usually performed at the level of the azygous vein. In cases where the esophageal tumor is located in midesopahgus, the esophageal dissection may have to be carried more proximally toward the thoracic inlet.

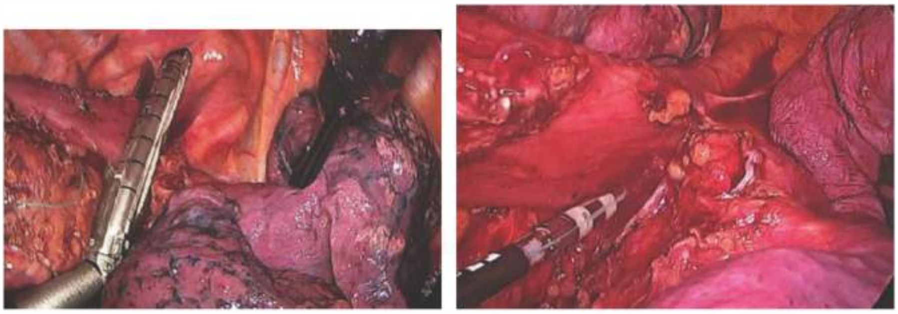

FIG 11 ● Dissection **(left)** and mobilization **(right)** of the esophagus.

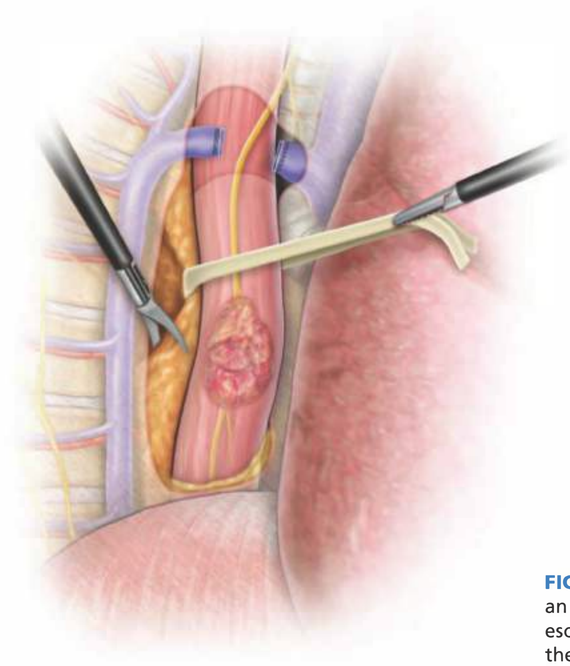

FIG 12 ● The mobilization of the intrathoracic esophagus using an ultrasonic dissector. The azygous vein is routinely divided. The esophagogastric anastomosis is usually performed at the level of the azygous vein.

ESOPHAGOGASTRIC ANASTOMOSIS

- The gastric conduit is pulled into the right chest and the sutures attaching to the esophagogastrectomy specimen are divided (**FIG 13**). The esophagus is divided 2 cm above the azygous vein with an Endo GIA linear stapler (**FIG 14**). The proximal esophageal margin and distal gastric margin are evaluated with frozen section.
- The 2-0 Prolene purse-string suture is placed through the mucosa and muscular layers of the esophagus. A 25-mm or 28-mm anvil is placed in the esophageal lumen and the purse-string suture is tied around the shaft of the anvil. A second purse-string suture is placed as well.
- A gastrotomy is performed along the proximal lesser curvature of the gastric conduit. An end-to-end anastomosis (EEA) circular stapler is inserted through the gastrotomy and the pin is deployed proximally along the great curvature. The anvil and EEA stapler are connected and the stapler is deployed (**FIGS 15** and **16**).
- The esophagogastric anastomosis should be inspected and checked for completeness (**FIG 17**). The "doughnuts" should be complete to ensure esophageal and gastric mucosal apposition. A nasogastric tube is then passed under direct vision.
- The gastrotomy site is resected with one to two applications of the Endo GIA stapler (**FIG 18**). The staple line is oversewn with interrupted 3-0 silk sutures.
- The anastomosis is reinforced with 3-0 silk sutures placed between the muscular layer of the esophagus and the serosa of the gastric conduit.
- A pleural flap is harvested and used to wrap the esophagogastric anastomosis. Omentum or intercostal muscle flaps could be used as alternatives for coverage of the esophagogastric anastomosis.

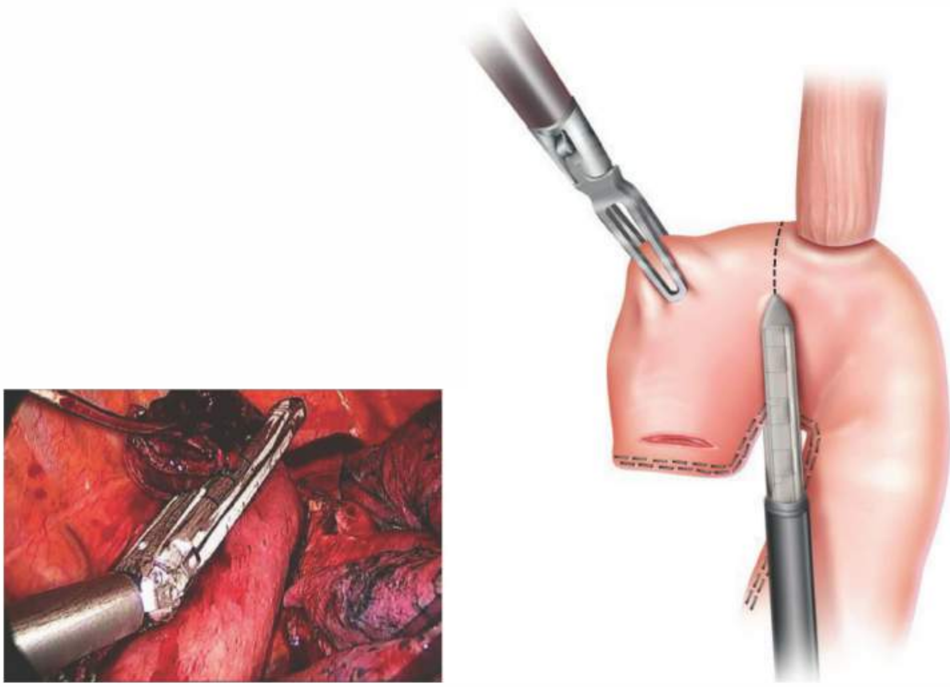

FIG 18 ● The completion of the esophagogastric anastomosis with resection of the gastrotomy site (**left**) with a linear endoscopic stapler (**right**).

PEARLS AND PITFALLS

Preoperative evaluation	▪ Preoperative staging should include a PET/CT scan and EUS. Patients with transmural tumors and nodal disease benefit from preoperative chemotherapy and radiation. ▪ Patients with a history of previous gastric surgery may require the use of a colonic or jejunal conduit. ▪ Patients should undergo pulmonary function tests and echocardiography to assess perioperative risk.
Mobilization of the stomach	▪ The right gastroepiploic artery and vein must not be injured. The primary blood supply to gastric conduit is derived from this vascular arcade. ▪ The gastric conduit should be 4 to 5 cm in diameter. ▪ The gastric conduit tip could be ischemic and should be resected if there is necrosis detected.
Esophagogastric anastomosis	▪ The anastomosis should be covered with a vascularized pedicle, such as omentum, pleura, or intercostal muscle. An anastomotic leak within the thorax could result in life-threatening mediastinitis. ▪ A two-layer anastomosis should be performed regardless of the technique.
Postoperative care	▪ Postoperative barium esophagram should be obtained 5 to 7 days after the procedure to evaluate the integrity of the esophagogastric anastomosis. Contained leaks can be managed with bowel rest and antibiotics. Large leaks typically require operative repair.

POSTOPERATIVE CARE

- Patients should be extubated in the operating room if possible. A chest radiograph is obtained in the recovery room or intensive care unit (ICU). An epidural catheter is used to administer local anesthesia for optimal pain control and pulmonary toilet.
- The nasogastric tube is placed on low continuous suction to avoid gastric stasis and aspiration.
- Fluid balance should be closely monitored to avoid volume overload and respiratory complications.
- Enteral nutrition can be initiated on postoperative day 3 to minimize perioperative malnutrition.

- A barium swallow study is obtained on postoperative days 5 to 7 to assess the anastomosis for a leak. A liquid diet can be initiated if the barium study is negative for a leak. The diet is slowly advanced to a soft mechanical diet.
- Patients are typically discharged when they are tolerating a soft diet and are able to ambulate without difficulty.

OUTCOMES

- In modern surgical series for Ivor Lewis Esophagectomy, the perioperative mortality rates range from 1.4% to 4.4%. The anastomotic leak rates range from 0% to 3.5%. The overall morbidity rates range from 26.6% to 45%.
- The overall 5-year survival rate for patients undergoing Ivor Lewis esophagectomy ranges from the 25.2% to 33.3%. Patients with positive nodal disease have a worse prognosis compared to patients with negative nodal disease.

COMPLICATIONS

- Pneumonia
- Anastomotic leak
- Thoracic duct injury and chyle leak
- Delayed gastric emptying
- Reflux
- Aspiration pneumonitis
- Pulmonary embolism
- Acute myocardial infarction

Chapter 31

Minimally Invasive Esophagectomy

Benjamin Wei Robert J. Cerfolio Mary T. Hawn

DEFINITION

- The incidence of esophageal cancer, especially adenocarcinoma, has increased dramatically over the past decades. This phenomenon is secondary to the increasing incidence of obesity contributing to rising rates of reflux and Barrett's esophagus in the United States.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with esophageal malignancy present with progressive dysphagia and weight loss. The incidence is higher in men and in smokers. Patients often have a long-standing history of gastroesophageal reflux symptoms. The physical examination is usually unremarkable.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients with dysphagia should be evaluated with an upper endoscopy and biopsy of suspicious lesions. Patients with biopsy-proven carcinoma are staged to determine treatment. The staging process includes computed tomography (CT) of the chest and abdomen, an integrated positron emission tomography (PET)/CT, and endoscopic ultrasound. Patients with T3 or N1 disease are treated with neoadjuvant chemoradiation and restaged prior to resection.

SURGICAL MANAGEMENT

Preoperative Planning

- If the patient is unable to maintain adequate nourishment during neoadjuvant therapy or is malnourished and too weak for resection, we place a jejunostomy tube (J-tube), preferably with a laparoscopic approach. This allows for staging and the ability to rule out metastatic disease. A percutaneous endoscopic gastrostomy tube should be avoided in any patient that is being considered for esophageal resection. Additionally, having the J-tube placed up front minimizes the abdominal portion of the esophageal resection procedure.

Positioning for the Abdominal Portion

- The patient is positioned in the supine position with both arms tucked and a Foley catheter in place. We do not routinely use an arterial line or a central line. A nasogastric tube (NGT) is routinely placed. If one is placed, care must be taken to pull it far back into the esophagus as well as to remove all esophageal temperature probes or other devices prior to stapling the stomach. If body habitus or other concerns prevent arm tucking, it is not a necessity.

TECHNIQUES

PORT PLACEMENT

- A Veress needle entry technique is used to place a 5-mm trocar approximately 15 cm inferior to the xiphoid and 3 cm to the left of the midline. The abdomen is then inspected for evidence of distant disease and any suspicious areas are biopsied and sent for frozen section. Four additional trocars are placed: (1) 12-mm trocar is placed 7 cm inferior to the right costal margin and 3 cm from the midline, (2) 5-mm trocar is placed 6 cm superior to the 12-mm trocar and usually to the right of the falciform ligament, (3) 5-mm trocar just off midline to the right and inferior to the base of the xiphoid to retract the left lateral segment of the liver. A 5-mm locking grasper positioned underneath the left lateral segment of the liver and the diaphragm is grasped anterior and to the right of the esophageal hiatus taking care to avoid the phrenic vein, and (4) 5-mm trocar 2 cm below the left costal margin in the anterior axillary line (**FIG 1**).
- The patient is positioned in moderate reverse Trendelenburg position. The surgeon stands on the patient's right side and uses the two right-sided ports. The assistant stands on the patient's left and uses the left subcostal port and camera port.

FIG 1 ● Abdominal port placement for gastric mobilization.

CRURAL DISSECTION AND ESOPHAGEAL MOBILIZATION

- The gastrohepatic ligament is divided using an ultrasonic dissector. The right crus of the diaphragm can then be identified at the esophageal hiatus. The phrenoesophageal ligament is divided anteriorly, taking care to follow the stomach toward the angle of His, lateral and inferior to the left esophageal crus. The crura are dissected circumferentially and the esophagus is isolated.
- Once the retroesophageal window is completed, a Penrose drain is placed around the gastroesophageal junction. The two tails are sutured together with a single 2-0 Vicryl stitch to use as a handle to assist in the crural dissection and for intrathoracic pull-up and manipulation during the second portion of the procedure (**FIG 2**). Dissection of the lower 5 to 7 cm of the esophagus is then performed while the assistant places the Penrose on traction. This can mostly be performed with blunt dissection. If the left pleural space is entered, we place a chest tube at the completion of the abdominal portion of the operation. Radiation changes can make this part of the dissection more difficult.

FIG 2 ● Placement of a Penrose around the gastroesophageal junction. It is important to suture the Penrose so that it can be used to help deliver the conduit into the chest.

GREATER CURVATURE DISSECTION

- On the distal aspect of the greater curvature of the stomach approximately 5 cm proximal to the pylorus, the greater curvature is grasped and elevated anteriorly by the surgeon's left hand and the assistant places the transverse colon on downward traction. The surgeon divides the gastrocolic ligament well inferior to the projected course of the right gastroepiploic vessels. Because the right gastroepiploic vessels will serve as the primary blood supply for the gastric conduit, great care is taken to avoid injuring these vessels during greater curvature dissection (**FIG 3**).
- The lesser sac is entered at least 1 to 2 cm inferior to the right gastroepiploic vessels projected course. Once the lesser sac is entered, the posterior stomach wall is grasped and elevated anteriorly and to the patient's right side with the surgeon's left hand to open the dissection tension plane. This maneuver positions the gastroepiploic vessels anteriorly and helps protect them from injury due to inadvertent grasping (**FIG 4**).
- Dissection is then carried proximally, taking care to stay superior to the transverse colon as it courses toward the splenic flexure. This is accomplished by lifting the posterior stomach wall anteriorly and toward the patient's right side with the surgeon's left hand while the assistant retracts the greater omentum inferiorly and to the patient's left. The proximal aspect of the greater curvature is mobilized by dividing all short gastric vessels until the left crus of the diaphragm is reached. If there is excess omentum impeding the view, we will place a "fat stay" using a 2-0 Vicryl suture on an MH needle. The suture is placed through the fat, the needle is removed, and the assistant grasps both ends of the suture and extracts them through the left-sided trocar. The trocar is then removed and reinserted so that the suture comes through the track but not the trocar. Tension is placed on the suture until the fat is retracted; then, the suture is secured with a hemostat at the level of the skin.
- We leave some omentum along the superior aspect of the greater curvature of the stomach to be used to buttress the intrathoracic anastomosis.

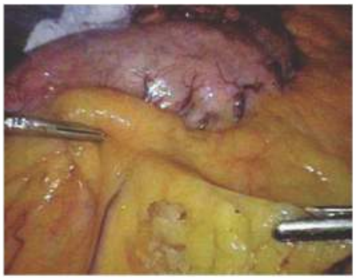

FIG 3 ● Identification of the right gastroepiploic vessels adjacent to the greater curvature and entering the lesser sac.

FIG 4 ● Grasp the posterior wall of the stomach inferiorly through the lesser sac, rolling the gastroepiploic vessels onto the anterior stomach wall. This assists in protecting the right gastroepiploic artery as the dissection is carried proximally along the greater curvature of the stomach.

LESSER SAC AND LEFT GASTRIC PEDICLE DISSECTION

- The posterior attachments to the stomach are divided, exposing the origin of the left gastric vessels along the lesser curvature. In exposing the left gastric artery, the adjacent fat and lymph nodes should be elevated anteriorly to allow for resection with the specimen.
- The left gastric vessels are then identified on the medial aspect of the lesser curvature. Once these vessels are skeletonized, a white vascular (2.5 mm) staple load is fired across the left gastric artery at its origin from the celiac axis (FIG 5).

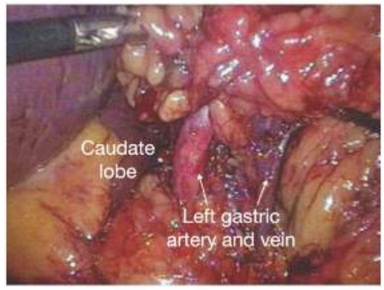

FIG 5 ● Exposure of the left gastric pedicle along the lesser curve.

THE PYLORUS

- The gastrocolic ligament is divided beyond the pylorus with care of staying away from the origin of the right gastroepiploic vessels.
- A Kocher maneuver is performed to further mobilize the pylorus. One good assessment of mobility of the stomach is whether the pylorus can be placed adjacent to the right crus.
- We do not perform a pyloromyotomy or pyloroplasty and instead inject botulinum toxin into the anterior wall of the pylorus.
- Botulinum toxin (100 units) is diluted into 5 mL of saline and drawn into a syringe. A 20-gauge spinal needle is inserted into the anterior aspect of the pylorus (FIG 6). The total volume of botulinum toxin is divided into at least three to four separate injection sites along the anterior pylorus.

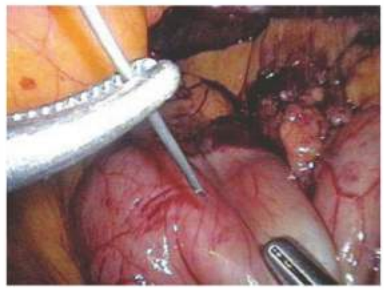

FIG 6 ● Percutaneous injection of 100 units of botulinum toxin into the anterior wall of the pylorus.

CREATION OF THE GASTRIC CONDUIT

- The lesser curvature is cleared of omentum at approximately the level of the incisura to allow for an avascular landing zone for the first staple load on the stomach (FIG 7).
- The conduit is created with sequential applications of a 60-mm stapler using green (4.8 mm) loads aiming toward the angle of His. The goal is to create a conduit that is 6 to 8 cm in width. Once divided, staple-line integrity and hemostasis are verified.
- The conduit is then sutured to the proximal stomach remnant using two interrupted 2-0 Vicryl stitches of alternate color to facilitate orientation following the thoracic pull-up (FIG 8). The tails are left at least 5 cm long to assist in intrathoracic location/manipulation and the first stitch is always placed at the superior apex of the conduit to diminish pull-up tension.
- The surgeon then places the Penrose drain and proximal stomach into the posterior mediastinum. We do not routinely enlarge the hiatus unless there appears to be constriction of the conduit.
- A laparoscopic J-tube is placed if not already present per standard laparoscopic technique to optimize postoperative nutrition.

FIG 7 ● Lesser curvature dissection in preparation for creation of the gastric conduit.

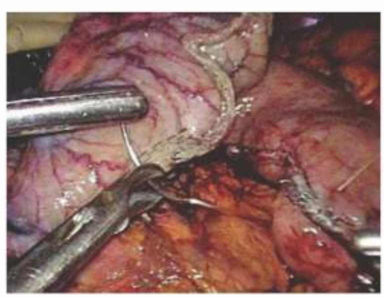

FIG 8 ● Suturing gastric conduit to the proximal stomach to allow for the conduit to be delivered into the posterior mediastinum during the thoracic portion of the operation.

POSITIONING AND PORT PLACEMENT FOR THE ROBOTIC THORACIC PORTION

- After the abdomen portion is completed, the single lumen endotracheal tube is exchanged for a double lumen tube.
- The patient is placed in a left lateral decubitus position and then rolled even more anteriorly. This allows all of the benefits of prone positioning without the anesthesia delays. The patient's body needs to be turned so that the robot can approach the patient from over his or her back and right shoulder.
- The first port placed is the camera port, which is 9 cm from the right axillary port. We use a 5-mm port here initially, with a 5-mm thoracoscope to assist in placing the other ports. Carbon dioxide (CO_2) is insufflated into the chest at a pressure of 12 cm H_2O.
- Port placement is shown in **FIG 9**. It is important to note that the three anterior ports comprise robotic arm 1; the camera port and robotic arm 2 are in a line that runs slightly posterior, headed toward the patient's right hip. If the line is in the anterior axillary line, you will be too close to the diaphragm for robotic arm 2. After the camera port is placed, the robotic arm 3 is placed as posterior and inferior as possible and a seeker needle is inserted first to ensure its safe trocar placement. Robotic arms 1 and 2 are the 8-mm ports through which most of the dissection takes place; robotic arm 3 is a 5-mm port and used primarily for retraction of structures during the dissection.
- The access port for the assistant is positioned last. This port should be triangulated behind robotic arm 2 and the camera port so that the robotic arms will not interfere with the assistant. Care should be taken to avoid the internal mammary artery and the diaphragm when this access port is placed. The insufflation tubing is switched to the access port so that it does not interfere with the movement of the robotic arms.
- **FIG 10** demonstrates the anatomic structures of the right hemithorax as seen from the camera port during the robotic portion of the Ivor-Lewis esophagectomy.

FIG 9 ● Port placement for robotic thoracic phase of esophagectomy. *C*, camera port; *1*, robotic arm 1; *2*, robotic arm 2; *3*, robotic arm 3; *A*, assistant port.

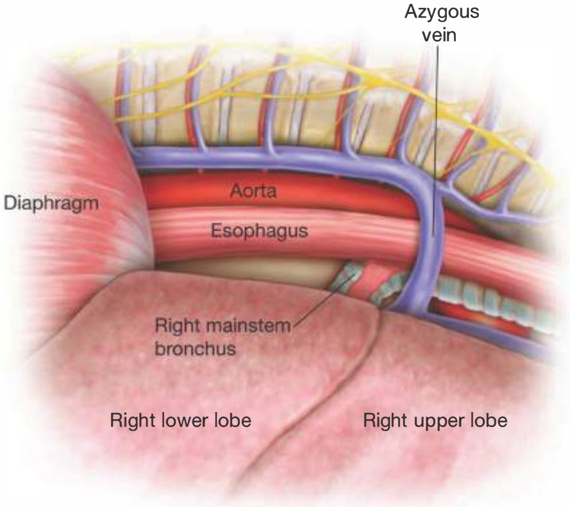

FIG 10 ● Structures of right hemithorax as seen from camera port during robotic Ivor-Lewis esophagectomy.

ESOPHAGEAL DISSECTION AND NODE RETRIEVAL

- Robotic arm 3 holds the lung anteriorly. Robotic arm 2 has a Cadiere forceps and lifts the mediastinal pleura. Robotic arm 1 has a thoracic dissector that incises the mediastinal pleura along the lung (**FIG 11**). The inferior pulmonary ligament is generally divided and lymph node within the ligament resected.
- The mediastinal pleura along the right mainstem bronchus is opened and divided all the way up to the azygous vein and all the way down to the diaphragm. The subcarinal lymph nodes are located posterior and inferior to the right mainstem bronchus and resected. Care should be taken to achieve proper hemostasis of this area, as the subcarinal nodes tend to be well vascularized.

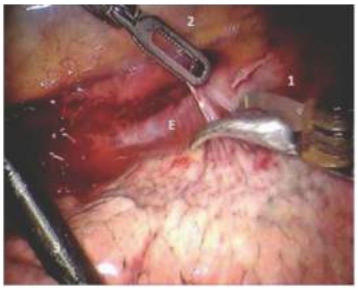

FIG 11 ● Incision of mediastinal pleura overlying esophagus. *E*, esophagus; *1*, robotic arm 1; *2*, robotic arm 2.

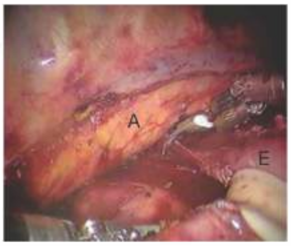

FIG 12 ● The esophagus *(E)* is dissected off the aorta *(A)*. We perform an en bloc dissection from the pericardium to the aorta. Robotic arm 3 is used to grasp the Penrose drain that was placed around the esophagus in the abdomen. It is pulled anteriorly to assist with the esophageal dissection off of the pericardium and aorta.

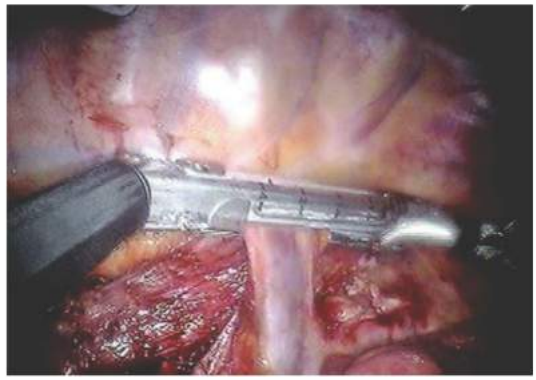

FIG 14 ● The azygous vein is stapled as posteriorly as possible.

- The posterior pleura along the hemiazygous vein going up to the azygous vein is opened. The bipolar thoracic dissector can be used to take the small arteries off the aorta that run to the esophagus. Clips are not necessary for these arteries (**FIG 12**).
- The lymph node dissection is carried out well above the azygous vein and to the posterior paraesophageal tissue (**FIG 13**).
- The azygous vein is dissected off the trachea. It is very important to staple the azygous vein posteriorly (**FIG 14**). This avoids a long azygous stump from getting in the way of performing an anastomosis.
- The esophagus should be completely mobilized from the thoracic inlet to the diaphragmatic hiatus. Performing this part of the operation robotically allows for a thorough harvest of the periesophageal tissue, including lymph nodes. The paraesophageal lymph nodes are dissected carefully off the left and right mainstem bronchi and aorta. Use of the bipolar device and careful dissection during this phase helps avoid thermal injury to the airway, which may present as an esophagobronchial fistula and can be catastrophic for the patient. The subcarinal nodes should be included in the specimen. After completion of the dissection, the pericardium should be visible to the level of the inferior pulmonary veins bilaterally (**FIG 15**).

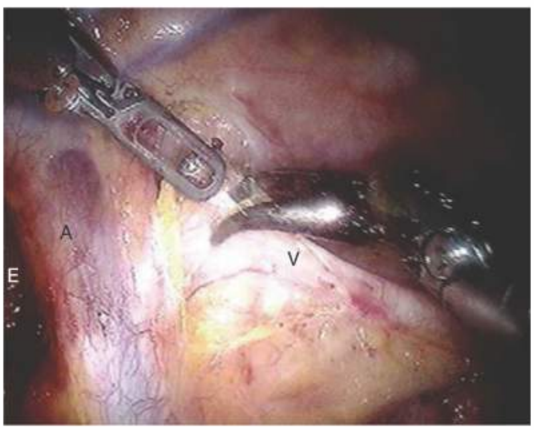

FIG 13 ● Dissection of paraesophageal tissue above the azygous vein *(A)*, vagus nerve *(V)*, and esophagus *(E)*.

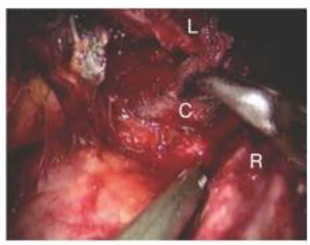

FIG 15 ● The entire left mainstem bronchus *(L)* is identified. We use the bipolar thoracic dissector to minimize thermal injury to the airway. *C*, subcarinal space; *R*, right mainstem bronchus.

DIVISION OF THE PROXIMAL ESOPHAGUS AND MOBILIZATION OF GASTRIC CONDUIT

- The Penrose drain encircling the conduit that was placed during the laparoscopic stage of the procedure is located in the inferior mediastinum and will be used to bring the conduit into the chest.
- The thoracic dissector in robotic arm 1 (right arm) is exchanged for the bipolar scissors. With traction applied to pull it distally, the proximal esophagus is divided just above the azygous vein to ensure the best possible margin away from cancer and/or Barrett's esophagus; it is beveled so that the posterior aspect of the esophagus is longer. Cautery is applied to cut and coagulate simultaneously (**FIG 16**).
- The scissors in robotic arm 1 are switched back to the Cadiere forceps, and the assistant helps pull the resected esophagus and gastric conduit gently into the chest with

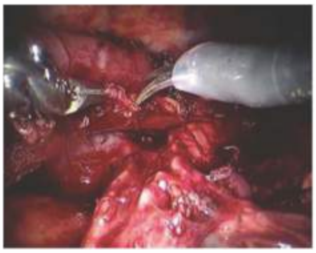

FIG 16 ● The esophagus is mobilized and ready to be cut. The esophagus is pulled downward and it is cut at the level of the carina just about above the azygous vein. Frozen section analysis is performed to ensure the proximal margin that is free of Barrett's metaplasia and cancer. Robotic hot shears are used to cut and coagulate the esophagus as it is cut.

FIG 17 ● The assistant uses a blunt Scanlon clamp, which is less traumatic than the robotic instruments. The clamp is placed through the nonrobotic access port and grasps the gastric conduit and carefully transports it into the right hemithorax.

an atraumatic clamp (rather than using the robotic arm, which because of its strength can damage the conduit) (**FIG 17**). Prior to dividing the sutures attaching the esophagus to the conduit, silk sutures are placed anteriorly and posteriorly, tacking the conduit to the pleura. This helps reduce the amount of tension on the anastomosis and maintain orientation of the conduit. Care should be taken to avoid twisting the conduit; the staples from conduit creation (i.e., the former lesser curve) should be oriented toward the lung. The esophageal specimen is then detached from the conduit (**FIG 18**).

FIG 18 ● The sutures attaching the conduit to the specimen are cut so that the specimen can be placed in a pouch and removed.

CREATION OF THE ESOPHAGOGASTROSTOMY

- A double-layered esophagogastrostomy is created. In general, we have found that the best instruments to use for robotic suturing are a long atraumatic forceps in robotic arm 2 and a suture-cut needle driver in robotic arm 1.
- First, interrupted 3-0 silk sutures are placed along the "back wall" of the anastomosis for the seromuscular layer (**FIGS 19** and **20**). Then, a transverse gastrotomy approximately 2 to 3 cm in diameter on the posterior surface of the stomach approximately 5 mm away from the row of silk sutures is created with electrocautery (**FIG 21**).

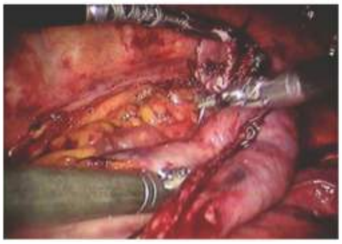

FIG 20 ● The spot where the first suture is placed on the conduit side should be located near the greater curve as far away from the staple line. The conduit is held in place by the bedside assistant to take all tension off of the first suture.

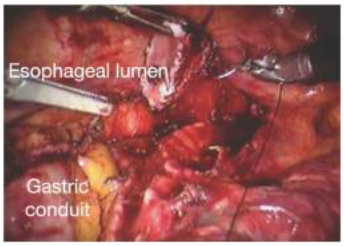

FIG 19 ● A two-layered completely hand-sewn chest anastomosis is performed. The first suture of the back row is placed furthest away from the surgeon. It is a 3-0 silk suture on an RB-1 needle and it is placed as shown to start on the esophagus. This sets up the anastomosis. The conduit is held by the assistant to keep it in place.

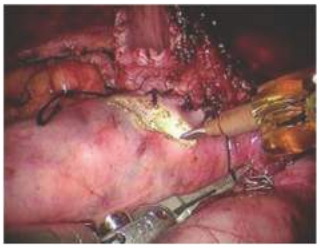

FIG 21 ● Once the posterior row of interrupted sutures are finished, the gastrotomy is performed. The location is carefully chosen approximately 5 mm from the interrupted back row of silk sutures and as far away from the staple line as possible. Note that the gastrostomy is performed on the posterior aspect of the stomach.

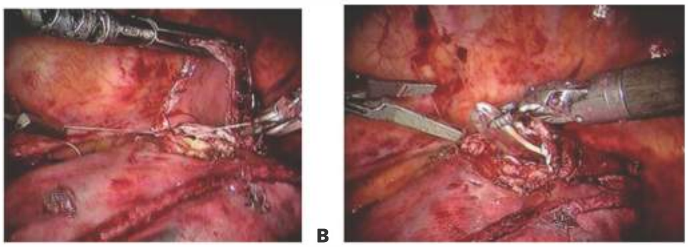

A B

FIG 22 ● **A.** The posterior inner layer of interrupted 3-0 Vicryl sutures is placed. **B.** The NGT is then slid through the anastomosis prior to placing the anterior inner layer of sutures. All the holes on the NGT are positioned into the gastric conduit to prevent evacuating the CO_2 insufflation and so no sutures go through the NGT inadvertently. An outer layer of interrupted silk sutures is placed after the inner layer is completed.

The gastrotomy should be located as far away from the staple line as possible, toward the greater curve of the stomach. Interrupted 3-0 Vicryl suture is used to create the full-thickness layer of the anastomosis around the circumference of the cut end of esophagus/gastrotomy. Typically, a suture is placed at each "corner" of the anastomosis and sutured in a running fashion to create the back wall (**FIG 22**).

- A running 3-0 Vicryl full-thickness suture is then placed in the "front wall," starting at the corner farthest away from the surgeon, to complete the anastomosis. The NGT is fed under direct vision into the conduit prior to completion of this layer. All the holes of the NGT are positioned in the gastric conduit to prevent evacuating the CO_2 insufflation. An additional row of interrupted 3-0 silk sutures is then placed to complete the double-layered anastomosis anteriorly.
- A tongue of omentum coming off the gastroepiploic artery is brought up from beneath the gastric conduit and tacked over the anterior side of the anastomosis with silk sutures (**FIG 23**). If possible, the omentum can be positioned between the anastomosis and the airway (left mainstem bronchus/trachea) to prevent fistula formation. The conduit is sutured to the right hemidiaphragm near the hiatus to prevent herniation of abdominal contents into the chest (**FIG 24**).

FIG 23 ● The omentum is then tacked down to buttress the anterior aspect of the anastomosis. We also leave a large pad of omentum between the conduit and underlying right and left mainstem bronchus to help prevent fistula formation.

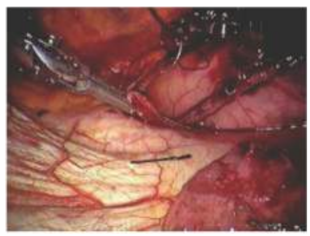

FIG 24 ● A tacking 3-0 silk suture between the gastric conduit and the right hemidiaphragm is placed to help prevent herniation of abdominal contents into the chest.

REMOVAL OF THE SPECIMEN/ CONCLUSION OF SURGERY

- The specimen is removed with a large bag via the assistant port, and frozen section examination is performed to confirm that the proximal and distal margins are clear of tumor and/or Barrett's mucosa. A chest tube is placed directly posteriorly and toward the apex through the incision for robotic arm 2. The ports are removed with the CO_2 insufflation turned off to ensure the absence of bleeding. The robot is undocked and moved away from the patient. The lung is reexpanded and the incisions are closed. We frequently remove the NGT prior to extubation.

PEARLS AND PITFALLS

Nutritional evaluation	■ Assess nutritional status preoperatively and have a low threshold for pretreatment J-tube placement to improve nutritional status prior to esophagectomy.
Aberrant arterial anatomy	■ Clip accessory or replaced left hepatic artery in the gastrohepatic ligament and assess liver viability prior to transection.
Excessive intraabdominal fat	■ Carefully locate the right gastroepiploic vessels prior to dividing the gastrocolic ligament. ■ Liberal use of fat stays to retract omentum to expose the short gastric vessels.

Avoid use of monopolar cautery around the airway	■ Balance risks of airway injury with benefit of taking all peribronchial nodes. ■ Devascularization injury to the airway can result in delayed esophagobronchial fistula and associated mortality.
Bedside fiberoptic endoscopic examination of swallowing (FEES) prior to initiating oral intake	■ Aspiration is common following esophagectomy. Perform FEES prior to contrast study evaluating the anastomosis. ■ Some advocate for delayed oral intake for 4–6 weeks following esophagectomy.
Delayed gastric emptying	■ Emptying of the gastric conduit is poor even with the use of concomitant emptying procedures. ■ Patients must be counseled to keep their head of bed elevated and not eat close to bedtime.

POSTOPERATIVE CARE

- The postoperative care of patients who undergo esophagectomy is based on a team approach. Most literature shows improved outcomes in high-volume centers. This is secondary to a more experienced team not only in the operating room (OR) but also on the floor. Low-molecular-weight heparin is administered prior to surgery and on every postoperative day (POD). Our postoperative care algorithm is as follows for each POD:
  - POD 1
    - The patient receives about 100 to 125 mL per hour of lactated Ringer's solution.
    - The J-tube is placed to gravity.
    - Patient begins ambulating three to four times a day.
  - POD 2
    - Trophic tube feeds are started though the J-tube at 10 mL per hour.
    - The intravenous fluid given is decreased based on urinary output, and changed to 5% dextrose in half normal saline.
    - Ambulate four to six times a day.
  - POD 3
    - The chest tube is usually removed.
    - The patient continues to ambulate four times a day.
    - J-tube feedings are advanced as tolerated.
  - POD 4
    - The patient receives a bedside fiberoptic endoscopic examination of swallowing (FEES).
    - If the vocal cords are normal on FEES, the patient is sent to radiology for an upper gastrointestinal (UGI) swallow. This test evaluates two important components:
      - The anastomosis
      - The time for emptying of the gastric conduit
  - POD 5
    - If the swallow is negative, the patient is advanced to 30 mL per hour of thickened liquids by mouth.
  - POD 6 or POD 7
    - The patient is usually discharged home.

OUTCOMES

- We presented the world's largest series of consecutive robotic Ivor-Lewis esophagectomy procedures in January 2013; we have now completed over 70 robotic esophageal resections. From our experience, we have learned that the keys to preventing complications in this operation are contingent on the following:
  - Performing a mucosa-to-mucosa anastomosis without tension
  - A well-perfused conduit
  - Adequate functional status of the patient at the time of surgery

COMPLICATIONS

- Despite adherence to these technical concepts during surgery, postoperative complications can commonly occur. The most frequent complications include the following:
  - Anastomotic leak: When it is subtle, it can be managed conservatively by keeping the patient NPO and observation for a week. If it is large, an esophageal stent should be placed endoscopically for 8 to 12 weeks. Video-assisted thoracic surgery (VATS) decortication and drainage of effusion should be performed if there is any evidence of new or infected pleural material.
  - Pulmonary complications are common after any thoracic surgery and include atelectasis and pneumonia, including aspiration pneumonia in particular.
  - Chylothorax: This is a complication that can require reoperation. We generally choose to manage this with percutaneous embolization of the thoracic duct for high-output fistulas. If the output is greater than 400 mL per day, it should be immediately treated.
  - Atrial fibrillation: The incidence of atrial fibrillation after an esophagectomy is reported to be about 20% and correlates to the extent of the mediastinal node dissection performed during the operation. As such, patients should be on telemetry in the postoperative period.

Chapter 32

Treatment of Esophageal Perforation: Cervical, Thoracic, and Abdominal

Nathalie Boutet   Moishe Liberman

DEFINITION

- Esophageal perforation is defined as a tear in both the mucosa and muscularis propria layers of the esophagus.

DIFFERENTIAL DIAGNOSIS

- The presentation of esophageal perforations is variable and thus the differential diagnosis can be quite extensive. In cases without obvious etiology, cardiac and pulmonary pathologies will often have been ruled out before the diagnosis of esophageal perforation is made. Myocardial infarction, aortic dissection, pneumonia, pneumothorax, gastroesophageal reflux, and esophageal spasm are among the pathologies that can present with symptoms similar to esophageal perforation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- History may include recent events of forceful vomiting, blunt abdominal trauma, ingestion of caustic substances or foreign bodies, or recent upper gastrointestinal (GI) endoscopy.
- Patients may report a history of dysphagia of rapid onset accompanied by neck, chest, or abdominal pain. Dysphonia and a febrile state may also be reported.
- A thorough review of esophageal function should be obtained as symptoms of achalasia or dysphagia may impact on the choice of treatment.
- Evaluation of comorbid conditions such as heart disease and pulmonary function should be performed. A history of prior surgical and radiation therapy should be sought.
- Physical exam may reveal the presence of subcutaneous emphysema in the neck or chest. Reduced air entry may signal the presence of an associated pleural effusion or pneumothorax.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Evaluation of other diagnoses found in the differential will often lead to basic imaging studies being performed in these patients, such as a chest x-ray. One can expect to find air in the subcutaneous tissues of the neck, chest wall and mediastinum (**FIG 1**), and in the prevertebral space on the lateral views. Associated plain film findings may include pleural effusion, pneumothorax, hydropneumothorax, pneumoperitoneum, or pneumoretroperitoneum.
- Cervical and thoracic computed tomography (CT) scans with oral contrast can be performed to diagnose esophageal perforations. An extraluminal leak of contrast medium can be seen in the prevertebral or pleural spaces (**FIG 2**). CT scan also allows for the evaluation of other potential causes of clinical presentation. CT scan is the investigation of choice when diagnosis is uncertain. Pneumomediastinum, pneumoperitoneum, and air in the subcutaneous tissues of the neck will often be seen in cases of esophageal perforation (**FIG 3A,B**). CT also allows for the evaluation of the neck, mediastinum, abdominal cavity, and pleural spaces, which can aid in operative incision planning and/or drainage planning in nonoperative cases.[1]

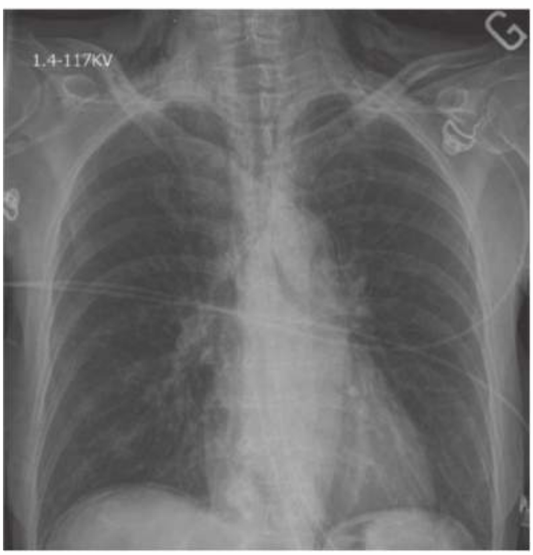

FIG 1 • Chest x-ray showing subcutaneous emphysema and pneumoperitoneum.

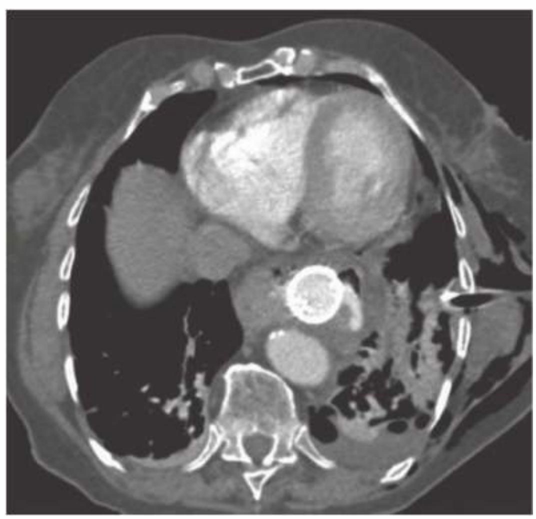

FIG 2 • CT scan with extraluminal leak of water-soluble oral contrast in the mediastinum. Subcutaneous emphysema is also present.

A B

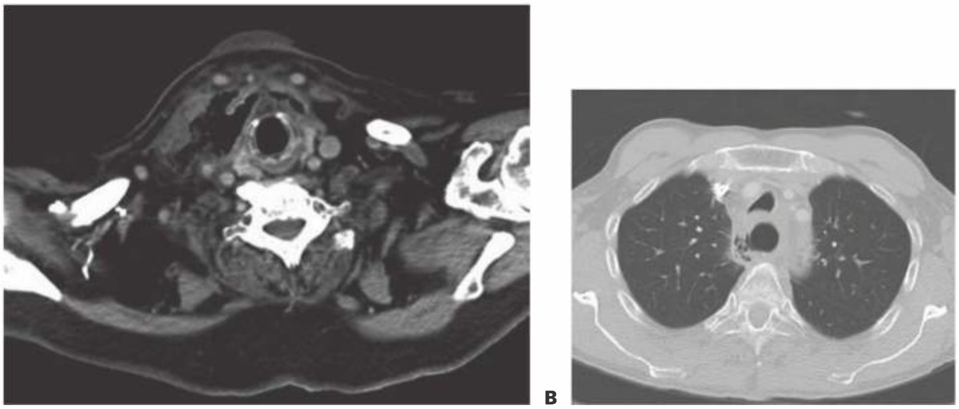

FIG 3 ● **A.** CT scan showing subcutaneous emphysema in the neck following cervical esophageal perforation. **B.** CT scan showing pneumomediastinum.

- Gastrografin studies can also be performed and should be immediately followed by a barium swallow in the event of negative findings, as barium studies are more sensitive than Gastrografin. Water-soluble contrast should be avoided when tracheoesophageal fistula is considered in the differential. With CT scan and endoscopy, oral esophagograms are not usually necessary in the modern day diagnosis of esophageal perforation.
- Diagnosis can also be made using endoscopy (**FIG 4**). Endoscopy should always be performed under general anesthesia in the operating room at the time of esophageal repair, exclusion, stenting, clipping, or decision regarding conservative management. It should always be performed by an experienced upper GI endoscopist and is very important in not only assessing the site of the perforation but also in evaluating for distal obstruction, quality of the esophagus, size of the hole, associated upper GI pathology, and mucosal quality/necrosis. It is primordial that insufflation be kept to a minimum in order to avoid increasing the extent of the perforation.

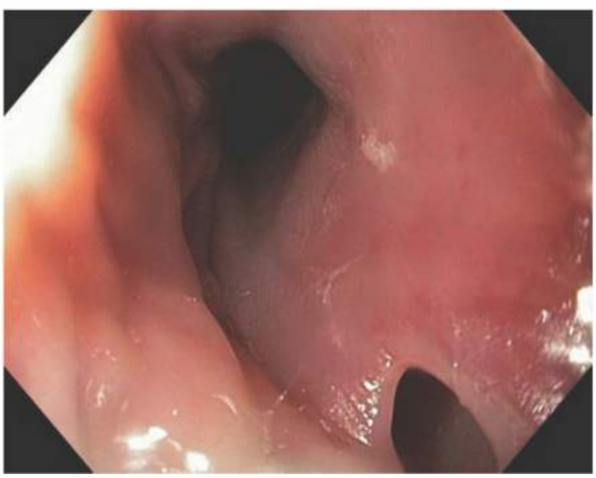

FIG 4 ● Esophagogastroscopy showing an esophageal perforation in the **bottom right** corner. The esophageal lumen is seen in the **upper left** corner. Note the clear margins of the perforation and the absence of mucosal necrosis.

SURGICAL MANAGEMENT

Preoperative Planning

- Appropriate resuscitation is mandatory prior to surgical treatment. Diagnosis should be confirmed either by CT scan, water-soluble contrast/barium swallow, or endoscopy. This is critical as approaches to cervical, thoracic, and abdominal esophageal perforations are drastically different. Broad-spectrum intravenous antibiotics should have been started as soon as the diagnosis is made.
- We recommend on-table endoscopy under general anesthesia in all cases in order to precisely delineate the location, size, and extent of the hole and assess the quality of the esophagus (including evaluation of possible downstream obstruction). Additionally, endoscopy can be used as a treatment option (stenting, clipping) or as an adjunctive procedure during repair (perforation cannulation, percutaneous endoscopic gastrostomy, percutaneous endoscopic jejunostomy). In cases requiring thoracotomy, laparotomy, or cervical exploration, a flexible soft-tipped guidewire is typically placed through the perforation using endoscopy in order to make it simple and expedient to find the site of perforation during surgical exploration and minimize dissection (**FIGS 5** and **6**).

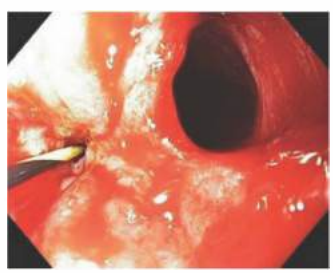

FIG 5 ● Esophagogastroscopy showing insertion of a guidewire into the esophageal lumen with a large perforation seen on the right.

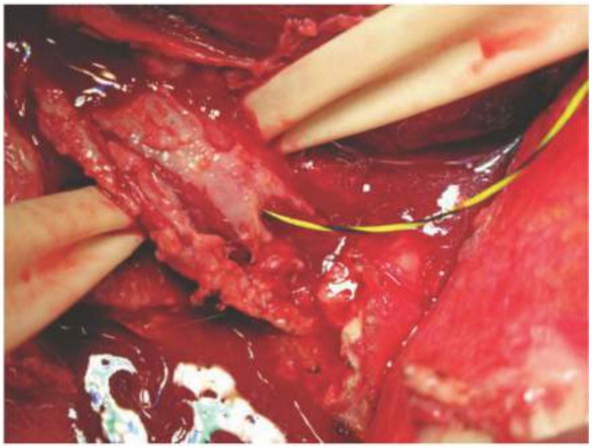

FIG 6 • Dissected esophagus with guidewire through site of esophageal perforation.

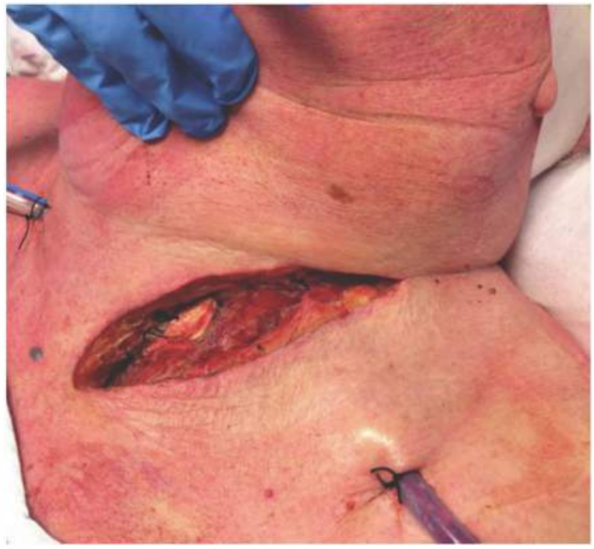

FIG 7 • Slight hyperextension of the neck allows easy access for neck dissection. Incision along the medial border of the sternocleidomastoid muscle.

Positioning

- Cervical perforation
  - The patient is placed in dorsal position with a bolster under the scapulae to obtain a slight hyperextension of the neck. The endotracheal tube is secured to the right corner of the mouth and the head is slightly turned to the right side (**FIG 7**).
- Upper two-thirds thoracic perforation
  - The patient is placed in left lateral decubitus with a double lumen endotracheal tube in place. The flexion point of the operating table should be located at the level of the 5th thoracic vertebra. An axillary roll is placed under the thoracic cage, two fingerbreadths below the left axilla to protect the brachial plexus. The table is flexed in order to open the intercostal spaces on the right side. The right arm is positioned anterosuperiorly to the head. Once positioning is adequate, the position of the double lumen endotracheal tube is confirmed with bronchoscopy and the right lung is isolated from ventilation.
- Lower one-third thoracic perforation
  - The patient is placed in right lateral decubitus with a double lumen endotracheal tube in place. All specifics of positioning are the same as for the left lateral decubitus position previously described.
- Abdominal perforation
  - The patient is placed in dorsal position with both arms abducted.

TECHNIQUES

CERVICAL PERFORATION REPAIR AND DRAINAGE

Skin Incision

- The medial border of the left sternocleidomastoid muscle is identified. An incision is performed along the border of the muscle (**FIG 7**). The platysma is incised in the orientation of the skin incision.

Dissection

- The sternocleidomastoid muscle is dissected and retracted laterally, exposing the vessels of the neck. The carotid sheath is left intact and retracted laterally. If necessary, the middle thyroid vein is ligated and the larynx and trachea are retracted to the right. Care is taken to not damage the left recurrent laryngeal nerve, which lies in the tracheoesophageal groove. The prevertebral plane is entered, moving the esophagus anteriorly (**FIG 8A,B**). The entire space is dissected as far caudally as the carina.

Repair

- In most instances, the site of the perforation is not identified nor should any extensive amount of time be spent searching for it. If the perforation is visualized and easily accessible, it can be repaired. The first step of the repair is the lengthening of the opening in the muscularis propria as this is often smaller than the orifice in the

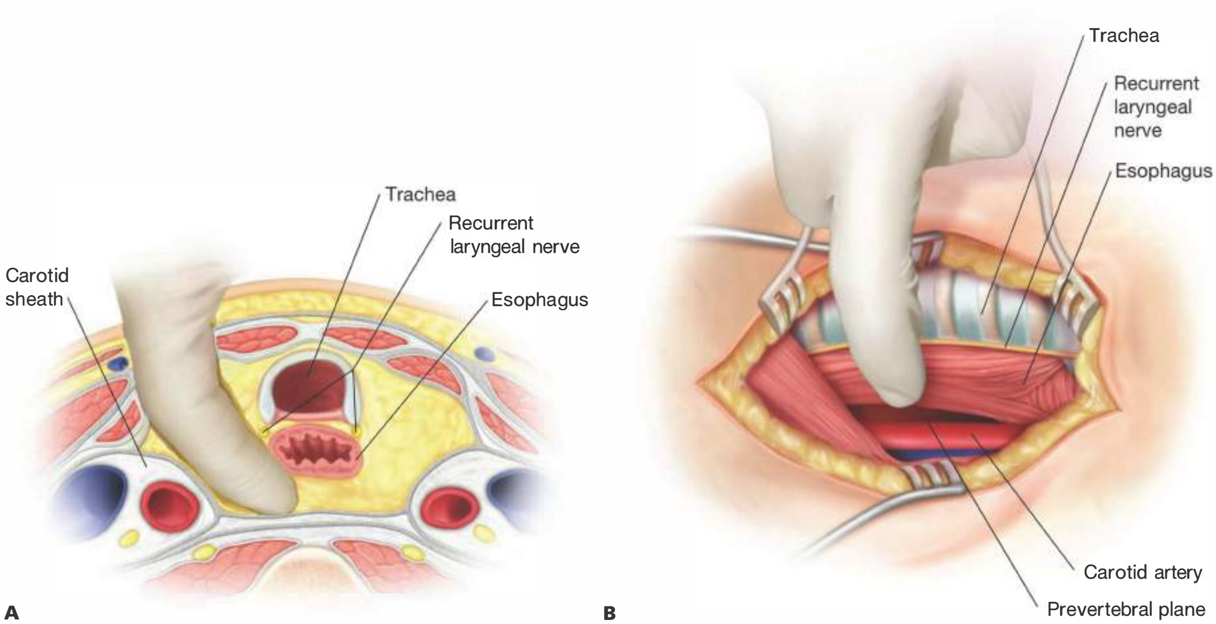

FIG 8 ● **A.** Transverse section showing the prevertebral space. Dissection is carried medially to the carotid sheath. The recurrent laryngeal nerve is protected within the tracheoesophageal groove. **B.** Lateral view of the dissected prevertebral space with trachea, esophagus, and recurrent laryngeal nerve retracted anteriorly.

mucosa (**FIG 9**). Once the entire length of the perforation is exposed, the repair is performed with single interrupted absorbable sutures on the mucosal plane and nonabsorbable sutures on the muscular plane (**FIG 10**). In most cases, the inflammation at the site of perforation will prevent easy identification of both mucosal and muscular planes. In such instances, it is appropriate to proceed with a single layer repair using single interrupted absorbable sutures. A rubber bougie should be placed in the esophagus orally to assure that the repair does not result in esophageal obliteration or significant stenosis.

Sternocleidomastoid Flap

- Leaks from primary repairs of esophageal perforations are common and it is preferable to protect the repair with a vascularized flap. For perforations of the cervical esophagus, the sternal head of the sternocleidomastoid muscle is detached using electrocautery and rotated to

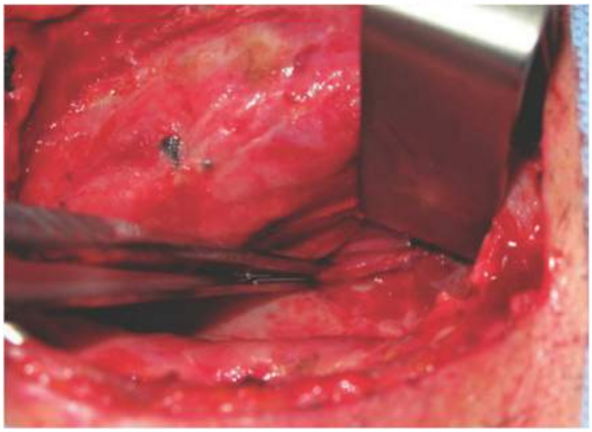

FIG 9 ● Esophageal perforation at the tips of the forceps. The esophageal lumen is seen with normal mucosa.

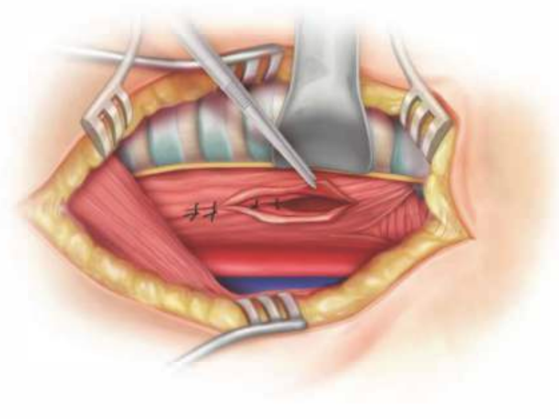

FIG 10 ● Repair of esophageal perforation in two planes of single interrupted sutures (mucosa and muscularis propria).

cover the site of the perforation. The muscle is fixed with multiple interrupted sutures around the repair. The muscle should be tightly opposed to the repair site and cover it entirely (**FIG 11**). In the case of concomitant tracheal injury, the flap should be placed in between the repaired esophagus and the trachea to avoid the formation of a tracheoesophageal fistula.

Drainage

- Regardless of whether the site of perforation was identified and/or repaired, the prevertebral space is irrigated abundantly and drains are left in place. Drains are brought out through separate skin stab wounds.

Closure

- The platysma is reapproximated in the superior portion of the incision with absorbable sutures. The skin incision is closed with staples.

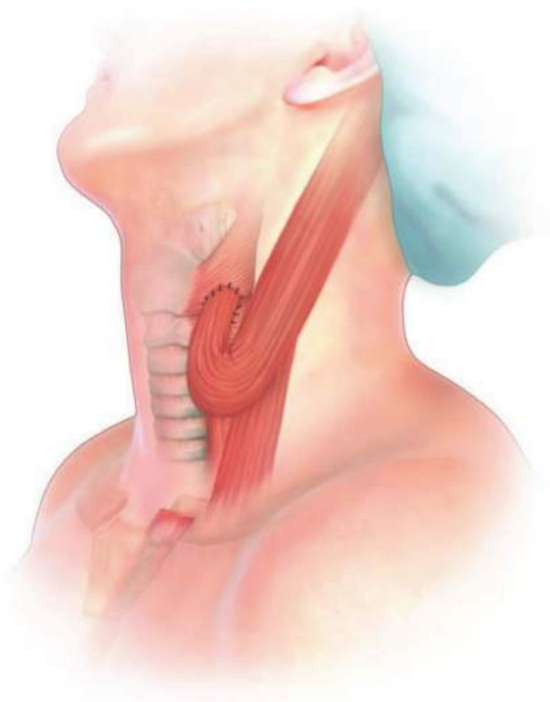

FIG 11 ● Sternocleidomastoid flap. The sternal head is dissected and rotated to cover the entire repair site. The flap is fixed to the repair with single interrupted sutures.

THORACIC PERFORATION REPAIR AND DRAINAGE

Skin Incision

- With the patient in lateral decubitus, left for perforations of the upper two-thirds and right for the lower third of the esophagus, the tip of the scapula is identified and an incision following the orientation of the underlying ribs is placed two fingerbreadths caudally (**FIG 12**).

Dissection

- The incision is carried through to the latissimus dorsi. The muscle is incised exposing the serratus anterior. The serratus anterior is preserved and retracted anteriorly. With single lung ventilation, the 5th intercostal space is entered by cutting the intercostal muscles immediately above the 6th rib. The 6th rib is sectioned anteriorly and posteriorly. A 1 to 2 cm portion of the 6th rib can be removed. In very high perforations, a 4th intercostal space may be chosen to aid in repair, and in very low perforations, a lower incision (6th, 7th, or 8th interspace) may be chosen.

FIG 12 ● Patient positioned in left lateral decubitus. The scapula is drawn along with the incision site two fingerbreadths below the tip of the scapula following the orientation of the underlying ribs.

Intercostal Flap Preparation

- The periosteum of the 5th rib is opened longitudinally in the center of the bone and retracted inferiorly. The neurovascular bundle is dissected off of the inferior border of the 5th rib using a periosteal elevator. The intercostal muscles and the neurovascular bundle are transected anteriorly and the resulting flap is moved posteriorly to avoid injury with retractors used to open the intercostal space (FIG 13).

Repair

- The site of perforation should be identified (FIG 14). The esophagus should be mobilized circumferentially above and below the perforation and Penrose drains should be placed around the esophagus to aid in retraction and repair (FIG 15A,B). The repair should proceed in one or two layers of interrupted nonbraided absorbable suture (3-0 polydioxanone [PDS]) over a bougie (FIG 16).

Intercostal Muscle Flap

- The previously prepared intercostal flap is approximated to the site of repair and fixed with interrupted horizontal mattress, 3-0 silk sutures (FIG 17).

Drainage

- The thoracic cavity is irrigated abundantly and two thoracic drains are inserted and positioned close to the site of perforation. Drains are fixed at the skin.

Closure

- The ribs are reapproximated with figure-of-eight sutures of heavy Vicryl. The lung is reexpanded before tying the sutures and appropriate drain position is confirmed. The serratus anterior is resewn to its fat and the latissimus dorsi muscle is repaired with running sutures of 0 Vicryl. The subcutaneous fat is reapproximated with a running suture of 2-0 Vicryl before closing the skin with staples.

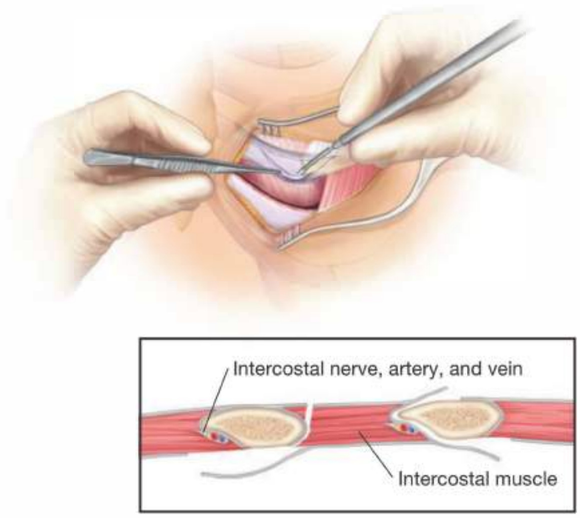

FIG 13 ● Dissection of intercostal flap. The intercostal muscles are dissected from the superior rib by removing the periosteum and following the lower border of the superior rib. Care is taken to preserve the neurovascular bundle with the flap as this is essential to flap viability. The dissection plane is depicted in the inset.

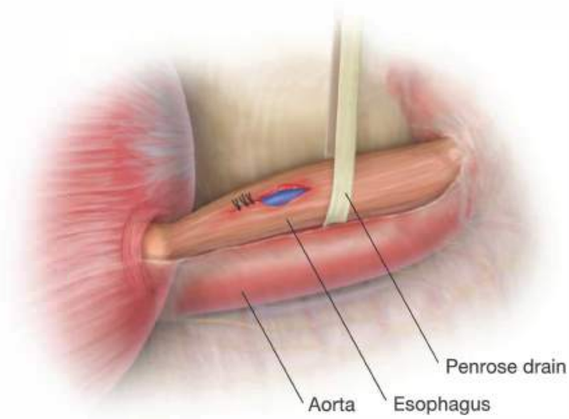

FIG 16 ● Single layer repair of thoracic esophageal perforation over bougie with single interrupted sutures.

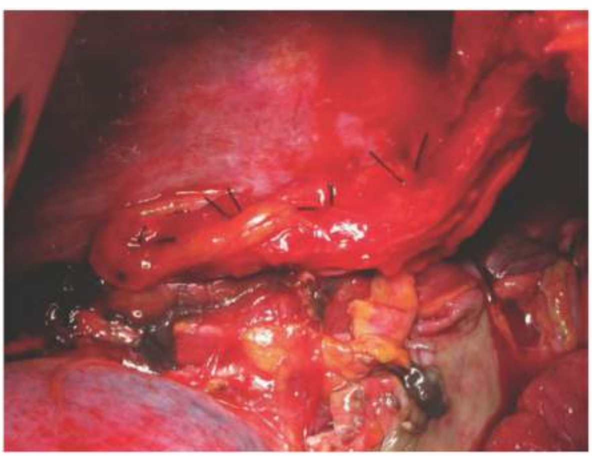

FIG 17 ● Intercostal muscle flap fixed to site of thoracic esophageal perforation repair. The flap is fixed with single interrupted sutures and covers the repair entirely.

ABDOMINAL PERFORATION REPAIR AND DRAINAGE

Skin incision

- A midline laparotomy is performed from the xiphoid process to the umbilicus.

Dissection

- The gastrosplenic ligament is dissected off of the greater curvature of the stomach using an energy vascular sealing device. The short gastric vessels are sealed and divided and the angle of His is dissected. The left and right crus are identified and the esophagus is dissected free. A Penrose drain is placed around the gastroesophageal junction for exposure.

Repair

- The site of perforation needs to be identified and the steps for repair are the same as for cervical and thoracic perforations. A Nissen fundoplication is then performed to cover the esophageal repair (see Part 1, Chapter 22). A fundoplication should not be performed in patients with history of achalasia. In such cases, a patch of omentum can be fixed on the repair with absorbable sutures.

Drainage

- The abdominal cavity is irrigated abundantly and Jackson-Pratt drains are placed around the area of repair.

Closure

- The rectus abdominis aponeurosis is closed with a running suture of PDS 1. The skin is then closed with staples.

ESOPHAGECTOMY AND DIVERSION

- In cases of severe sepsis, hemodynamic instability, a necrotic esophagus, and/or a very late presentation, esophagectomy and diversion is a lifesaving procedure. Resection and diversion is always a last option.

Skin Incision and Dissection

- Esophagectomy can either be performed using a transthoracic approach (right thoracotomy; see "Thoracic Perforation Repair and Drainage") or using a transhiatal approach through a midline laparotomy.

Resection

- The gastroesophageal junction is stapled off and a draining gastrostomy and feeding jejunostomy are performed. The entire esophagus is brought out through a left cervical incision (**FIG 18A**) and amputated just proximal to the perforation. As much proximal esophagus as possible should be left in place in order to aid in future restoration of GI continuity.

Stoma Formation

- The esophagus is then tunnelled under the skin of the left chest and brought out to the skin as an end esophagostomy. The stoma is sewn to the skin using 3-0 Vicryl or 3-0 PDS interrupted sutures and an enterostomal appliance is applied to the skin (**FIG 18B**). Three to 6 months after diversion, the GI continuity is restored using either a gastric pull-up or a colon bypass. Primary esophagectomy and anastomosis is rarely done in case of perforation.

Closure

- Closure is performed as previously described in the thoracic and abdominal perforation repair and drainage sections.

A

B

FIG 18 ● **A.** Thoracoabdominal esophagus dissected and brought out through a left cervical incision. **B.** End result of cervical esophagostomy with enterostomal appliance removed. Note that the conserved esophagus extends below the clavicle, showing preservation of a maximum length of tissue above the site of perforation.

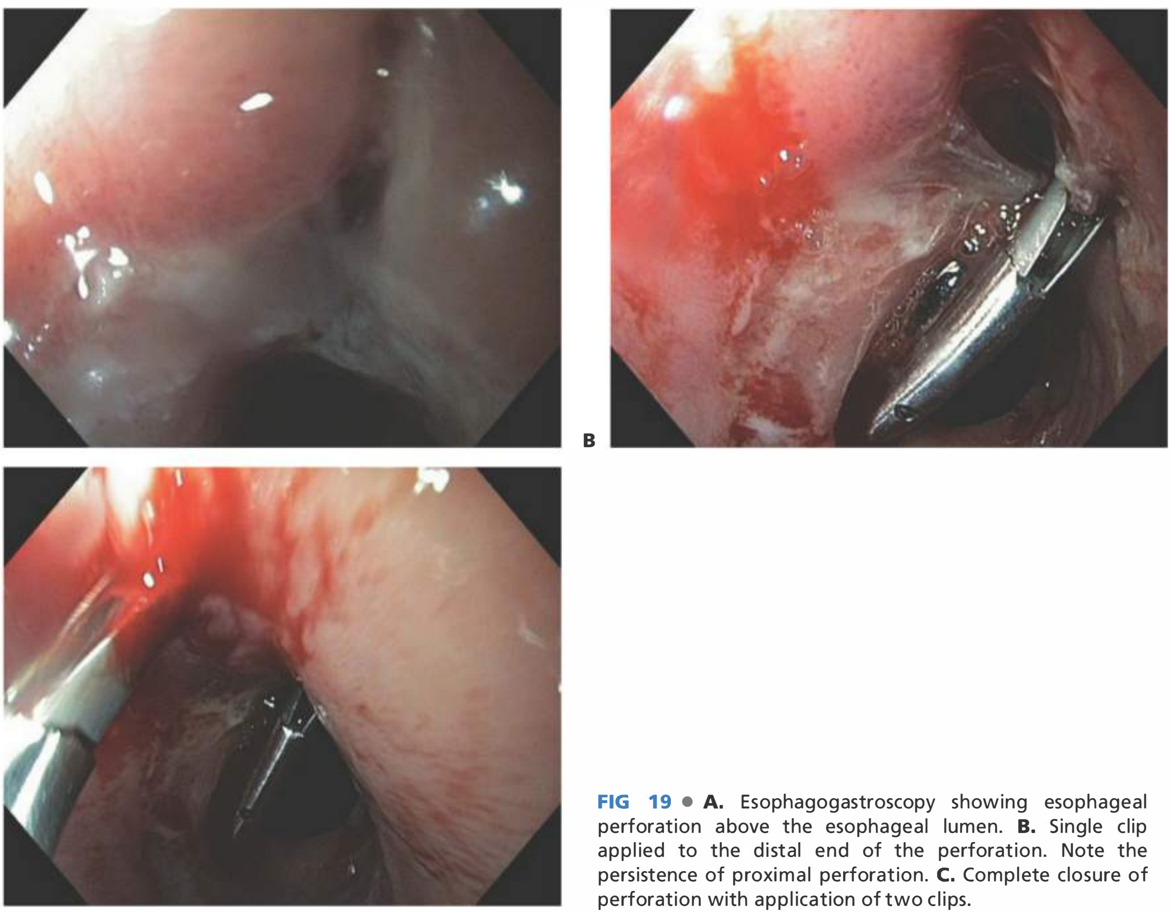
ENDOSCOPIC APPROACHES

Endoscopic Repair/Clipping

- In select cases of very early perforation in a clean esophagus and a very stable patient, an endoscopic closure of the mucosal defect can be attempted. This is typically performed in cases of endoscopic perforation where the perforation is immediately recognized and sent directly to a highly specialized center.
- The patient is placed under general anesthesia in the operating room and flexible endoscopy is performed. The mucosal defect should be inspected for any signs of ischemia, necrosis, or infection (see **FIG 4**).
- Distal obstruction should be ruled out using endoscopy prior to attempting endoscopic repair.
- If the patient is stable, the mucosal defect is small and the hole appears closable, a series of through-the-scope endoscopic clips may be applied from distal to proximal in order to attempt complete closure (**FIG 19A–C**).

Endoscopic Stenting

- Temporary endoluminal esophageal stenting is becoming more popular for the acute treatment of esophageal perforation.[2] The decision to use a stent in the esophagus for the treatment of esophageal perforation is based on the clinical status of the patient, on preoperative imaging and on the location, and the size and site of the perforation on intraoperative endoscopy.
- As experience with stenting in esophageal perforation is increasing, the indications are expanding and a stent can often be used in a very septic patient. If spillage can be controlled using a stent and percutaneous (chest tubes, pigtail drains) and/or thoracoscopic/laparoscopic adjunctive procedures are performed to allow for abscess drainage, one can often temporize a very sick patient quickly and save the patient from the long-term morbidity of an esophageal resection and diversion procedure.
- If a stenting approach is chosen, a percutaneous gastrojejunostomy is first placed to allow for gastric drainage and



A B C

FIG 19 ● **A.** Esophagogastroscopy showing esophageal perforation above the esophageal lumen. **B.** Single clip applied to the distal end of the perforation. Note the persistence of proximal perforation. **C.** Complete closure of perforation with application of two clips.

FIG 20 ● **A.** Guidewire in the esophageal lumen. **B.** Metallic stent. **C.** Plastic stent.

postpyloric feeding. A guidewire is then passed into the stomach and the stent is placed under endoscopic or fluoroscopic vision (FIG 20A). Fully covered metallic stents (FIG 20B) or silicone-polyester (plastic) stents (FIG 20C) should be used in cases of benign esophageal perforation so that they can be easily removed without causing esophageal damage. Stents are typically removed 4 to 8 weeks following perforation. In case of benign esophageal perforation, esophageal stent migration is typical due to the lack of stenosis or tumor. It is therefore important to use the largest diameter stent possible (typically 23 mm), a very long stent (to help with esophageal wall apposition and prevent migration), and to proximally cover the whole by at least 6 to 7 cm if possible.

CONSERVATIVE APPROACH

- In cases of esophageal perforation in patients who are hemodynamically stable, the perforation is discovered early (<24 hours) and there is objective evidence of a contained leak with a contrast study demonstrating contrast extravasation without pooling in the mediastinum and draining back into the esophagus, a conservative approach can be chosen.[3]
- These patients should be kept strict NPO with a nasogastric tube in place (inserted endoscopically). They should be placed on intravenous antibiotics, intravenous fluids, and intravenous proton pump inhibitors. They should be closely monitored for fever, tachycardia, and leukocytosis.
- If signs of sepsis develop, they should be taken to the operating room for endoscopic stenting or esophageal repair/diversion. In cases of successful conservative treatment of esophageal perforation, a Gastrografin swallow should be performed at 7 to 10 days following perforation to assess healing of the perforation.
- Nutrition can be provided using either nasogastric/nasojejunal feeding or total parenteral nutrition.

Gastrostomy/Jejunostomy

- Classically, esophageal repair in the neck, chest, or abdomen was performed in addition to a laparotomy or laparoscopy in order to perform a gastrostomy (for gastric drainage) and a feeding jejunostomy (for feeding). In cases where there is no peritoneal soilage, this can be accomplished in less than 5 minutes prior to esophageal repair using a Percutaneous Endoscopic Gastrostomy with Jejunal feeding limb (PEG-J) (FIG 21). A PEG-J performed prior to repair or diversion on the operating table at the time of endoscopy saves the patient a laparotomy and greatly expedites the operation.

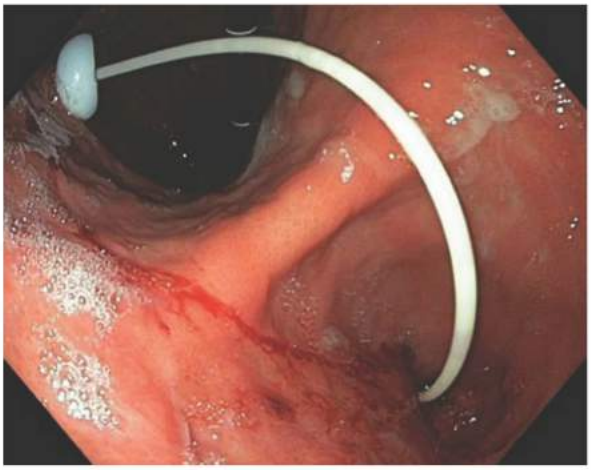

FIG 21 ● Endoscopic view of a PEG-J.

PEARLS AND PITFALLS

History	■ Symptoms of achalasia preclude the use of a Nissen fundoplication in abdominal perforations. ■ Obstructive symptoms should be addressed intraoperatively to avoid postoperative downstream pressure buildup on the esophageal repair.
Presentation	■ A high index of suspicion is required to diagnose esophageal perforations. ■ Diagnostic delays over 24 hours are associated with increased mortality.
Preoperative evaluation	■ Always perform on-table endoscopy under general anesthesia before making definitive decisions regarding surgical, endoscopic, or conservative treatment.
Endoscopic treatment	■ Esophageal stenting can be applied in selected stable patients. It can also be used as a bail out in patients who are extremely ill, in combination with percutaneous or video-assisted thoracic surgery (VATS) drainage, to temporize a septic patient.
Repair	■ Suturing of the esophageal defect is mandatory in perforations of the abdominal and lower two-thirds of the thoracic esophagus, whereas it is optional in more proximal (cervical) perforations. ■ Using flaps greatly reduces the risks of ongoing leaks postoperatively.
Drainage	■ Adequate drainage of the surgical site prevents formation of abscesses and, in the case of postrepair leak, allows for controlled leakage.
Underlying esophageal cancer	■ Primary repair of a perforated esophageal cancer is inappropriate.
Postoperative nutrition	■ Percutaneous Endoscopic Gastrostomy with Jejunal feeding limb (PEG-J) can make the operative management of intrathoracic and cervical esophageal perforation quicker, simpler, and less morbid.
Last resort	■ Esophagectomy and diversion should be a last resort as the operation is extremely morbid and many patients never go on to definitive reconstruction for restoration of GI continuity.

POSTOPERATIVE CARE

- Close monitoring of patients with esophageal perforation is mandatory and treating physicians should have a high index of suspicion for leaks. Patients should be kept NPO for 7 days postoperatively with a nasogastric tube or gastrostomy in place. Ins and outs should be monitored and the appearance of the liquid drained noted. Patients should be kept on intravenous antibiotics and intravenous proton pump inhibitors until oral contrast study 7 to 10 days postrepair.
- On postoperative days 7 to 10, a water-soluble contrast study should be performed. The absence of leak should be confirmed with a barium swallow before the nasogastric tube is removed and a liquid diet is begun. Diet is then progressed as tolerated and drains are removed.

OUTCOMES

- Outcome is dependent on multiple factors including the patient's hemodynamic status on presentation, the patient's age, the site of perforation, delay to diagnosis more than 24 hours, and the presence of underlying esophageal neoplasia.
- Mortality varies from 2% to 27% and morbidity from 53% to 81%.[4]

COMPLICATIONS

- Ongoing leak
- Tracheoesophageal or esophageocutaneus fistula
- Empyema
- Intraabdominal, mediastinal, thoracic, or cervical abscess
- Esophageal stricture
- Sepsis, septic shock

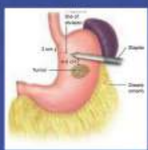
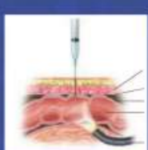
Part 2 Operative Techniques in Gastrointestinal Surgery





Chapter 1

Inguinal Hernia: Open Approaches

Michael D. Paul   Kamal M.F. Itani

DEFINITION

- Inguinal hernia is one of the most commonly encountered clinical problems for the general surgeon.
- An inguinal hernia is an opening in the myofascial plain of the oblique and transversalis muscles that can allow herniation of intraabdominal or extraperitoneal organs.
- There are three potential spaces for an inguinal hernia: (1) an indirect hernia occurs lateral to the inferior epigastric vessels and through the opening that accommodates the cord structures in men and the round ligament in women, (2) a direct hernia occurs through Hesselbach's triangle, and (3) a femoral hernia occurs through the femoral canal medial to the femoral vein.

DIFFERENTIAL DIAGNOSIS

- Patients present with complaints of either a bulge in the groin or groin pain.
- The differential diagnosis for a groin bulge includes inguinal lymphadenopathy, hydrocele, varicocele, a testicular mass, a cord lipoma, or an iliac or femoral aneurysm.
- The differential diagnosis for groin pain includes testicular pathology, ilioinguinal strain, or an athlete's hernia.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The presence of an inguinal hernia can almost always be confirmed on physical examination. Both groins and testicles should be assessed for masses. A reducible mass is best felt with the patient standing and providing intermittent Valsalva such as a cough. A femoral hernia will be felt below the inguinal ligament, adjacent to the femoral vessels.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- If the diagnosis cannot be definitely made with physical examination, ultrasound or computed tomography (CT) scan can be used to assess the integrity of the abdominal wall.

SURGICAL MANAGEMENT

- The bulk of surgical treatment is discussed in the "Techniques" section. Here, consider indications and other more general concerns, such as the following:

Preoperative Planning

- The role of routine antibiotic prophylaxis for elective inguinal hernia remains controversial. There is a body of literature indicating no statistically significant advantage to the use of antibiotic prophylaxis in the performance of routine inguinal hernia repair with or without the use of mesh. Nevertheless, many surgeons argue that antibiotic prophylaxis with a first-generation cephalosporin to cover skin flora is both inexpensive and safe and that such practice should not be considered inappropriate. In the acute setting of a small bowel obstruction secondary to an incarcerated hernia, appropriate perioperative antibiotics should be given within 60 minutes of the initial skin incision.
- Patients should be asked to void preoperatively. In most elective cases, a Foley catheter is not necessary.
- Deep vein thrombosis (DVT) prophylaxis with pneumatic compression devices starting prior to surgery and continuing in the recovery phase is now standard of care.
- Anesthesia options for inguinal herniorrhaphy include general, spinal, and local anesthesia with or without intravenous sedation. Emergent cases of small bowel obstruction secondary to an incarcerated inguinal or femoral hernias will require general anesthesia.

Positioning

- The patient is positioned supine with arms out on arm boards.

TECHNIQUES

- The approach to the inguinal canal is the same for all anterior groin hernia repairs.
- Gentle palpation of the inguinal area allows the identification of the spermatic cord. An oblique incision or incision along a skin crease or hairline centered around the cord structures is then made (**FIG 1**).
- Using electrocautery, the soft tissue is dissected to the superficial epigastric vessels, which are ligated. The dissection is then carried down through Camper's fascia and the more fibrous Scarpa's fascia. The next layer is the transparent innominate fascia and the external oblique aponeurosis. Palpation along the external oblique aponeurosis moving laterally and inferiorly should exclude a femoral hernia.
- The external ring is identified and is covered with the external spermatic fascia, which is continuous with the innominate fascia. The external oblique aponeurosis is opened with a scissor, starting medial at the external ring and moving superior/lateral parallel to the inguinal ligament (**FIG 2**). Elevating the fascia and using a scissor protects the ilioinguinal nerve from sharp or thermal injury. The ilioinguinal nerve lies just below the aponeurosis of the external oblique and anterior to the cord. If injury to the nerve occurs, it is best divided and excised proximally, allowing the nerve to retract into the muscle or preperitoneal space.
- The medial and lateral external oblique flaps are then dissected free. Insertion of Weitlaner retractors below

FIG 1 ● Incision for repair of an inguinal hernia is centered over the palpable spermatic cord along a hairline crease (*AB*, lower line). Alternatively, incision is done parallel to the inguinal ligament (*AB*, upper line towards *C* representing the anterior superior iliac spine).

the flaps greatly facilitates exposure of the spermatic cord. The iliohypogastric nerve can be identified running between the internal and external oblique superior and medial to the spermatic cord. It exits the external oblique medial and superior to the external ring (**FIG 3**).

- The spermatic cord is mobilized and isolated in the inguinal canal at the pubic tubercle but not medial to it (**FIG 4**). This will reduce the chance of damaging the posterior inguinal canal and any collateral circulation to the testes. A Penrose drain is placed around the cord structures and can be used to provide traction during dissection of the cord.
- The spermatic cord is explored for evidence of an indirect hernia. The cremaster muscle fibers are not divided but are split parallel to the cord. The genital branch of the genitofemoral nerve lies posterior in the cord and is best preserved by splitting the cremasteric muscles. Inspection on the anterior medial aspect of the cord will identify an indirect hernia (**FIG 5**).
- The indirect hernia sac is then dissected from the cord structures using sharp and blunt dissection. The sac is dissected down to the internal inguinal ring and freed from surrounding structures. Care must be taken to avoid damage to the vas deferens, which is closely associated with the sac proximally. The hernia sac is then reduced through the internal ring. The sac can also be transected and ligated. If ligated, the sac should be opened to assure that there is not a sliding component to the hernia.

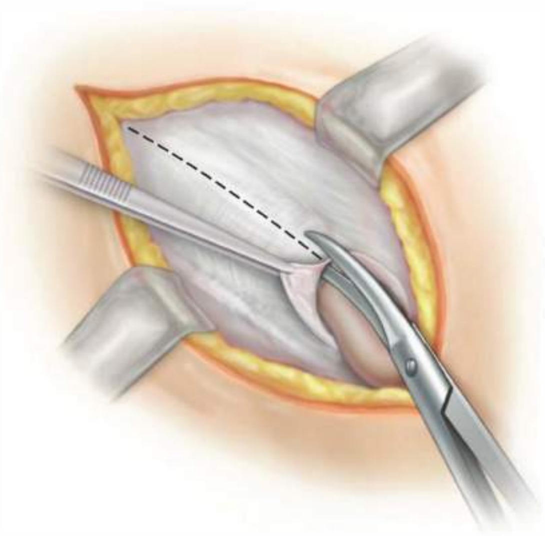


FIG 2 ● The external oblique is opened from the superficial ring toward the deep ring while avoiding injury to the ilioinguinal nerve.

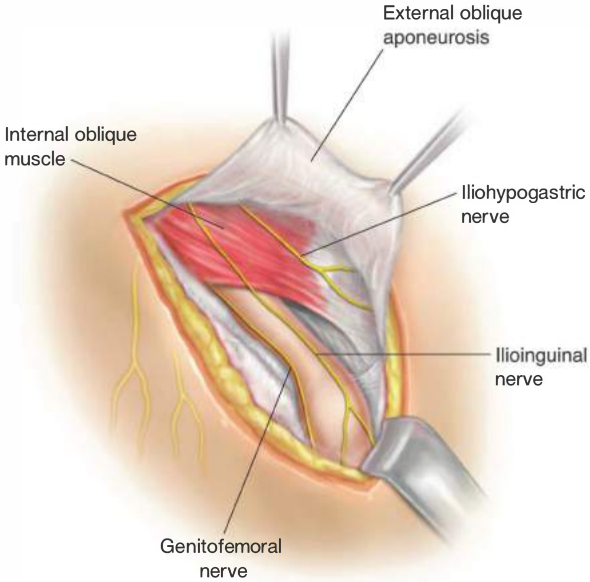

FIG 3 ● Location of the ilioinguinal and genitofemoral iliohypogastric nerves.

FIG 4 ● The isolation of the spermatic cord is done above the pubic tubercle to prevent injury to the inguinal floor.

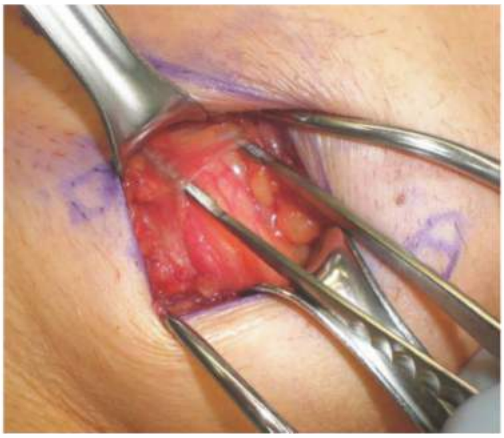

FIG 5 ● In very large inguinal hernias, it may be necessary to isolate the hernia sac prior to mobilization of the cord. Here, the cremasteric muscle fibers are split in order to access the indirect sac.

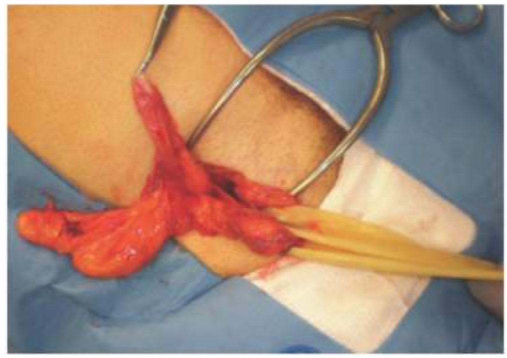

FIG 6 ● Cord lipomas, which can act as leads to a sac, should be resected in order to reduce the incidence of recurrent inguinal hernias. The hernia sac lies anteromedial to the cord and is separated from a large cord lipoma.

- In female patients, the round ligament can be completely transected, allowing for closure of the internal ring during repair.
- A cord "lipoma" is not a lipoma (suggesting growth of adipose tissue) but is rather extra or preperitoneal fat. It is usually associated with an indirect hernia but could also be present without an associated sac. Cord lipomas should be dissected free and resected as they can act as a lead point for a hernia sac (**FIG 6**).
- A sliding hernia is an indirect hernia that has part of its sac made up of retroperitoneal viscus. This could be bladder, cecum, or sigmoid colon. The safest method of managing a sliding hernia is a safe dissection of the indirect sac and simple reduction back to the preperitoneal space. The danger with high ligation of an indirect hernia sac, without proper inspection of the sac, is injury to the bowel within a sliding hernia.
- Following inspection of the spermatic cord and reduction of any indirect sac and excision of any preperitoneal fat, attention is turned to the posterior inguinal canal.
- Gentle retraction of the spermatic cord will facilitate exposure. Any defects or weakness of the floor should be assessed. In large direct hernias, a purse-string suture around the defect or imbrications of the floor with figure-of-eight sutures will reduce the direct bulge, allowing one to work unencumbered by it.

BASSINI REPAIR

- The Bassini repair is rarely performed today but remains the foundation for all hernia repairs. It is a primary tissue repair that consists of suturing of the transversus abdominis muscle, internal oblique muscle, and transversalis fascia medially to the inguinal ligament laterally.[1,2] It is an option to consider in cases where contamination is likely and the use of mesh becomes contraindicated.

Technique

- Bassini's original description of the procedure included resection of the cremasteric fibers. Although still advocated by some, it is not routinely done.
- After elevation and lateral retraction of the spermatic cord, the inguinal canal is carefully inspected for defects and weaknesses.
- The muscular and aponeurotic arch formed by the lower fibers of the transversus abdominis muscle and the internal oblique muscle is used to identify the medial edge of the repair.[3] In his repair, Bassini opened the transversalis fascia,[1] but most surgeons today would often omit this step and place the sutures between the aponeurotic arch and the deeper transversalis fascia to the inguinal ligament. If the anatomic layers are not clear, as in recurrent hernia surgery, opening the floor and clearly defining the anatomy will ensure the incorporation of the three anatomic layers medially: the internal oblique muscle, the transversus abdominis muscle, and the transversalis fascia.
- If the decision is made to open the inguinal canal floor, it is done by incising the transversalis fascia from the pubic tubercle to the internal inguinal ring. Care should be taken not to injure the inferior epigastric vessels, which are directly posterior to the transversalis fascia. Once the transversalis fascia is opened and the undersurface of the fascial flaps is exposed, one can easily identify the three anatomic layers described earlier and more carefully inspect the femoral canal.

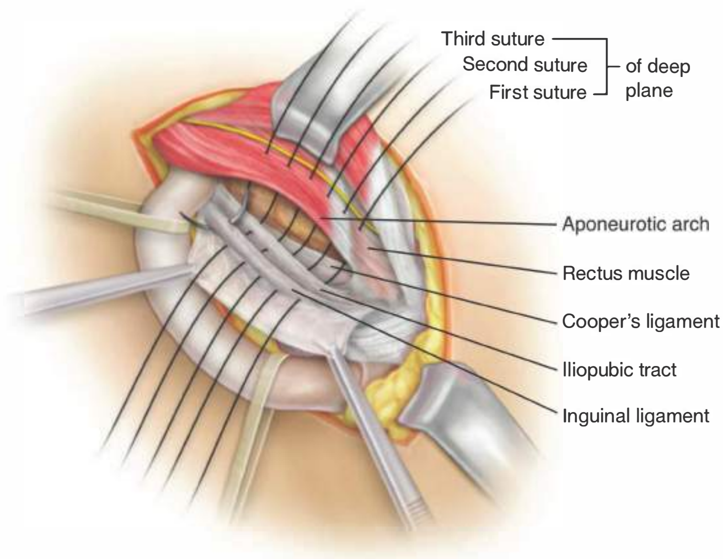

FIG 7 ● If the transversalis fascia is opened in a Bassini repair, the iliopubic tract may be incorporated into the lateral stitch.

- Once the muscular aponeurotic arch and the inguinal ligament are properly exposed and a femoral hernia is ruled out, single interrupted permanent polypropylene sutures are used to perform the repair. The first stitch is the most medial and should include the lateral edge of the rectus sheath if possible. It is placed from the rectus sheath and aponeurotic arch to the fascia overlying the pubic tubercle and not the inguinal ligament. This is an important technical point in order to reduce recurrence at the pubic tubercle, a common site.
- Subsequent sutures should be placed from the muscular aponeurotic arch, incorporating all three layers, to the inguinal ligament. Medially, each suture is taken 2 cm from the edge of the arch. Laterally, the suture should incorporate few fibers of inguinal ligament, thus avoiding the underlying femoral vessels. Different fibers should be incorporated with each suture to avoid tearing the inguinal ligament. Upon reaching the internal inguinal ring, the ring is tightened, allowing the tip of a forceps to pass through the ring and avoiding strangulation of the cord structures.
- If the transversalis fascia has been opened, the iliopubic tract will be identified. The medial stitch should first incorporate the iliopubic tract and then the inguinal ligament (**FIG 7**).
- The spermatic cord is returned to its normal anatomic position, lying superior to the newly reconstructed inguinal floor, and closure of the superficial layers is performed in the standard fashion (**FIG 8**).
- In order to decrease tissue tension after the repair is completed, a relaxing incision can be made vertically for few centimeters on the anterior rectus sheath parallel to the repair line. This will allow relaxation of the aponeurotic arch toward the inguinal ligament.

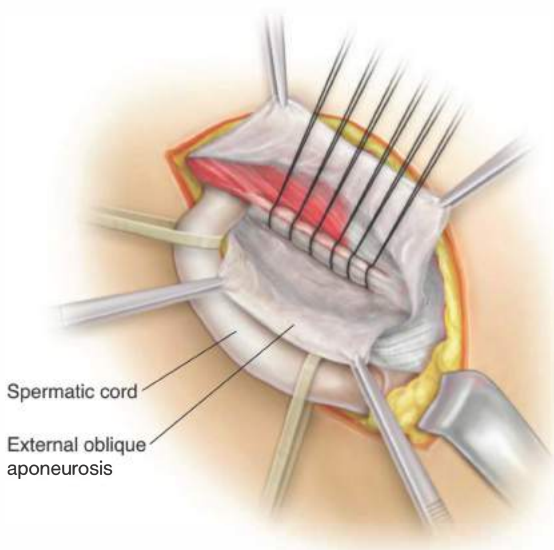

FIG 8 ● The Bassini repair is carried lateral until the internal ring is re-created.

SHOULDICE REPAIR

- After Bassini, the Shouldice repair is the most popular inguinal hernia tissue repair.[4] It continues to be used as the primary inguinal hernia repair in the Shouldice clinic and by others who trained at the Shouldice clinic.[5] It can also be used in situations where mesh is contraindicated such as in contaminated cases.

Technique

- Like the Bassini repair, the Shouldice repair starts with a resection of the cremasteric muscle as an important step of the repair. Although some still advocate this step, we do not think that this adds to the durability of repair and it potentially exposes the genital branch of the genitofemoral nerve to injury.
- The transversalis fascia is opened from the medial aspect of the internal ring to the fascial thickening of Cooper's ligament. This should be done with caution as the inferior epigastric vessels will be encountered just below the transversalis fascia. The opening of the transversalis fascia allows identification of all three layers of the posterior wall (transversalis abdominis muscle, internal oblique muscle, and transversalis fascia). Flaps of transversalis fascia are developed medially and laterally by carefully sweeping the underlying preperitoneal fat (**FIG 9**).
- Dissection of the lateral flap should be carried to Cooper's ligament to identify any femoral hernias and clearly expose the iliopubic tract. Although not done at our institution, incision of the superficial thigh fascia (cribriform fascia) to assess the femoral canal and to improve mobility of the external oblique has been reported and practiced at the Shouldice Hospital in Ontario.
- Originally performed with stainless steel wire, this repair is now performed with 2-0 Prolene sutures. A four-layer repair is performed using two continuous sutures. The first layer begins medially, anchoring the suture from the transversalis fascia to the fascia overlying the periosteum of the pubic tubercle. Leaving a portion of suture long enough to tie to, the stitch is run laterally, approximating the posterior rectus sheath to the iliopubic tract. When the rectus sheath can no longer be brought to the iliopubic tract without tension, the stitch is transitioned to the posterior transversalis fascia and is run superior and lateral until the internal ring is re-created (**FIG 10**).

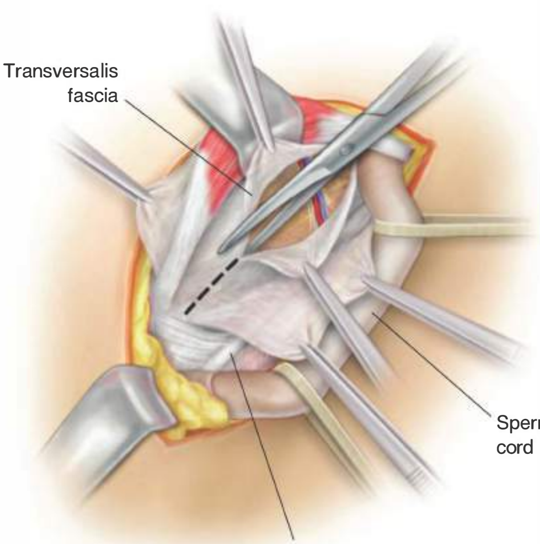

FIG 9 ● In a Shouldice repair, the transversalis fascia is opened. It is necessary to protect the inferior epigastric vessels from injury.

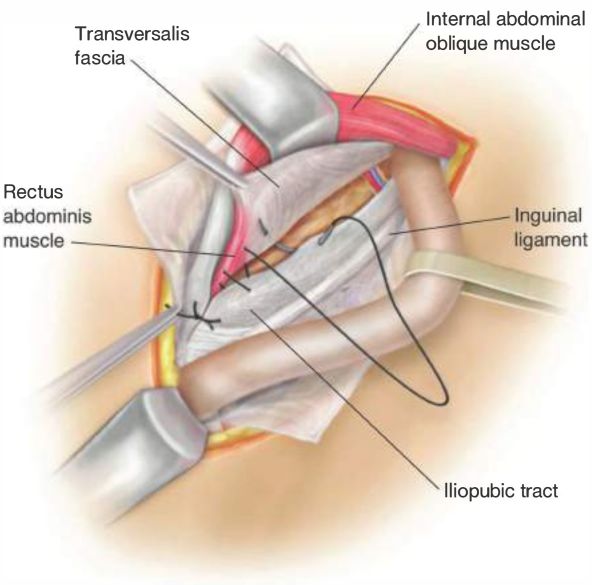

FIG 10 ● The first row in a Shouldice repair incorporates the aponeurotic arch by taking posterior bites through the transversalis fascia and approximating the arch to the ileopubic tract.

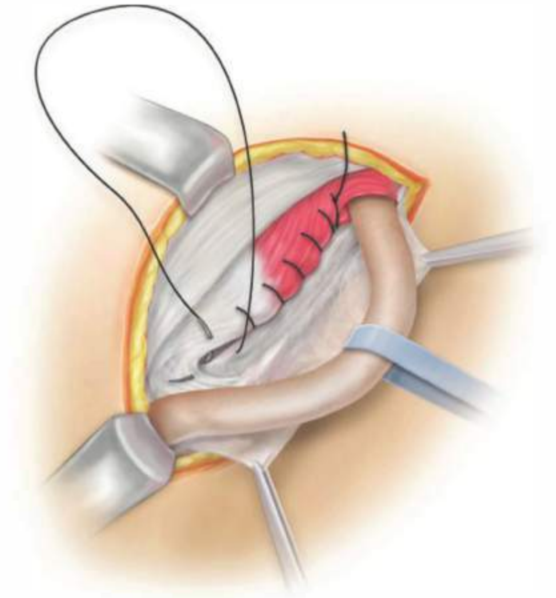

FIG 11 ● Starting at the internal ring, the third suture layer of a Shouldice repair incorporates the internal oblique and the underlying transversus abdominis medially, which are approximated to the undersurface of external oblique just above and parallel to the inguinal ligament laterally.

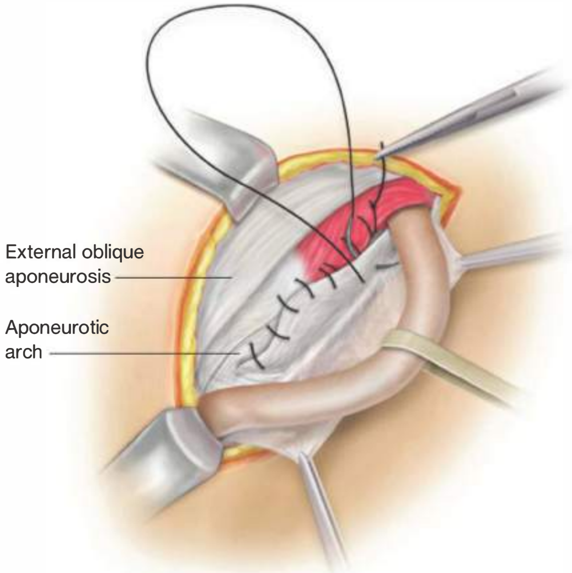

FIG 12 ● In the Shouldice repair, the fourth layer reapproximates the internal oblique to the undersurface of the external oblique, thus effectively reenforcing the third layer.

- The suture is then reversed, and a second layer is started using the same Prolene suture. The second layer approximates the three layers, including the free edge of the medial transversalis fascia, the internal oblique, and the transversus abdominis to the inguinal ligament. The second suture line is brought over the anchoring stitch, reinforcing the medial aspect of the repair, and tied to the anchoring stitch of the first suture line. This effectively imbricates the first layer.
- The third and fourth layers are also run continuously. Starting at the internal ring, the first stitch is blindly placed in the internal oblique and transversus abdominis and approximated to the posterior external oblique aponeurosis, just above the inguinal ligament. This is run medially, creating a ridge just superior and parallel to the inguinal ligament (**FIG 11**).
- The fourth layer is run back to the internal ring, buttressing the third layer, again taking the transversus abdominis and internal oblique, and approximating them to undersurface of the external oblique. The suture is tied to its tail (**FIG 12**).

THE MCVAY REPAIR OR COOPER'S LIGAMENT REPAIR

- The Cooper's ligament repair is a primary tissue repair that was described and advocated by Dr. McVay in 1958. Following 300 cadaver dissections, he noted that the internal oblique and external oblique do not attach to the inguinal ligament. Rather, they attach to the pubic bone at the location of Cooper's ligament attachment.[6] He concluded that repair of the inguinal defect would be anatomically correct if the three layers (internal oblique aponeurosis, transversus abdominis, and transversalis fascia) were sutured to Cooper's ligament and then transitioned to the inguinal ligament following closure of the femoral myopectineal defect.
- The repair provides closure of the femoral, indirect, and direct spaces and, as such, can be used to repair any hernia defect that may occur in the groin.[7] However, and due to the tension created by this repair, the risk of injury to the femoral vessels, and the risk of recurrence at the suture transition from Cooper's ligament to inguinal ligament, this repair is now mostly reserved for femoral hernias. The postoperative morbidity and mortality increase significantly in patients undergoing emergent repair, highlighting the importance of repairing femoral hernias in an elective setting.

Technique

- Following examination of the spermatic cord, the posterior wall of the inguinal canal is opened from the deep inguinal ring to the pubic tubercle. Care should be taken to avoid injury to the inferior epigastric vessels that lie just posterior to the transversalis fascia near the deep ring.[8]

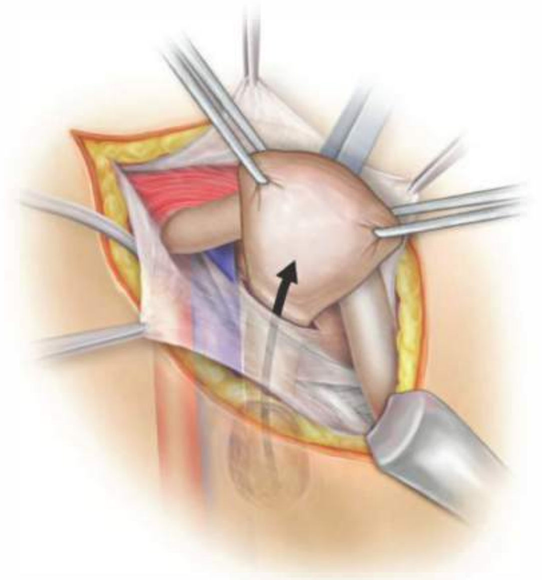

FIG 13 ● When addressing a femoral hernia, the sac is opened and its contents inspected prior to reduction of the sac.

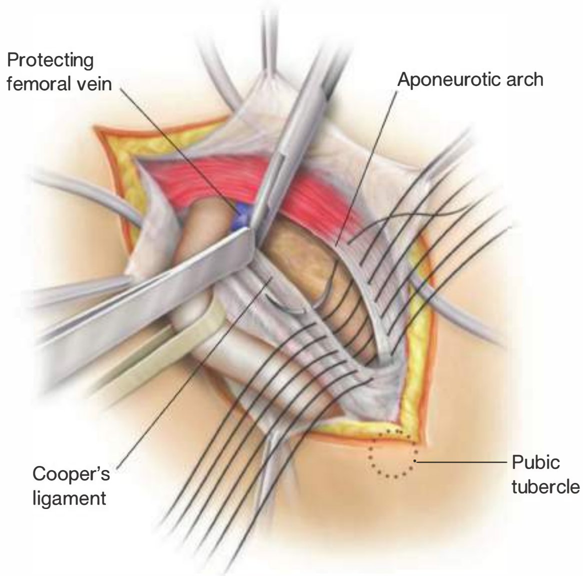

FIG 14 ● In a McVay repair, the transversus abdominis, internal oblique aponeurosis, and transversalis fascia are approximated to Cooper's ligament.

- This provides exposure to the preperitoneal space (space of Bogros), femoral vein, and femoral canal. The femoral hernia sac is found medial to the femoral vein and is reduced.
- If an incarcerated or strangulated femoral hernia cannot be reduced with traction from the preperitoneal space and pressure from below the femoral ring on the anterior thigh, the medial lacunar ligament can be incised to enlarge the femoral ring. If still unable to reduce the hernia, the inguinal ligament can be divided and then repaired following reduction of the hernia (**FIG 13**).
- Incising the posterior wall of the inguinal canal exposes the three aponeurotic layers: the internal oblique muscle and aponeurosis, the transversus abdominis muscle and aponeurosis, and the transversalis fascia. Starting medially, simple interrupted sutures are used to approximate the internal oblique aponeurosis, transversus abdominis muscle and aponeurosis, and the transversalis fascia to Cooper's ligament (**FIG 14**).
- A transition stitch is placed, incorporating the triple layer, Cooper's ligament, the femoral sheath at its medial aspect, and the inguinal ligament. If the femoral sheath cannot be identified, it may be omitted. The femoral sheath is intimately associated with the femoral vein. If bleeding occurs following a stitch in the femoral sheath, it should be immediately removed and direct pressure applied. It should not be tied as this would result in tearing of the femoral vein. If the stitch is placed too lateral on Cooper's ligament, the femoral vein can be compressed leading to thrombosis (**FIG 15**).
- The remainder of the inguinal floor is repaired by approximating the triple layer to the inguinal ligament and continuing, lateral, to the level of the internal ring (**FIG 16**).
- This repair creates tension. The distance to Cooper's ligament from the aponeurotic arch of the transversus and internal oblique can be up to 8 cm. To release this tension, a relaxing incision is required. This involves

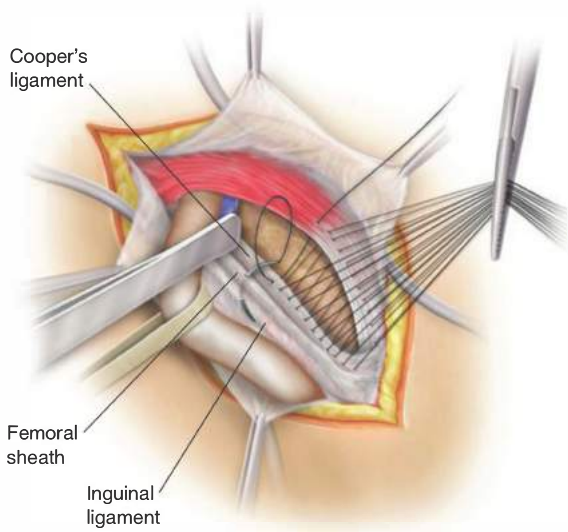

FIG 15 ● The transition stitch of a McVay repair incorporates Cooper's ligament, the medial femoral sheath, and the inguinal ligament. If bleeding occurs, the stitch is immediately removed and pressure should be held.

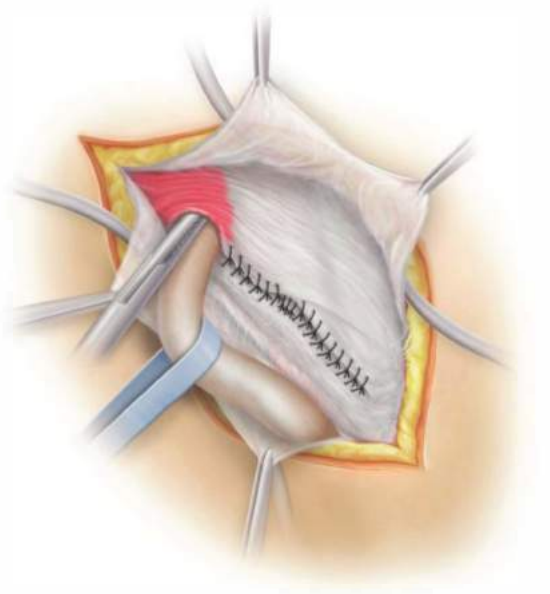

FIG 16 ● The final step of a McVay repair is the approximation of the aponeurotic arch to the inguinal ligament beyond the transition stitch in order to re-create the internal ring.

first exposing the rectus sheath behind the external oblique aponeurosis. Sparing the external oblique component, the rectus sheath is then incised vertically from the tubercle extending cephalad for approximately 6 cm along its lateral edge. The relaxing incision should be performed before the sutures are tied (**FIG 17**).

- The external oblique and skin are closed as described previously.
- Alternatively, a mesh can be used to perform a McVay repair. This is outlined in the "Lichtenstein Repair" section. Laterally, the mesh is sutured to Cooper's ligament up to the point where the femoral vein exits at which point the suture is transitioned to the inguinal ligament.

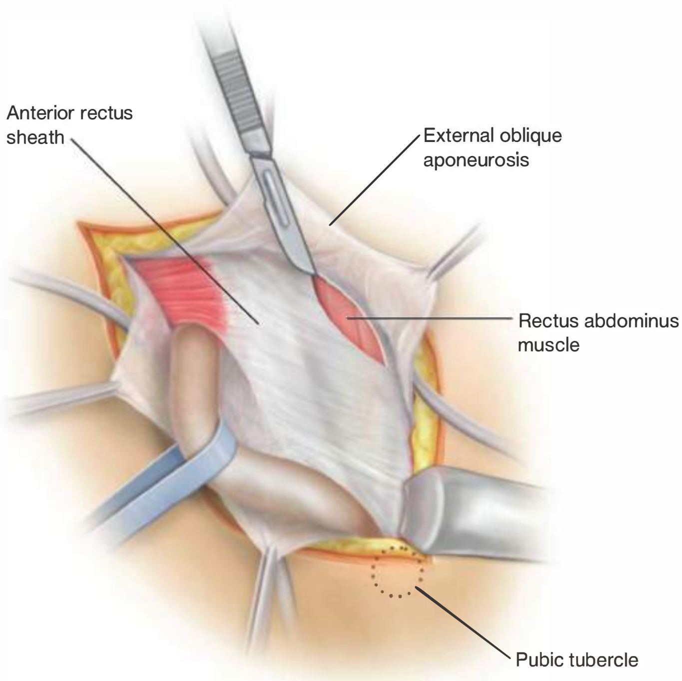

FIG 17 ● A relaxing incision performed on the rectus fascia will relax the repair and should be performed prior to tying the sutures.

LICHTENSTEIN REPAIR

- The use of prosthesis in inguinal herniorrhaphy is a dynamic field with frequent introduction of new devices, prosthesis, and modifications in technique. Although we cannot include all of them, a thorough understanding of the mechanics and anatomy will provide the foundation that new technology can build on. The Lichtenstein hernia repair uses prosthetic material to bridge the muscular aponeurotic defect in the inguinal region, creating an onlay mesh repair. It is an operation that is straightforward and is considered to be a "tension-free" repair.[9,10]

Technique

- After the spermatic cord has been evaluated for an indirect hernia, attention is then focused on the inguinal floor.
- Any protrusion of a direct hernia can be imbricated to flatten the posterior wall.
- A sheet of at least 3 in × 6 in mesh, preferably consisting of soft polypropylene, is fashioned so that the mesh overlaps the rectus by 1 to 2 cm and reaches the inguinal ligament. The mesh should extend underneath the external oblique past the deep inguinal ring. A slit is made on the proximal end of the mesh to accommodate the spermatic cord. This creates two tails of mesh. In females, if the round ligament is ligated, obviously, no slit is required (**FIG 18**).
- The mesh is first placed underneath the spermatic cord. With the medial aspect of the mesh overlying 2 to 3 cm on the pubic tubercle, a Prolene suture is used to anchor the mesh. The suture should include the fascia overlying the tubercle but not the periosteum. Overlapping the pubic tubercle with mesh is important as this is a frequent site of recurrence (**FIG 19**).
- The first stitch is run continuously from the patch to the inguinal ligament every 1 cm. This stitch is continued until it runs past the deep inguinal ring.
- The medial sutures are interrupted, attaching the patch to the rectus sheath, and eventually will include the internal oblique muscle or aponeurosis. These sutures should be spaced every 2 to 3 cm and are placed to prevent migration of the mesh. The mesh should wrinkle rather than lay flat in order to accommodate shrinking of the mesh and prevent tension.
- The tails are then sutured together around the spermatic cord and to the inguinal ligament, creating a new internal ring. The medial tail should lie anterior to the lateral tail. The tails are then tucked superiorly underneath the external oblique aponeurosis, extending at least 3 cm past the internal ring.
- The spermatic cord is then placed in its anatomic position lying on top of the mesh and the external oblique is closed over the cord recreating the external inguinal ring.

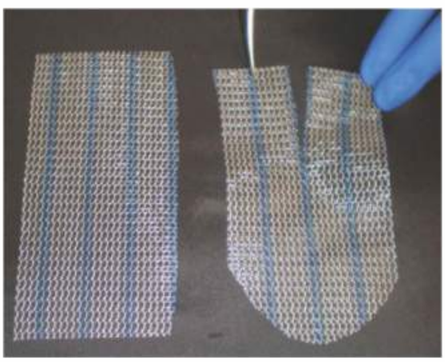

FIG 18 ● Mesh consisting of soft polypropylene fashioned from a 3 in × 6 in piece of mesh for a Lichtenstein repair.

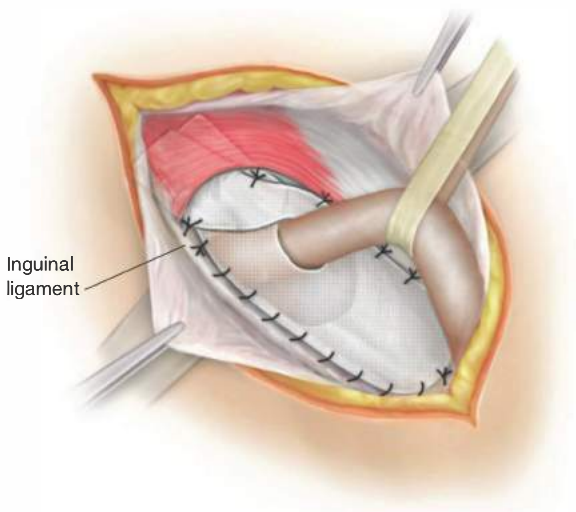

FIG 19 ● In a Lichtenstein repair, the mesh is used to bridge the aponeurotic arch medially and the inguinal ligament laterally.

PROLENE HERNIA SYSTEM AND PLUG SYSTEM

- First introduced in 1998, the Prolene Hernia System (PHS) is an evolution of both the Lichtenstein repair and the preperitoneal approach for inguinal hernia repair. Whereas the Lichtenstein approach uses solely an onlay mesh and the preperitoneal approach uses solely an underlay approach, the PHS uses both (**FIG 20**). It was designed to completely cover the myopectineal orifice, treating indirect, direct, and femoral defects.[11,12] Direct and indirect hernias may be approached differently and are presented separately.

Technique

Indirect hernia approach

- After examination of the spermatic cord and complete reduction of the indirect sac, the floor of the inguinal canal is examined. If the posterior wall of the inguinal

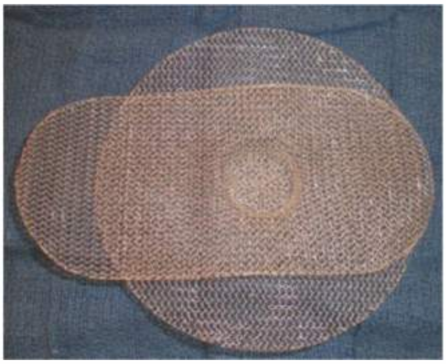

FIG 20 ● PHS mesh comes in three different sizes: small, medium, and extended. The extended mesh is shown in this photograph.

canal looks intact, the preperitoneal space is entered through the deep inguinal ring.

- The preperitoneal space is accessed through the internal ring. The preperitoneal fat and peritoneum are separated from the transversalis fascia. This is facilitated by introducing a Raytech sponge through the internal ring and doing this dissection bluntly with care not to injure the inferior epigastric vessels. The borders of dissection should be inferior to the pubic tubercle, below Cooper's ligament, and lateral to past the deep inguinal ring. This creates a space where the posterior leaflet of the mesh will cover all defects within the myopectineal orifice.

Direct hernia approach

- If the direct hernia is easily reduced, the method described earlier for developing the preperitoneal plane can be used. Alternatively, the preperitoneal space can be accessed directly through transversalis fascia. The transversalis fascia is entered, and the epigastric vessels are identified. A Raytech sponge may be used to create a space that extends below the pubic tubercle and inferior to Cooper's ligament. Because the dissection of the preperitoneal space was started more medially than the indirect method, it is important to ensure adequate dissection of the lateral defect. The space should be extended past the deep ring, ensuring adequate coverage of the lateral myopectineal orifice.

Insertion of Prolene hernia system mesh

- The PHS mesh consists of two leaflets connected in the middle (FIG 20). Proper preparation of the mesh is integral for proper deployment. The circular posterior leaflet is designed to sit in the preperitoneal space and the oblong oriented leaflet is designed to lie on top of transversalis fascia with the short end toward the pubic tubercle. Insertion of the posterior leaflet starts with folding the oblong portion of the mesh and holding it with a ring forceps close to the connector. This will allow easier insertion of the posterior leaflet of the mesh through either the internal ring or the opening made into transversalis fascia by pushing the mesh with the ring forceps (FIG 21).

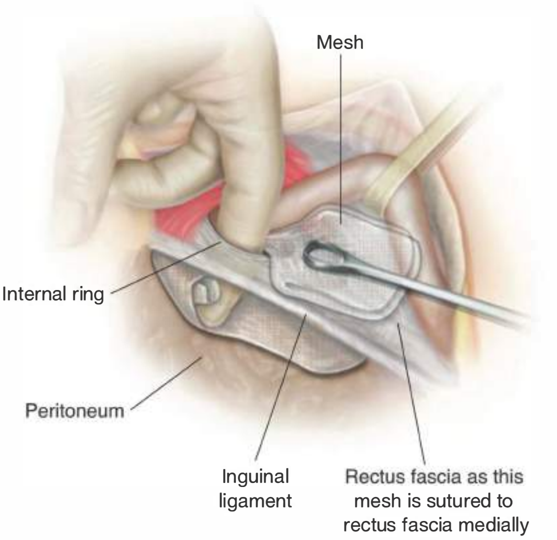

FIG 21 ● In a PHS repair, the posterior leaflet of the mesh sits below transversalis fascia above the peritoneum and reduced sac and covers the femoral defect. The anterior leaflet of the mesh lies above transversalis fascia and is sutured to the inguinal ligament laterally and rectus fascia medially.

- The mesh is then fully inserted through the internal ring, or the direct defect, creating an umbrella shape of the circular mesh. When gently pulling the anterior leaflet mesh out of the defect, the posterior leaflet should expand above the preperitoneal fat and peritoneum. This could be assisted by gently pushing the edges of the posterior mesh with the back of a forceps. It is important to ensure that this mesh expands to below the pubic tubercle, below Cooper's ligament, and lateral to cover the internal ring (FIG 22).

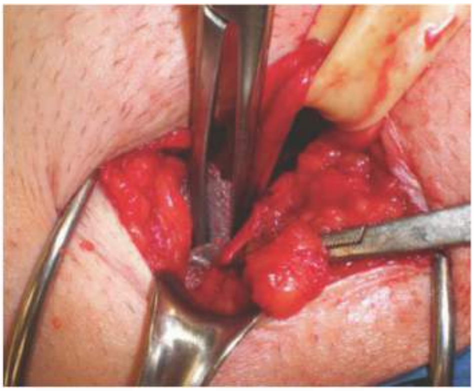

FIG 22 ● Insertion of the posterior leaflet of the PHS mesh.

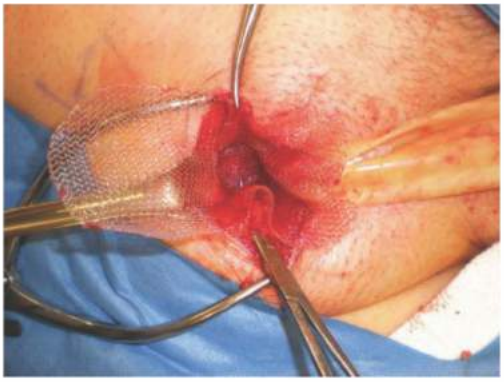

FIG 23 ● The PHS mesh with the posterior leaflet in place.

- The connector between the anterior and posterior leaflets is allowed to sit in the internal ring or within the opening made into transversalis fascia. This opening can be tightened around the connector with one or two interrupted 2-0 Prolene sutures (**FIG 23**).
- The anterior leaflet of the mesh is then treated as a Lichtenstein repair. A 2-cm overlap is allowed between the anterior leaflet of the mesh and the pubic tubercle. The anchoring suture to the fascia overlying the pubic tubercle is run between the lateral edge of the anterior leaflet and the inguinal ligament up to the level of the internal ring. The suture is then tied to itself. Medially, the mesh is anchored with few interrupted sutures to the rectus fascia.
- A slit is made in the lateral border of the anterior leaflet to accommodate the spermatic cord. The edges of the slit are then approximated to each other around the cord and to the inguinal ligament. The proximal portion of the anterior mesh is tucked flat underneath the external oblique aponeurosis proximally.
- The external oblique aponeurosis is closed in the standard fashion.

Closure

- The spermatic cord is placed in its normal anatomic position on the re-created floor of the inguinal canal.
- The external oblique aponeurosis is then closed with a continuous absorbable suture starting proximally and moving distally, thus re-creating the external inguinal ring. The ilioinguinal and iliohypogastric nerves should be protected during this step to avoid injury and entrapment (**FIG 24**).

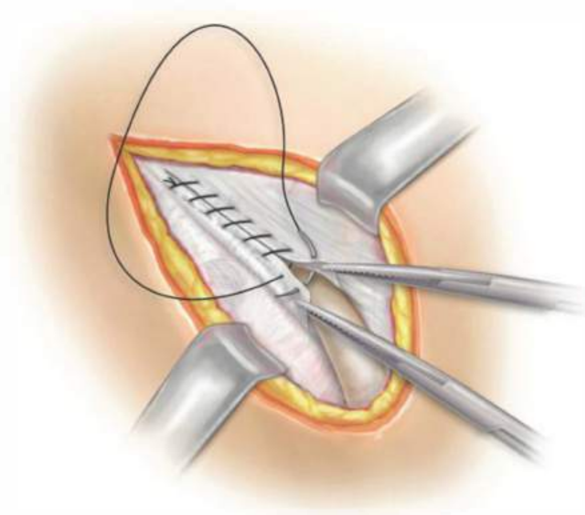

FIG 24 ● The external oblique is reapproximated, avoiding the ilioinguinal or iliohypogastric nerve.

- Several interrupted absorbable sutures are placed to reapproximate Scarpa's fascia and the subcutaneous tissue layers (**FIG 25**).
- The skin is closed with a running absorbable subcuticular suture and an occlusive dressing is placed.
- Following the removal of the sterile drapes, the testicles at the site of repair should be examined. If retracted, gentle traction on the scrotum will reduce the testicle back to its anatomic position. If left in the inguinal canal, it may permanently scar in thatlocation.

FIG 25 ● Scarpa's fascia is reapproximated.

PEARLS AND PITFALLS

Unable to locate the hernia defect	■ If unable to locate a direct or indirect hernia defect, then open the inguinal floor medial to the inferior epigastric vessels to examine the femoral canal.
Primary repair on tension	■ If the tissue quality is poor, use a mesh prosthesis to allow for a tension-free repair. ■ If mesh is contraindicated, a relaxing incision in the anterior rectus fascia should be performed. ■ Avoid use of mesh in contaminated operative fields.
Meticulous hemostasis	■ Patients undergoing hernia repair are often on antiplatelet or anticoagulants for cardiac disease. Meticulous hemostasis is important to prevent postoperative hematoma and wound complications.

POSTOPERATIVE CARE

- Most patients are discharged on the day of repair. Patients should void prior to leaving the recovery area.

OUTCOMES

- Elective repair of inguinal hernia is associated with low recurrence rates. Tension-free mesh repairs have the lowest rates of recurrence in adult populations. The overall recurrence rate is 3% to 5% for mesh repairs and 10% to 15% for suture repairs.[13]

COMPLICATIONS

- The rate of complications after inguinal herniorrhaphy has been reported between 15% and 50%.[14] When evaluating patient-centered outcomes, the overall rate of complications is consistently above 30%. The knowledge of complications, experience with handling them, and anticipation of adverse events can reduce their occurrence and guide informed consent.
- The most frequent complication is the development of a seroma. This has been reported to be between 2.4% and 13.6%. The introduction of bacteria by aspiration of a seroma has been widely reported. In the presence of mesh, any attempt at aspiration should be reserved to patients with suspected infection for diagnostic purposes. A seroma should spontaneously resolve over 6 to 8 weeks. Careful ligation of vessels, limiting dissection of soft tissue, and closure of dead spaces can reduce seroma formation.
- The risk of hematoma is reported between 5.5% and 6.5%. Meticulous hemostasis and knowledge of the vascular anatomy of the groin can reduce occurrence. Small hematomas may be treated conservatively; however, large hematomas inducing significant pain or creating tension will usually require evacuation.
- The risk of hemorrhage requiring transfusion is very rare. Intraoperative injury to major vessels is most likely to occur when suturing to Cooper's or the inguinal ligament. The femoral artery and vein are bordered by Cooper's ligament posteriorly and the inguinal ligament anteriorly. Superficial bites under direct vision should reduce the chance of injury. If an injury does occur, immediate removal of the suture, without tying the suture, and holding direct pressure usually prevent excessive bleeding. If the injury is not recognized, or the suture is tied resulting in a tear of the femoral vein, the inguinal ligament should be divided and a vascular repair should be initiated.
- The reported rate of surgical site infection in clean, nonemergent, inguinal hernia repairs ranges from 0.5% to 3%. This rate of infection is higher for recurrent and emergent hernia operations. Guiding principles of surgical infection prevention are applicable. In case of infection, early opening of the wound and appropriate antibiotic therapy for cellulitis and systemic symptoms will treat the majority of superficial infections. Deep surgical site infections, which are likely associated with foreign material such as suture or mesh, require fastidious wound care and drainage. Although usually not required in the early stages of therapy with early recognition and proper wound care, the mesh may ultimately need to be removed or debrided.
- Urinary retention is reported to occur in 0.2% to 2.42% of the cases. Urinary retention is lowest in patients having regional anesthesia compared to general anesthesia. For those patients with retention, bladder catheterization is required. Bladder injury should be rare. In the case of an iatrogenic injury during a sliding hernia, a two-layer repair of the bladder with absorbable suture will suffice.
- Ischemic orchitis occurs in less than 1% of the cases. It may progress to testicular atrophy, but its clinical course is difficult to predict. Ischemic orchitis is most often caused by thrombosis of the testicular vein within the spermatic cord but can also be from arterial injury. A Doppler ultrasound can evaluate blood supply to the testicles. Reducing cord dissection, preventing overly tight internal ring reconstruction, and transecting large distal hernia sacs and leaving them in situ can reduce this risk.
- Injury to the vas deferens should be rare. When an injury is recognized, and surgical repair is indicated, microsurgical repair with an operating microscope gives superior outcomes. However, repair may also be performed over a 0 Prolene suture, which is brought through the vas at a point distal to the reanastomosis. The Prolene is then brought through the skin and removed on day 3. If unable to repair an injured vas, ligation with permanent suture, and preventing further dissection of the vas, may allow reconstruction in the future. When the vas is injured by rough handling or becomes entrapped by mesh, painful ejaculation or dysejaculation can develop from the resulting partially obstructed lumen.

- Chronic or severe pain following inguinal herniorraphy is reported in 10% to 14% of the cases. It remains a perplexing and challenging problem. It is associated with preoperative chronic pain and with recurrent inguinal hernia repair.[15] The identification and protection of the ilioinguinal, genitofemoral, and iliohypogastric nerves are important in preventing nerve entrapment injuries. If a nerve is injured, it should be transected and ligated proximally, allowing it to retract into the muscle or preperitoneal space. Operative treatment with planned resection of the three nerves can improve or resolve the pain. However, a multidisciplinary pain team approach is imperative for optimal patient outcomes.

Chapter 2

Inguinal Hernia: Laparoscopic Approaches

Benjamin K. Poulose Michael D. Holzman Rebeccah B. Baucom

DEFINITION

- Inguinal hernias can be divided into indirect, direct, and femoral based on location.
- Inguinal hernia repair is one of the most common procedures performed by general surgeons in the United States, with 750,000 to 800,000 cases annually.
- Inguinal hernia will affect nearly 25% of men and less than 2% of women over their lifetime.
- The majority of femoral hernias occur in women (around 70%), but indirect inguinal hernias are still the most common type of hernia in women.
- Indirect inguinal hernias result from a patent processus vaginalis and are responsible for most pediatric inguinal hernias.

ANATOMY

- The myopectineal orifice includes both the inguinal and femoral regions. The inguinal ligament divides the myopectineal orifice into the inguinal region superiorly and the femoral region inferiorly.
- The boundaries of the inguinal canal are as follows: anteriorly, the aponeurosis of the external oblique and the internal oblique muscle laterally; posteriorly, the transversalis fascia and the transversus abdominis muscle; superiorly, the arch formed by the internal oblique muscle; inferiorly, the inguinal ligament; medially, the aponeurosis of the external oblique and its insertion on the pubic symphysis (**FIG 1**).
- An indirect hernia passes with the spermatic cord (or round ligament, in women) through the inguinal canal via the internal and external rings.
- A direct hernia passes through the posterior wall of the canal (i.e., the transversalis fascia and transversus abdominis), medial to the inferior epigastric vessels, above the inguinal ligament. This region is considered Hesselbach's triangle.
- Femoral hernias pass through the femoral canal, medial to the femoral vessels, inferior to the inguinal ligament.
- The nerves at risk for traction injury in most anterior inguinal hernia repairs include the ilioinguinal nerve, iliohypogastric nerve, and the genital and femoral branches of the genitofemoral nerve.

PATHOGENESIS

- Indirect hernias occur as a result of a patent processus vaginalis and are congenital. The hernia involves a peritoneal sac passing through the inguinal canal alongside the spermatic cord or round ligament.

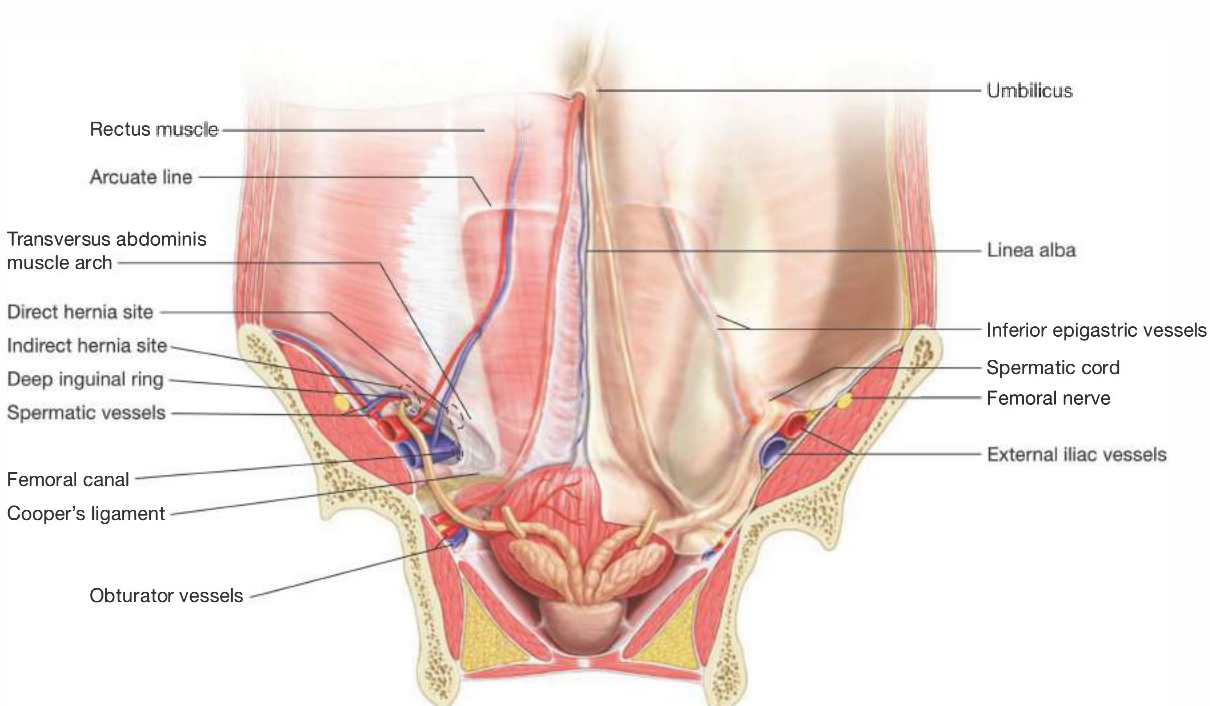

FIG 1 ● Anatomy of the inguinal canal, intraabdominal view.

- Direct hernias tend to occur secondary to increased intraabdominal pressure. Predisposing factors include chronic cough, constipation, straining and difficulty with urination, obesity, and ascites.

NATURAL HISTORY

- The natural history of untreated inguinal hernias is not fully known, although many believe that progression is inevitable. Traditionally, repair of all inguinal hernias has been recommended to prevent progression, hernia symptoms, and strangulation.
- Watchful waiting is a reasonable strategy especially in men with minimal symptoms, as the rate of acute hernia incarceration with bowel obstruction, strangulation of intraabdominal contents, or both is less than 2 per 1,000 patient-years.[1]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients present with a groin bulge as their primary complaint. Over time, this tends to increase and may be associated with pain or discomfort in the groin, thigh, or testicle.
- Some are asymptomatic and detected on physical exam by a primary care physician.
- Significant pain at initial presentation, particularly if not accompanied by an obvious bulge, may not be due to hernia. Often, these patients will have chronic pain even after groin exploration.
- Patients who develop progressive symptoms with increasing hernia size tend to have the best outcomes after surgical repair with significant improvement in pain.
- Physical examination is the best way to diagnose inguinal hernias, and both sides should be evaluated for the presence of a hernia. The patient should be examined supine and upright, with a finger palpating the external ring while the patient performs a Valsalva maneuver. A bulge detected below the inguinal ligament in the medial thigh suggests a femoral hernia.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Adjunctive imaging studies are rarely required for diagnosis of inguinal hernia.
- Ultrasound may be helpful but is dependent largely on the skill of the sonographer. Valsalva maneuvers should be employed, and the exam should be performed with the patient supine and upright.
- Some inguinal hernias can be seen on computed tomography (CT), although small studies suggest that the sensitivity and specificity are only 85% and 65% to 85%, respectively. Therefore, if a hernia is not visualized on CT, the diagnosis is not ruled out.
- The role of magnetic resonance imaging (MRI) with and without Valsalva is unclear but may be available at some centers. MRI is most useful in differentiating sports-related injuries from true inguinal hernias.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis for a groin bulge includes hernia, lymphadenopathy, hydrocele, abscess, hematoma, femoral artery aneurysm, or undescended testicle.

NONOPERATIVE MANAGEMENT

- Patients with minimally symptomatic hernias may be candidates for nonoperative management or watchful waiting.[1] This approach entails follow-up after 6 months and annually by a care provider, along with instructions regarding the signs and symptoms of acute incarceration or strangulation.
- Delay of repair for 6 months has been shown not to have an adverse effect on surgical outcomes.[2]
- Patients who experience significant pain with activity, those who have prostatism or constipation, and those with overall good health status are likely to benefit most from surgical repair.[3]
- After 2 years, about 25% of patients who are minimally symptomatic will develop worsening symptoms and request surgical repair.[1]

SURGICAL MANAGEMENT

- Techniques for the laparoscopic management of inguinal hernia include the transabdominal properitoneal approach (TAPP) and the totally extraperitoneal (TEP) technique.
- Laparoscopic repair is especially useful for recurrent or bilateral inguinal hernias.
- A recent meta-analysis comparing open and laparoscopic repairs (TAPP and TEP) for primary unilateral hernias demonstrated that both laparoscopic approaches resulted in less chronic groin pain and numbness compared to open repair. TAPP and open repairs had a lower risk of recurrence compared to TEP. TAPP was associated with a higher risk of perioperative complications compared to open repair.[4]

Preoperative Planning

- General anesthesia is usually required for laparoscopic repairs, whereas open repairs can be performed with the use of local anesthesia.
- Immediately prior to surgery, the patient should be instructed to void or a Foley catheter should be placed. Most patients can adequately void preoperatively, precluding the need for a urinary catheter, which may increase the risk of urinary retention as well as infection.
- For recurrent hernias, it is imperative that the surgeon review previous operative reports. In general, the approach used to repair a recurrence should use fresh surgical planes to facilitate the repair. For a previous open repair that has recurred, a laparoscopic approach is usually favored. If a mesh plug has been used, a TAPP approach may be significantly easier than TEP due to the high chance of peritoneal violation and need to debulk the plug.
- For a previous laparoscopic repair that has recurred, an open approach may be easier to perform. Given the variety of laparoscopic inguinal hernia techniques used, many have found that repeat laparoscopic repair of a recurrence is possible in experienced hands.
- Caution should be taken in patients with previous prostatectomy or entrance into the space of Retzius, which can make laparoscopic repair much more challenging. In these cases, serious consideration should be given to an anterior

approach. As with repairing laparoscopic inguinal hernia repair recurrences, a laparoscopic approach can be attempted, if deemed advantageous, by an experienced laparoscopic hernia surgeon.

Positioning

- The patient is positioned supine with arms tucked and legs secured in order to prevent slippage with changes in table position during the procedure.
- The surgeon stands on the contralateral side from the hernia being repaired.

LAPAROSCOPIC TRANSABDOMINAL PROPERITONEAL INGUINAL HERNIA REPAIR

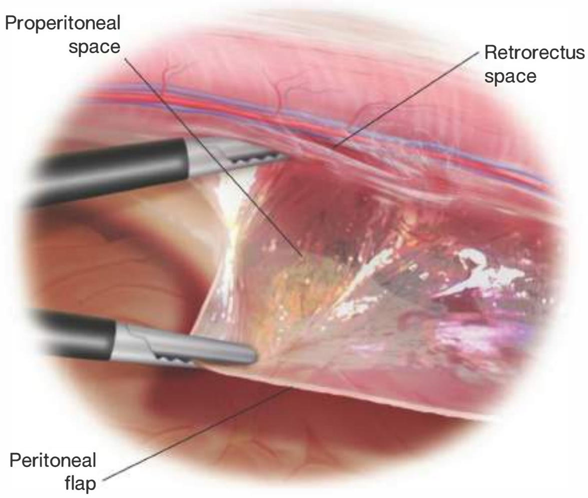
Establishment of Pneumoperitoneum and Port Placement

- The first trocar is placed at the level of the umbilicus, typically beginning in the umbilicus and extending the incision inferiorly. Pneumoperitoneum can be established either with a Veress needle or by placing a 12-mm Hasson port.
- Two 5-mm ports are then placed lateral to the rectus sheath approximately 1 to 2 cm above the level of the umbilicus (**FIG 2**). A 5-mm 30-degree laparoscopic is used and is placed in the port ipsilateral to the hernia. The surgeon uses the umbilical port and port contralateral to the hernia.
- The patient is placed in the Trendelenburg position displacing the pelvic viscera cephalad.

Peritoneal Incision

- The inferior epigastric vessels are identified on the side of the hernia. During a TAPP, if there is a high suspicion for inguinal hernia by history and physical examination, dissection commences on the symptomatic side even if no obvious hernia is seen from the intraperitoneal view. Note that chronically incarcerated properitoneal fat may occupy the hernia defect precluding clear visualization of the defect itself.
- The peritoneum is incised with Metzenbaum scissors beginning lateral to the inferior epigastric vessels (**FIG 3**). This dissection can typically be done without the use of electrosurgery. The correct plane of dissection in the TAPP repair is the true properitoneal plane. It is extremely easy to inadvertently dissect the retrorectus plane with this approach (**FIG 3**). Should this occur, dissection can proceed (similar to the TEP approach) but dissection into the retrorectus space without the benefit of balloon tamponade can incur increased blood loss. Dissection during TAPP should proceed between the peritoneum and transversalis fascia. The peritoneal flap is mobilized high up on the lower abdominal wall, extending laterally to the anterior superior iliac spine and medially to the ipsilateral medial umbilical fold.
- Care should be taken to avoid injury to the inferior epigastric vessels which lie posterior to the rectus muscles in the retrorectus plane. Maintaining a plane of dissection in the true properitoneal space minimizes the risk of injury to these vessels.

FIG 2 ● Port placement. **A.** For TAPP, ports are placed at the umbilicus and lateral to the linea semilunaris at the level of the umbilicus. **B.** TEP ports are placed in the midline at the umbilicus, 2 cm above the symphysis pubis, and the final in between the first two, at least 4 cm cranial to the second port.



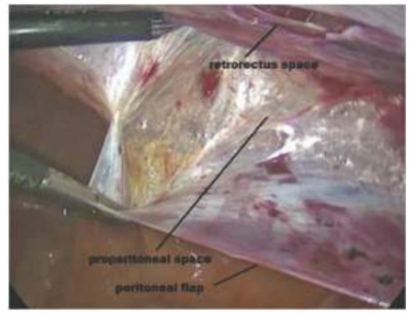


FIG 3 ● Creation of the peritoneal flap during TAPP. Beginning lateral to the epigastric vessels, the peritoneum is incised and the properitoneal space dissected, creating a flap. The retrorectus space, seen at the top of this figure, may be inadvertently entered, resulting in increased bleeding.

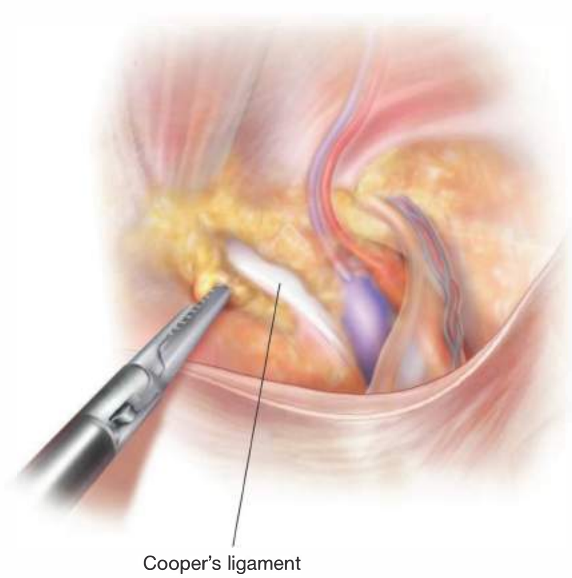
Dissection of the Properitoneal Plane

- Beginning laterally, retract the peritoneum medially, and dissect the properitoneal plane, leaving the fat against the abdominal wall to preserve small nerves and vessels.
- The inferior epigastric vessels are again identified and the properitoneal plane is developed medial to these vessels toward Cooper's ligament. During the initial learning curve of this procedure, the overwhelming tendency is to dissect too far medially and posteriorly into the region of the bladder. Confirmation of the trajectory of dissection toward Cooper's ligament can be obtained by a brief intraperitoneal view. Once Cooper's ligament has been identified, it is exposed for about 2 cm anticipating fixation at its superior aspect (**FIG 4**). A direct sac usually obscures Cooper's ligament until the sac is reduced entirely into the true pelvis.
- After Cooper's ligament has been identified, a dissection lateral to the inferior epigastric vessels is commenced attempting to dissect the properitoneal fatty tissue anteriorly while maintaining integrity of the peritoneum. This dissection is taken to the level of the iliopubic tract.

Reduction of the Hernia

- At this point, attention is turned to an indirect hernia sac if present, and it is dissected away from the cord structures. The peritoneum is now separated from the transversalis fascia overlying the inferior epigastric vessels. As the indirect hernia sac is approached, gentle but persistent cephalad traction is applied to reduce the hernia sac. Typically, if it can be done safely, the entire sac is reduced into the true pelvis. As the sac is reduced, the medial vas deferens and lateral testicular vessels are identified. In women, the round ligament is identified. The sac is dissected away from these structures. In women, the round ligament can often be separated from the peritoneum.



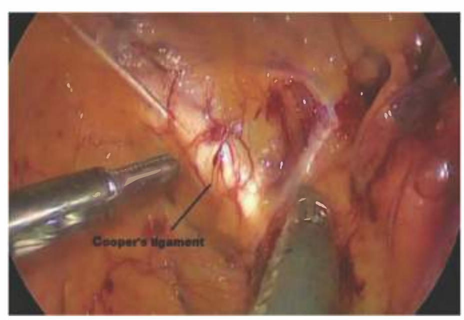


FIG 4 ● Cooper's ligament. Dissection proceeds medially toward Cooper's ligament. Once identified, approximately 2 cm of the superior aspect of Cooper's ligament is cleared for mesh fixation.

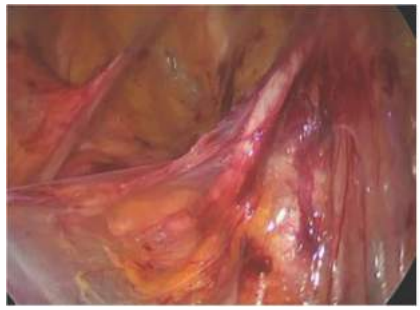

FIG 5 ● Dissection of peritoneum off posterior structures. Once the hernia is reduced, the peritoneum is separated from the cord structures and iliac vessels to allow adequate exposure of the myopectineal orifice. This allows room for generous mesh overlap and is a key step in preventing hernia recurrence.

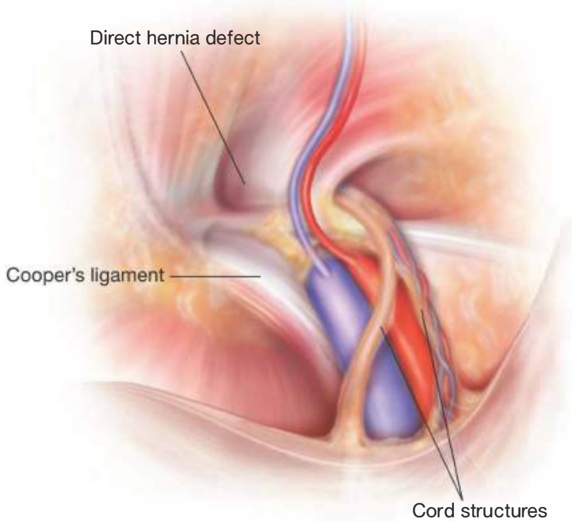
Should this not be possible, efforts are made to divide the peritoneum along the axis of the round ligament, reapproximating the peritoneum after an adequate dissection has been performed. Division of the round ligament should be avoided if possible to minimize risk of pain from transection of the genital branch of the genitofemoral nerve. However, if transection is necessary to perform an adequate hernia repair, the round ligament can be divided between clips or ligatures.

- Once the hernia is reduced, the peritoneum is separated from the iliac vessels, vas, and testicular vessels posteriorly toward the umbilicus (**FIG 5**). This ensures a generous exposure of the entire myopectineal orifice. In addition, separation of the cord structures from the peritoneum ensures the ability to place a solid piece of mesh across the myopectineal orifice without the need for keyhole creation (**FIG 6**). Should a keyhole configuration be employed, the dissection proceeds caudally to the vas and testicular vessels, beginning at the level of the internal ring. Care should be taken to dissect well posteriorly to allow mesh overlap

Mesh Placement and Fixation

- An appropriately sized (usually 14 cm [transverse axis] × 12 cm [craniocaudal axis]), lightweight, macroporous mesh should be chosen which will cover the hernia defect as well as the entire myopectineal orifice.



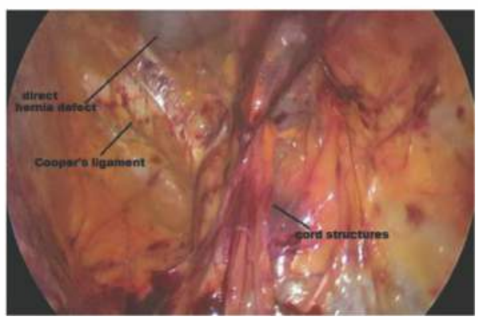


FIG 6 ● Completed dissection. The hernia has been reduced and dissection completed prior to mesh placement. Note the direct hernia defect; Cooper's ligament, which has been cleared superiorly; and the cord structures.

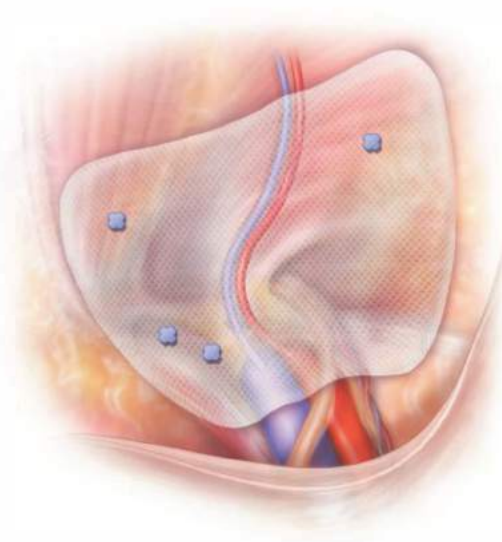

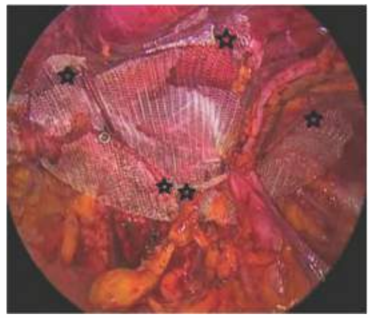

FIG 7 ● Mesh fixation. The mesh can be either a solid piece or one with a keyhole and should be taut. Fixation tacks are used sparingly: two above Cooper's ligament one in the posterior rectus sheath, and one laterally, well above the iliopubic tract.

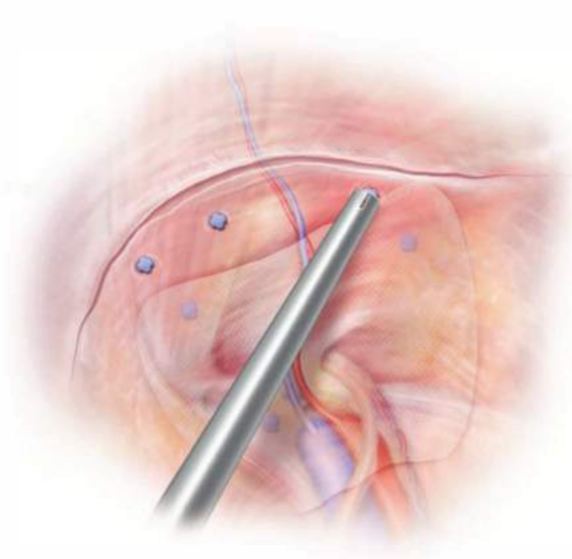
- The mesh is then grasped medially and inserted into the 12-mm port, aiming toward Cooper's ligament. A Maryland dissector can be used to position the lateral and superior aspect of the mesh.
- Prior to fixation, precise placement of the mesh over the entire myopectineal orifice is ensured. Care is taken to ensure at least 3 cm of overlap over any hernia defect.
- Minimal fixation is used to prevent migration of the mesh (**FIG 7**). For indirect hernias, two tacks are placed just above Cooper's ligament, one high medially over the posterior aspect of the rectus sheath, and one high laterally well above the iliopubic tract. For direct defects, some additional fixation is usually necessary to avoid early migration and recurrence. In general, no tacks should be placed below Cooper's ligament or below the iliopubic tract. Counterpressure should be used to feel the tip of the tacking device on all tacks except those placed adjacent to Cooper's ligament. There is little data to support any one type of fixation (absorbable vs. permanent). Initial results suggest that avoiding mechanical fixation with the use of sealants or glues may be feasible, especially with a TEP approach; however more conclusive information is needed.[5,6]

Closing the Peritoneal Flap and Incisions

- The peritoneal flap can usually be closed with tack fixation, taking care to avoid injury to the inferior epigastric vessels (**FIG 8**). All attempts are made to minimize



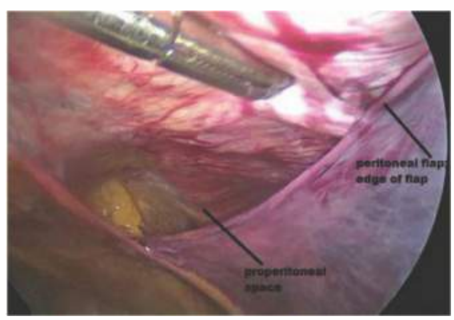


FIG 8 ● Peritoneal flap closure for TAPP. The peritoneal flap is closed with sequential tacks.

exposure of dissected tissue and mesh to the peritoneal cavity. During flap closure, care is taken to ensure that the posterior aspect of the mesh does not buckle or twist, which can act as a lead point for recurrence.

- After desufflation, trocars are removed under direct visualization. The 12-mm port site is closed with 0 Vicryl, and skin is approximated with 4-0 Monocryl sutures.

TOTALLY EXTRAPERITONEAL INGUINAL HERNIA REPAIR

Establishment of the Operative (Properitoneal) Space and Port Placement

- A 1- to 2-cm longitudinal skin incision is made inferior to the umbilicus and the subcutaneous tissues are divided. The anterior rectus sheath is identified just lateral to linea alba on the ipsilateral side of the hernia. The anterior rectus sheath is then divided using electrosurgery. The rectus muscle is retracted laterally and the retrorectus space is entered. An endoscopic balloon dissector is advanced immediately beneath the rectus muscle and advanced to the pubic symphysis (**FIG 9**). A 10-mm 0-degree laparoscope is placed into the lumen of the balloon and it is fully inflated and held in position for 2 minutes to achieve hemostasis. The balloon is removed and either a Hasson cannula (with stay sutures) or a balloon-tipped cannula is inserted into the extraperitoneal space. Usually, action of the balloon dissector dissects both the retrorectus space and the properitoneal space. This space is insufflated to a pressure of 12 mmHg and a 10-mm 30-degree laparoscope is used for visualization. The patient is placed in Trendelenburg position. Two 5-mm operating ports are inserted under direct visualization in the lower midline. The lowest is placed 2 cm above the pubic symphysis. The second port is placed at least 4 cm cranial from the first port (**FIG 2**). Use of a finder needle with local anesthetic can assist in placement of these ports.

Dissection of the Properitoneal Plane, Reduction of the Hernia, Mesh Placement, and Fixation

- These steps proceed similarly to that described for the TAPP approach discussed previously.

Desufflation

- After adequate hemostasis has been assured and mesh placement deemed appropriate, the 5-mm operating ports are removed and the insufflation removed. The peritoneum should be visualized closing the dissected space. Care should be taken to ensure that the mesh remains flat against the abdominal wall without folding, buckling, or twisting. The Hasson or balloon-tipped cannula is then removed and the anterior rectus sheath closed.

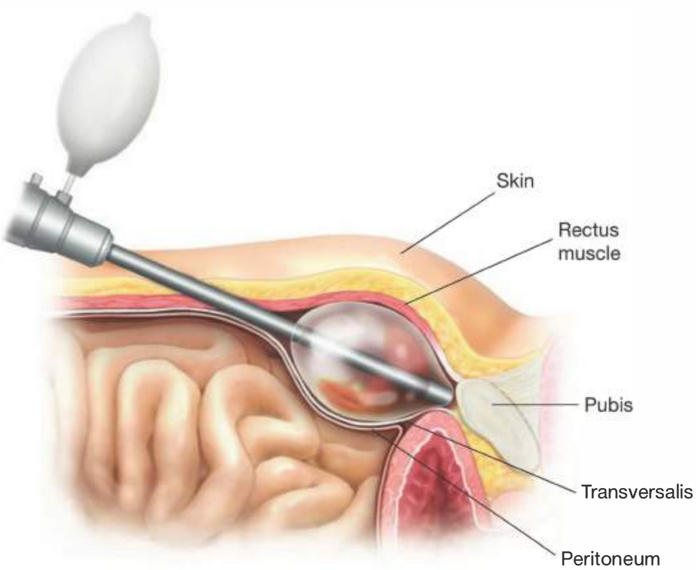

FIG 9 ● Endoscopic balloon dissector, TEP. The balloon dissector is inserted into the retrorectus space, advanced toward the pubic symphysis, and fully insufflated for 2 minutes to allow adequate hemostasis.

PEARLS AND PITFALLS

TEP—entrance into properitoneal space	■ Entrance into the properitoneal space during TEP should be performed at least 5-mm below the umbilicus as the peritoneum and transversalis fascia are fused to the umbilical stalk, preventing easy mobilization. Typically, the retrorectus space is first entered, with the balloon dissector expanding this plane. The dissector usually also expands the properitoneal plane. In some instances, the transversalis fascia may remain intact, requiring laparoscopic mobilization into the true properitoneal space.
TAPP—properitoneal dissection	■ Care is taken to enter the plane between the peritoneum and the transversalis fascia. If the transversalis fascia is inadvertently entered, attempts should be made to get back into the properitoneal plane. If this cannot be done, the dissection can proceed in the retrorectus space anterior to the transversalis fascia. This is usually a less hemostatic plane; care should be taken to avoid excessive bleeding.
TEP—avoidance of pneumoperitoneum	■ Maintaining integrity of the peritoneum and avoidance of pneumoperitoneum facilitates exposure with the TEP approach. Tears in the peritoneum should be repaired with either clips, absorbable loop ligatures, or sutures. A Veress needle can be placed into the peritoneal cavity in the upper abdomen to vent the pneumoperitoneum and reestablish visualization in the extraperitoneal space. Inability to control the peritoneal gas leak may necessitate conversion to a TAPP approach.
TAPP/TEP—avoidance of injury to aberrant obturator vessels and corona mortis venous plexus	■ Dissection of Cooper's ligament often exposes aberrant obturator vessels and the corona mortis venous plexus. Great care should be taken to avoid injury to these structures as hemostasis can be challenging. Additionally, these structures should be taken into consideration when mesh fixation is used adjacent to Cooper's ligament.
TAPP/TEP—large direct hernia sac	■ With large direct sacs, identification of Cooper's ligament can often be challenging. When a sizable direct hernia is encountered, the sac is reduced early in the dissection to identify Cooper's ligament.
TAPP—large indirect hernia sac	■ Reduction of a large indirect hernia sac is one of the most challenging maneuvers in laparoscopic inguinal hernia repair. Often, medial and lateral retraction of the sac can help facilitate dissection of the sac away from the cord structures and inferior epigastric vessels. Manual reduction (externally with fingers) can sometimes help dissect the entire sac back into the true pelvis. If complete reduction is unable to be achieved, transection of the sac can be performed. The testicular vessels and vas are clearly identified and separated from the tenacious sac. Laparoscopic clips are used to clip the proximal aspect of the sac and the sac is divided, allowing the open distal aspect of the sac to "parachute" back into the inguinal canal. The sac can then be mobilized in the standard fashion to facilitate mesh placement.

POSTOPERATIVE CARE

- In addition to the typical postoperative monitoring for hydration and adequate analgesia, it is important that the patient be monitored for urinary retention in the immediate postoperative period and a Foley catheter inserted, if needed.
- Diet can be advanced quickly within 12 hours postoperatively. Ambulation can resume once appropriately recovered from anesthesia. Patients are typically ready for discharge on the day of surgery.
- Constipation and straining should be avoided postoperatively. Light activity can be resumed within 1 day of surgery. Patients should be advised to avoid strenuous activity for at least 3 to 4 weeks postoperatively.

OUTCOMES

- Recurrence after TAPP appears to be equivalent to open repair, and TEP has a slightly higher risk of recurrence.[4]
- Overall, TEP and TAPP have been associated with less chronic pain than open repair.[4]

COMPLICATIONS

- Complications after inguinal hernia repair (whether open or laparoscopic) include surgical site infection, seroma or hematoma, mesh infection (all <1%), hernia recurrence (2% to 5% for primary inguinal hernia; around 10% for recurrent hernia), and chronic groin pain (around 0.5%).
- Men with bilateral hernias should be counseled regarding the slightly increased risk of decreased fertility associated with bilateral laparoscopic inguinal hernia repairs.[7]
- TAPP has been associated with an increased risk of intraabdominal and vascular injury, although this risk is low (<1%).
- Laparoscopic repair (TAPP and TEP) carries the risk of port site hernias (approximately 0.1% to 2%).

Chapter 3

Incisional Hernia: Open Approaches

Mark D. Sawyer Michael G. Sarr

DEFINITION

- An incisional hernia is a defect in the musculoaponeurotic layer of the abdominal wall occurring at the site of a prior incision. The sine qua non of any hernia is the presence of a fascial defect. Typically, a hernia is a protrusion of intraperitoneal abdominal contents through the defect, usually contained within a "sac" of peritoneum and covered with skin and perhaps subcutaneous fat. In certain circumstances such as the sequelae of an open abdomen, there may not be a true peritoneal sac nor a cutaneous cover.
- There are certain circumstances in which a pseudohernia can mimic a true hernia. Flank incisions can denervate the lateral abdominal wall, causing flaccidity and an outward bulge appearing to be a "hernia," even though the musculoaponeurotic layers are intact. Diastasis of the rectus muscles will also lead to a bulge especially on straining, but in both these circumstances, there is no actual defect in this musculoaponeurotic layer.
- Incisional hernias are classified as **incarcerated** when the contents of the hernia sac cannot be reduced back into the confines of the peritoneal cavity and **strangulated** when incarceration leads to vascular compromise and ischemia of the incarcerated contents. Strangulated contents may be salvageable if reduction can be accomplished prior to irreversible ischemia and necrosis.
- Incisional herniorrhaphies are designed to obliterate the musculoaponeurotic defect and restore continuity to the abdominal wall. This process may be accomplished in a number of ways but fall into three basic categories: (1) A primary repair with reapposition of the separated musculoaponeurotic edges is the simplest type of repair; (2) synthetic and biologic prostheses to restore abdominal wall continuity without primary apposition of the musculoaponeurotic layers, covering the defect in a bridging fashion with a "patch." Generally, repairs in this fashion are performed as an underlay or overlay with a substantial amount of overlap beyond the musculoaponeurotic edge (usually ≥5 cm) because sewing the prosthesis directly to the edges leads to an unacceptably high rate of hernia recurrence; and (3) a component separation technique, which are extensive, anterior or posterior lateral relaxing incisions to allow for greater tissue mobility, medialization of the rectus muscles, and decreased tension. The component separation is often reinforced using synthetic or biologic prostheses as underlays or overlays.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of incisional hernias involves anything else that could cause a mass effect of the abdominal wall.
  - *Pseudohernias* arising from flank incisions and *diastasis recti* may be mistaken for true hernias. Diastasis recti is usually seen in the absence of a previous midline incision. Flank pseudohernias may require imaging such as computed tomography (CT) of the abdomen to demonstrate that the musculoaponeurotic layers of the abdominal wall are intact.
  - Neoplastic masses, such as desmoid tumors or other soft tissue tumors, such as lipomas and sarcomas, can potentially be mistaken for hernias, especially an incarcerated hernia, because they do not change with straining or coughing and obviously cannot be reduced.
  - Infections causing fluid collections, such as an abscess or seroma formation after prior herniorrhaphy or abdominoplasty, can cause bulging that could be mistaken for a hernia and can occur or become evident weeks to years after the herniorrhaphy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most common symptom is discomfort or pain directly over the site of the hernia, especially when standing or otherwise increasing intraabdominal pressure; referred pain like a radiculopathy is rare. Patients will complain of a bulge, loss of abdominal wall support (often with back pain), or a feeling that they are "falling out" if the hernia is large. Patients often find the hernia cosmetically unacceptable. Localized borborygmi may also be evident to the patient, as may visible peristalsis.
- Hernias may cause varying degrees of intestinal obstruction—acute, chronic, or intermittent. Predisposing factors include chronic or acute incarceration and a small hernia neck, especially with a relatively large protrusion of intraabdominal content relative to the neck size. Intermittent, partial small intestinal obstruction may manifest as cramping, abdominal pain, or emesis, and patients may have learned to massage the hernias to provide relief. Acute or chronically incarcerated hernias may cause more severe obstructive symptoms, including acute, complete small intestinal obstruction or chronic, partial obstruction. Although much less common, large bowel obstruction may occur and manifest as constipation or acutely as obstipation.
- Examination of the patient with an incisional hernia should be performed in both the supine and erect positions. This approach may provide valuable information to the examiner—reducibility, the extent to which the hernia protrudes, and to what extent the abdominal domain has been lost. The two most prevalent findings on physical exam are the presence of a bulge over or lateral to the prior incision and a palpable fascial defect. If the hernia reduces spontaneously in the supine position, the examination can be aided by having the patient perform a Valsalva maneuver, standing, or both. Usually, the hernia can be elicited merely by having the patient lift his or her head off the examination table. Subtle and smaller hernias can be difficult to detect and may manifest during examination as a gentle,

slowly developing bulge under the examiner's fingers; in the obese patient, small hernias may be difficult or impossible to appreciate.

- The edges of the hernia defect should be determined circumferentially by palpation with the patient supine and relaxed. The dimensions are important in determining whether musculoaponeurotic apposition will be possible at the time of repair. Beware the possibility of a "Swiss cheese" hernia, that is, small multiple defects along the fascial incision, especially when the fascia had been closed previously with interrupted sutures; smaller defects may not be palpable.
- As noted previously, an incarcerated hernia must raise other possibilities in the differential diagnosis, such as seromas, abscesses, and both benign and malignant abdominal wall masses.
- The examiner should palpate carefully over any prior port site after a laparoscopic procedure for a subtle defect or "mass."
- Intramural hernias, where at least the most superficial musculoaponeurotic layer remains intact, can occur after lateral celiotomies where the abdominal wall has several layers. Spigelian hernias can present as intramural hernias. Intramural hernias are rare and can be difficult to diagnose and often impossible to feel. A Valsalva maneuver during CT or even ultrasonography may be diagnostic when physical exam and even a passive CT cannot demonstrate the hernia.
- For very large hernias that remain evident with the patient supine, an estimation should be made as to the extent to which the herniated contents have lost domain; that is, there is no longer adequate room within the abdominal cavity to accommodate the extruded contents after attempted reduction back into the coelomic cavity. CT of the abdomen is also particularly helpful in this regard. Loss of domain can preclude fascial apposition, even with concomitant component separation or relaxing incisions. Substantial loss of domain will cause undue tension in repairs, respiratory compromise, and an increased risk of recurrence after repair. Severe loss of domain precludes repair.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The best imaging technique for incisional hernia is CT. CT provides excellent and actionable information regarding the size and configuration of the hernia defect, can provide a visual estimate of loss of domain and other potential pathologies in the differential diagnosis, and will aid in planning of the operation. In large, complex hernias, the information can assist with decisions regarding the procedure of choice as well as the potential for adjunctive measures such as tissue (skin surface area) expanders. For flank hernias, CT can rule out a pseudohernia and is important to define the status of the oblique muscles cranial and caudal to the defect, as well as the paraspinal muscles, which will need to serve as fixation points for the hernia prosthesis.
- Routinely obtaining a CT to define the hernia defect, position, and size is controversial. For straightforward incisional hernias easily felt and defined at examination, CT has little benefit. For large, complex, or recurrent hernias, especially after prior repairs, CT can provide a wealth of information to define size and conformation, position of any prior prosthetics, issues of abdominal domain, unappreciated additional defects, and the status of the abdominal musculature such as loss or atrophy of specific muscle layers—critical information when planning a concomitant component separation.
- Magnetic resonance imaging (MRI) is acceptable but provides no more information than CT while being more expensive, time consuming, and difficult for the patient (and for many physicians as MRI is more difficult to interpret). Ultrasonography can be helpful, especially with the diagnosis of intramural hernias but is not generally useful and provides far less information than CT.

SURGICAL MANAGEMENT

Timing of Operation

- Although most incisional herniorrhaphies are elective operations, acutely incarcerated hernias are surgical emergencies, particularly when strangulation is suspected. Signs of strangulation may include: nausea and vomiting; peritonitis; acutely inflamed, indurated skin overlying the hernia; new onset of constant severe hernia pain; and the signs and symptoms of local or systemic sepsis.
- As a general rule, elective incisional herniorrhaphy should be delayed until optimum conditions for repair have been achieved; this approach will decrease recurrence rate. Timing of repair, however, is relative to the patient and the hernia; for example, a small-necked hernia considered at high risk for incarceration would prompt an earlier repair especially if symptomatic, whereas a patient with multiple, potentially remediable risk factors for recurrence, such as obesity, poorly controlled diabetes, tobacco use, malnutrition, constipation, or chronic cough, would argue for a delayed approach until these issues are addressed. More immediate concerns that should delay repair for the shorter term would include, open wounds on the abdominal wall, cellulitis, panniculitis, or cutaneous candidiasis; distant infections such as pneumonia or urinary tract infection; and uncontrolled, potentially reversible medical conditions such as diabetes, congestive heart failure, and chronic obstructive pulmonary disease (COPD). A nonmature ("nonpinchable") split thickness skin graft overlying the hernia is a relative indication for delay, as is waiting to receive recoverable operative notes from prior abdominal operations prior to operation.

Open versus Laparoscopic Repairs

- The topic of open versus laparoscopic repairs is controversial. Each has advantages and disadvantages, and the data regarding hernia recurrence, pain, and postoperative complications are roughly comparable. There are factors that may predispose toward one or the other approach in a particular patient; a surgeon routinely performing hernia repairs should be conversant with both. A recent Cochrane review examined 10 randomized controlled trials with a total of 880 patients comparing laparoscopic versus open ventral hernia repairs. They did not note any difference in recurrence rates or postoperative pain intensity. Laparoscopic repairs carried a greater risk of enterotomy and incurred greater in-hospital costs, but they were associated with a decreased risk of wound and mesh infection and shortened hospital stay.
- Factors favoring open repair: Theoretically, returning the abdominal musculature to its normal position of continuity could be expected to restore optimal anatomic and physiologic functionality of the mechanics of the abdominal wall, although

this remains unproven. Apposition of the musculature in its anatomic position is more easily accomplished in an open procedure. Although fascial apposition can be accomplished laparoscopically, as can a limited component separation, these are performed more efficiently and completely in an open procedure, and more complex component separations including the rectus sheath rollover technique can be accomplished. The fascial apposition performed laparoscopically usually leaves a cosmetically undesirable ridge of skin and subcutaneous fat above the repair. Dense adhesions, especially those resulting from an open wound and subsequent split thickness skin grafting, make a laparoscopic repair difficult or impossible.

Preoperative Planning

- Several factors can affect the recurrence rate of incisional hernia repair. With a recurrence rate of 10% to 30% or greater, attention to the factors that adversely affect recurrence rate in the preoperative phase is warranted.
  - Weight loss: If patients are substantially overweight, certainly if they meet medical criteria for severe obesity, an attempt at weight loss prior to repair is warranted. If the patients are not able to lose weight successfully after a reasonable period of time, however, it may be reasonable to proceed with repair.
  - Tobacco use: Experts in abdominal wall reconstruction are in general intolerant of tobacco use prior to hernia repair, certainly within 6 weeks prior to the repair and especially if a components separation is planned. The adverse effects of tobacco use on wound healing are well documented in the medical literature. It is worthwhile noting that nicotine substitutes such as gum would be expected to cause the same vasoconstriction and tissue ischemia as inhaled and oral tobacco products.
  - Abdominal wall strain: Voluntary and involuntary abdominal wall contractions can place an immense strain on a fresh abdominal wall reconstruction—coughing, constipation, emesis, and straining to urinate all place stresses on the abdominal wall that could have an adverse effect on herniorrhaphy. Any remediable causes of these problems should be addressed prior to operation.
  - Routine screening: It is worthwhile to make certain that patients are up-to-date with routine medical maintenance and screening such as colonoscopy so that other necessary intraabdominal conditions can be treated concomitantly, beforehand, or sequentially with the herniorrhaphy as appropriate.
  - Routine health maintenance: A general preoperative clearance is useful to make certain the patient is medically optimized for operation. Common diseases, such as hypertension, diabetes, COPD, and coronary artery disease, should be evaluated and optimized prior to operation to minimize perioperative risk.
  - Incisional hernia repair is usually a clean case. Because enterotomies can occur and repairs usually entail the placement of either a synthetic or biologic prosthesis, perioperative prophylactic antibiotics are indicated. Bowel preparation is not indicated. A preoperative shower with chlorhexidine gluconate (Hibiclens®) is prescribed at the preference of the surgeon. Adhesive drapes, such as Ioban™ (3M Corp, Minneapolis, MN) and Steri-Drape™ (3M Corp), are used frequently for the theoretic purpose of "isolating skin bacteria" from the wound and any prosthesis used, but strong evidentiary studies to support their use are lacking.
  - Many hernia cases will require advance notice to ensure that necessary materials and equipment are available.
    - Planned fixation of the prosthesis to the pubis or anterior iliac spine may require the use of a bone drill or bone anchors.
    - Specialized, procedure-specific equipment such as a Reverdin needle
    - Biologic prosthetics (fetal bovine, porcine, or human dermis and others) are expensive and may be stocked in limited supply. Be certain that the prosthesis required in size, thickness, and type is in stock and available the day of operation, as well as alternatives should the originally planned material not be usable as planned.

Positioning

- Most incisional hernias can be repaired with the patient supine; the drapes should extend at least 10 to 15 cm above and below the extent of the previous incision. There may be unappreciated defects discovered at the time of operation along the entire extent of the previous incision.
- For flank hernias, adequate exposure is paramount. Depending on the incision, a vertically placed bump under the spine providing lateral position may give sufficient access, whereas for more lateral incisional hernias, a complete lateral position may be necessary. See the following "Techniques" section.

Varieties of Repair

- The optimal repair of an open incisional hernia is a controversial topic. We will present our choices for what we consider the acceptable and optimal repairs, as well as general considerations that are valid regardless of the other technical details. For most purposes, we consider fascial apposition with a prosthesis underlay in the retrorectus or preperitoneal position to be the best repair for most open incisional hernias.

Choice of Mesh

- In general, the synthetic (alloplastic) meshes are preferable when there is no contamination precluding their use, whereas biologic prostheses are preferable when microbial contamination is present. There are innumerable choices for both synthetic and biologic prostheses and little to support the superiority of one particular type over another within their respective classes. It is useful to categorize broadly the various products by functional use. The most important distinction is synthetic versus biologic. The biologic prosthetics are in general more resistant to bacterial colonization and infection and may be chosen in a contaminated field, but they may remodel and weaken over time, especially when used in a bridging fashion. The synthetics are stronger than the biologic meshes and do not remodel, although a varied extent of shrinkage does occur, depending on the prosthetic material. The synthetics may be further subdivided into barrier and nonbarrier meshes. Barrier meshes are designed to allow them to be apposed to the abdominal viscera are in theory minimize adhesions to the side facing intracorporeally. Nonbarrier synthetics should only be used in a protected space, such as the preperitoneal or retrorectus spaces.

Procedure Categorization

Open

- Fascial apposition alone
- Fascial apposition with prosthesis underlay
  - Protected space mesh placement (preperitoneal and retrorectus)
  - Intraperitoneal mesh placement
- Fascial apposition with prosthesis overlay
- Components separation

Laparoscopic

- Prosthesis underlay
  - Suture fixation with tacks
  - Tack fixation alone
- Fascial apposition
- Components separation

WIDE ONLAY TECHNIQUE OF INCISIONAL HERNIORRHAPHY

- The concept behind this wide onlay repair is that the procedure can remain fully extraperitoneal, and the meshed prosthesis provides a large surface area for transgrowth through the mesh and thus a wide tissue fixation.

Placement of Incision

- The entire prior skin incision is excised along with any underlying fibrosis back to healthy epidermis and subcutaneous fat in attempt to minimize infection (**FIG 1A**).
- Dissection proceeds directly down to the hernia sac, being careful not to enter the sac. If the incision is longer than the hernia defect, only the skin and subcutaneous tissues that are chronically scarred with concerns for healing need be excised. This type of repair can be accomplished totally extraperitoneally. The lateral aspect of the hernia sac is mobilized medially back to the fascial defect. This maneuver may be accomplished purely by blunt dissection, but if the interface of sac and subcutaneous tissue is scarred, sharp dissection may be required (**FIG 1B**).

Creation of Space for Prosthesis

- The skin and subcutaneous tissue flaps are mobilized for at least 5 to 7 cm lateral to the edge of the hernia defect. This plane is created just anterior to the abdominal wall fascia (anterior rectus fascia and possibly out to the external oblique fascia or aponeurosis more laterally) to allow a wide, lateral overlap of the prosthesis. A 5- to 7-cm skin and subcutaneous flap is mobilized off the midline fascia past the cranial and caudal extents of the hernia defect (**FIG 1C**).

Reapproximation of Fascia Edges

- A decision needs to be made whether and how the fascial edges of the defect can be reapproximated (**FIG 2A**) or only bridged or "patched" by the prosthesis

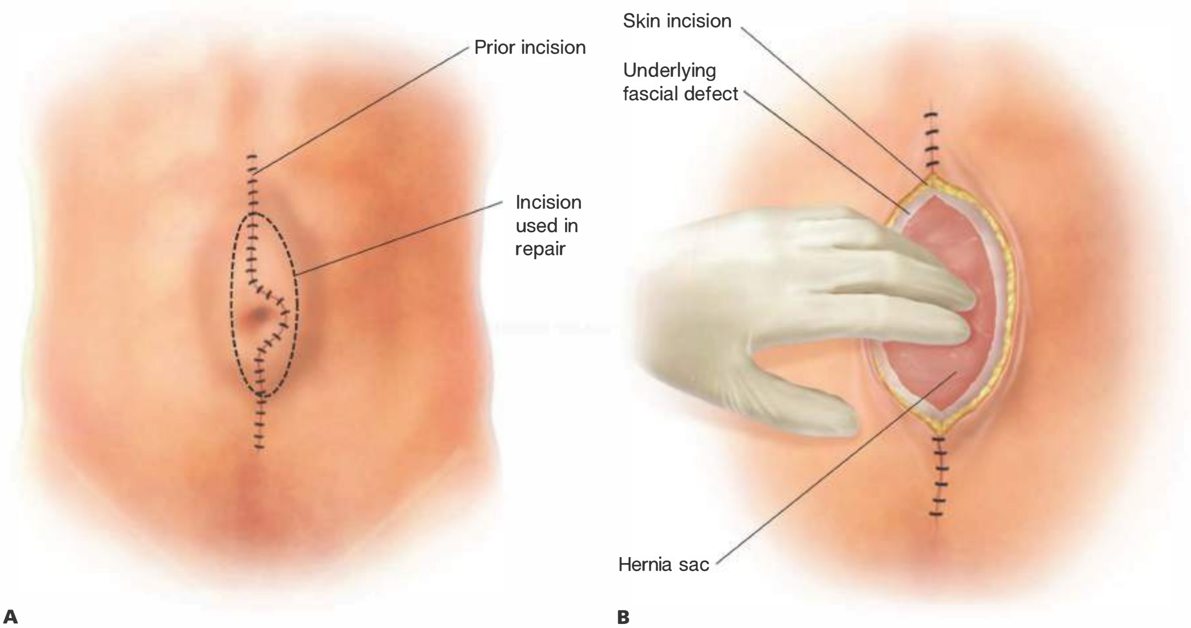

FIG 1 ● Incision and mobilization of hernia sac. **A.** The incision is centered over the hernia excising the prior incision; all subcutaneous scars should be excised back to healthy, vascularized subcutaneous tissue. **B.** The hernia sac is mobilized laterally to the medial edge of the hernia defect; try to not violate the hernia sac. *(continued)*

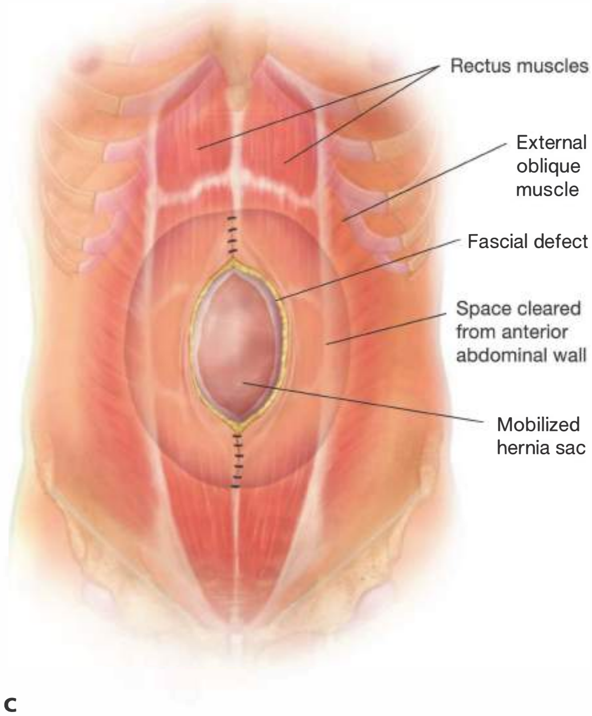
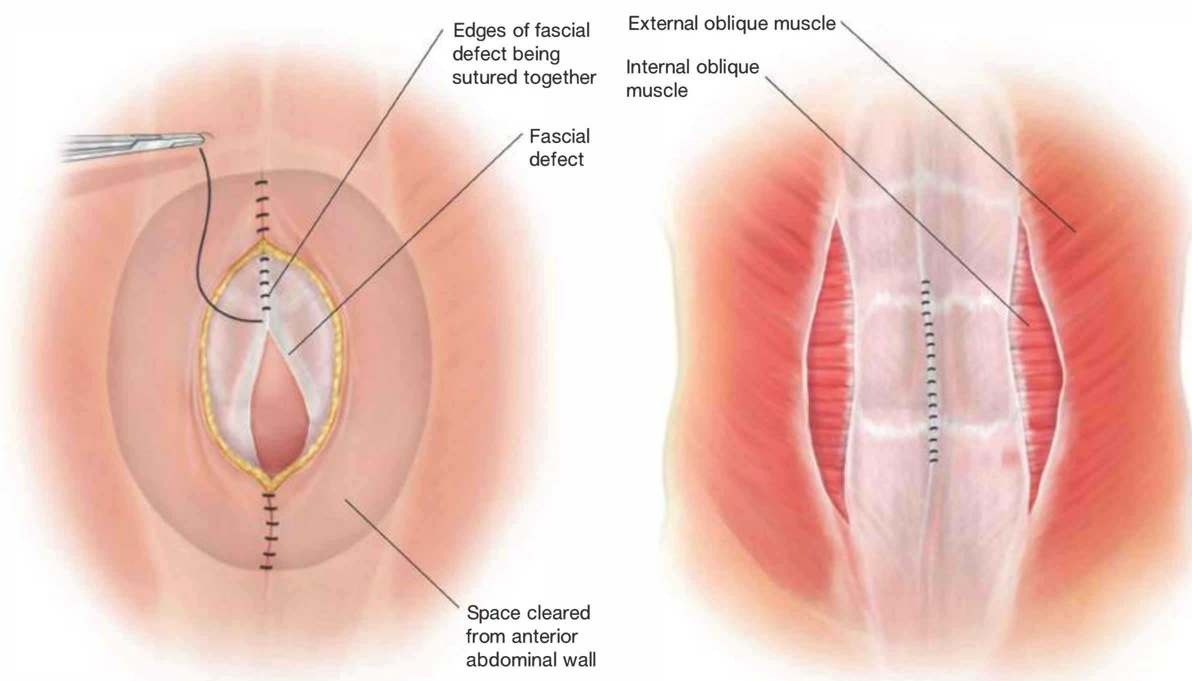
TECHNIQUES



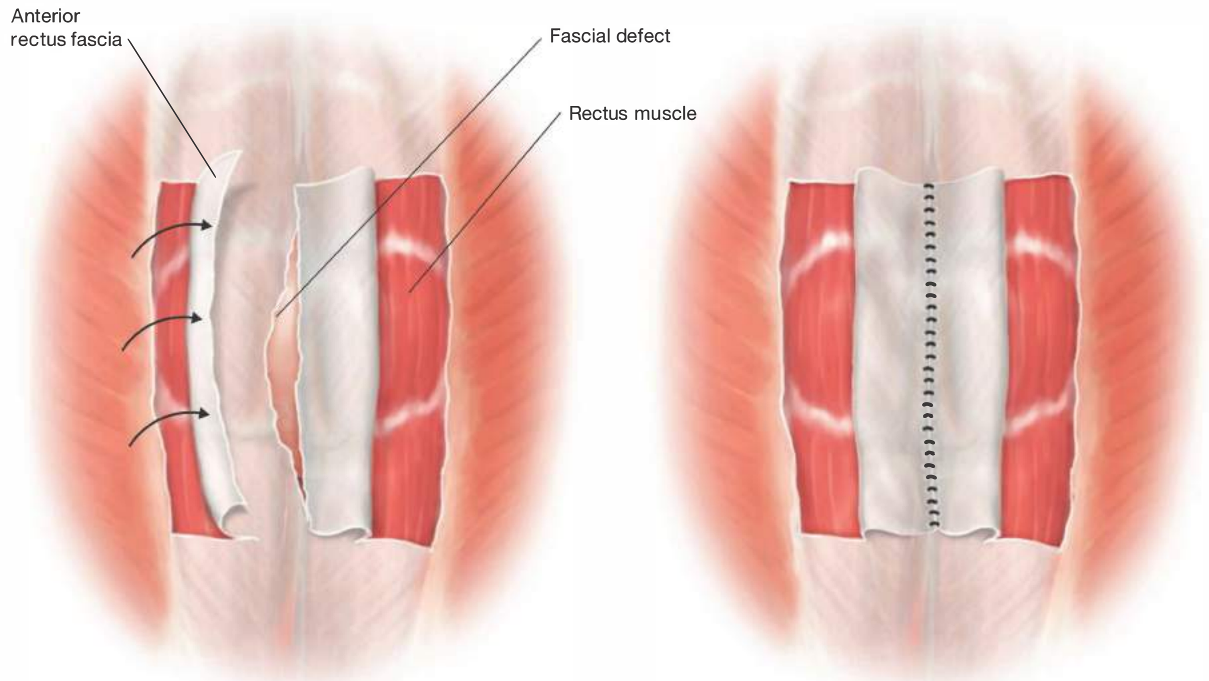
C

FIG 1 ● *(continued)* **C.** The anterior surface of the abdominal wall musculature is mobilized circumferentially at least 5 to 10 cm from the edges of the hernia defect to provide a wide surface area to allow transgrowth through the onlay meshed prosthesis for a stable tissue incorporation/fixation.



A B

FIG 2 ● Closure of hernia defect prior to placement of meshed prosthesis. **A.** *Primary reapproximation*—when possible, the medial edges of the defect are reapproximated with a running suture closure. **B.** Anterior components separation—when the defect cannot be approximated primarily, the external oblique muscle/aponeurosis can be incised 1 to 2 cm lateral to the lateral border of the rectus muscle to allow medialization of the rectus muscle for primary closure of the defect. *(continued)*



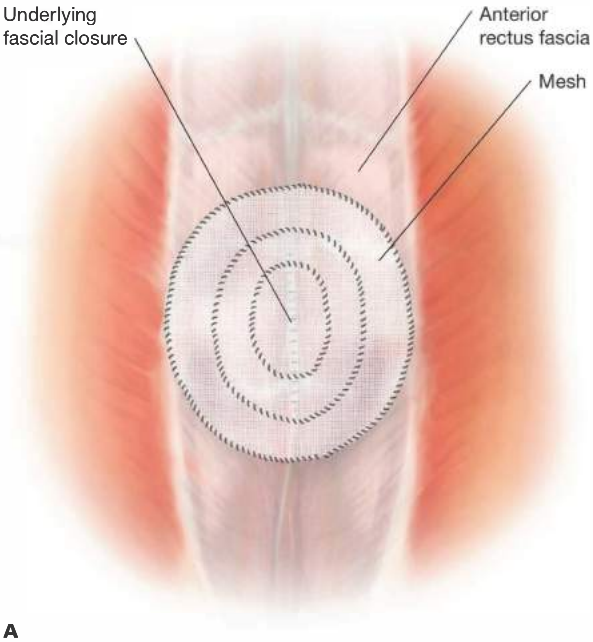
C

FIG 2 ● *(continued)* **C.** *Rectus rollover*—another alternative to the anterior lateral "release" or "relaxing" incision in **B** figure is to incise the anterior rectus fascia and mobilize the fascia medially to allow it to "rollover" medially for primary fascial closure—note, this technique does not fully medialize the rectus muscles but does allow fascial approximation over the hernia defect (see insert).

(**FIG 2B**) (see Part 2, Chapter 5). If the fascial edges are to be sutured together, some dissection under the fascial edges may be necessary to place the fascial sutures safely. Most surgeons believe that reapproximation of the fascial edges reinforced by a prosthesis provides a superior outcome compared to a bridge or patch of a persistent fascial defect. If the defect is wide and would require a more complicated abdominal wall reconstruction, the advantages and disadvantages should be considered. In this situation, the skin flaps can be dissected further laterally beyond the lateral border of the rectus muscle; then the external oblique fascia and muscle can be transected being careful not to disrupt the internal oblique muscle/fascia—a form of anterior components separation—this maneuver allows the rectus muscle to be "medialized" and the medial edges of the fascia to be sewn together (**FIG 2C**) (see Part 2, Chapter 5, for more in-depth description). This maneuver allows 4 to 6 cm of medialization of the rectus muscles on both sides. Another option to "approximate" the fascial edges of the defect is a rectus rollover technique (**FIG 2C**). With this technique, the anterior rectus fascia is incised just medial to its lateral border, mobilized off the underlying rectus muscle, and "rolled" medially. These edges of the rolled anterior rectus fascia can be sutured together in the midline. Note that the rectus muscles are not medialized with this technique.

Placement of Prosthetic Mesh

- A large sheet of prosthetic mesh is then sized to cover the anterior abdominal wall hernia defect and to extend a further 5 to 7 cm from the hernia defect (so-called "wide onlay") on all sides of the defect. The lateral edges of the prosthesis are sewn to the anterior abdominal wall fascia circumferentially with #0 or no. 1 suture material (e.g., 0 or no. 1 polydioxanone) (**FIG 3**). The use of absorbable versus permanent sutures is controversial. Proponents of permanent sutures believe that permanent sutures minimize the possibility of late migration or dislodgement of the prosthesis, whereas those surgeons favoring the longer lasting absorbable suture (such as polydioxanone) believe that permanent sutures can lead to suture granulomas and ultimately contamination and infection of the prosthesis. Although there is no good evidence supporting either argument, we prefer the absorbable suture provided there will be a large surface area for mesh transgrowth.
- In progressively smaller concentric circles, one or two additional suture fixation of the prosthesis to the underlying anterior abdominal wall can also be placed (**FIG 3A**). If the repair is a bridge repair, these concentric circles should not extend medial to the edges of the fascial defect because the underlying hernia sac and viscera can be injured. A porous synthetic prosthetic and not a solid prosthetic (ePTFE) is used to achieve the goal to provide a



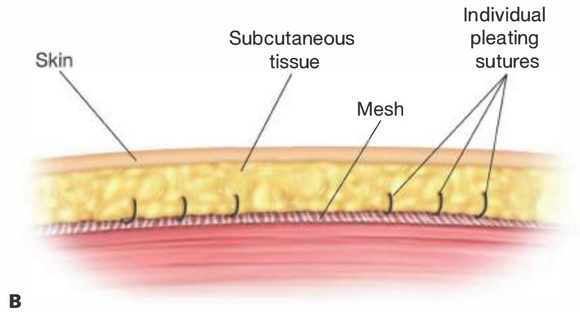


FIG 3 ● Implantation of meshed prosthesis. **A.** The prosthesis is sutured to the anterior surface of the fascia of the anterior abdominal wall. Several concentric circles of suture fixation can be performed. **B.** *Pleating of subcutaneous space*—in an attempt to obliterate dead space, the posterior aspect of the lateral skin/subcutaneous flap created to allow a wide onlay repair can be sewn to the anterior abdominal wall fascia. Prior to closing the skin, several closed suction drains are placed in this subcutaneous space and brought out cranially (skin is cleaner cranially than caudally) lateral to the lateral edge of the mobilized skin/subcutaneous flaps (not shown).

wide surface area for transgrowth through the mesh for tissue fixation.

- If an anterior components separation is performed, the prosthesis extends laterally to the lateral transected edge of the external oblique aponeurosis (a very wide onlay repair) or just 5 to 7 cm lateral to the medial edge of the hernia defect which is usually to the lateral edge of the rectus muscle.
- If a rectus rollover is performed, the prosthesis should extend 5 cm lateral to the site of incision in the anterior rectus fascia to provide solid points of fascial fixation of the prosthesis.
- For situations where there is bacterial contamination (clean–contaminated cases) or active infection, albeit treated, a synthetic mesh is contraindicated, and a bioprosthesis would be a better choice.

Wound Closure

- Most surgeons place one or two closed suction drains in the large subcutaneous space to prevent a seroma. When the drains should be removed is controversial; for a bioprosthesis, drains are mandatory to prevent a seroma.
- Prior to closing the skin, a pleating technique may be used, whereby the posterior adipose surface of the skin/subcutaneous flaps can be sewn to the anterior surface of the prosthesis in attempt to minimize the "dead space" and the possibility of seroma (**FIG 3B**).

RECTRORECTUS SUBLAY REPAIR: MODIFIED RIVES-STOPPA REPAIR

- Many believe that this repair has the best results of all current incisional herniorrhaphies. Whether it is better than a wide, intraperitoneal sublay (IPOM) can be debated, but there are no studies comparing the two repairs. This modified Rives-Stoppa repair is based on the principle of wide surface area of a meshed synthetic prosthesis placed in a very vascular field—the retrorectus space (to allow a stable, reliable anterior and posterior transgrowth for mesh fixation). Importantly, the prosthesis is neither in the less vascular subcutaneous space where the risk of infection and seroma is greater nor is the prosthesis direct in contact with the intraperitoneal viscera. Moreover, in most patients, the repair can be accomplished extraperitoneally.

Placement of Incision

- As with other repairs, the incision should be made directly over the hernia defect with resection of the skin incision and the underlying, poorly vascularized scar tissue. The skin incision preferably should not extend all the way up to the xiphoid or all the way down to the pubis but rather stay 5 to 8 cm away from xiphoid and pubis.

Mobilization of Retrorectus Space

- As described in the first technique (**wide onlay technique of incisional herniorrhaphy**), the subcutaneous hernia sac is mobilized back to the hernia defect for the entire circumference of the defect. The hernia sac, though, is neither incised nor opened unless a concomitant, "clean" intraperitoneal procedure is planned—for example, adhesiolysis, insertion of an adjustable gastric band, and so forth. It could

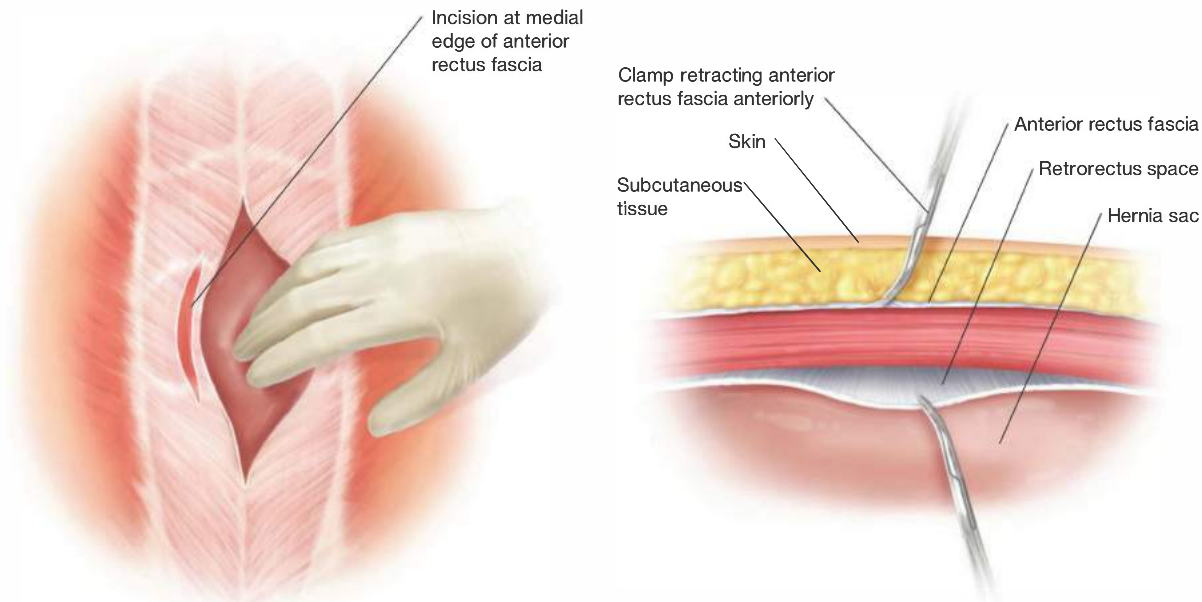

FIG 4 ● Dissection of retrorectus space. **A.** An anterior rectus fasciotomy is made at the medial edge of the rectus muscle (at lateral edge of the hernia defect) allowing access to the avascular retrorectus space. **B.** Lateral dissection is facilitated by retracting the medial edge of the anterior rectus fascia anteriorly and the medial edge of the posterior rectus fascia medially and posteriorly. Much of this dissection can be blunt.

be argued that clean–contaminated procedures, such as an elective cholecystectomy or hysterectomy do not pose a clinically significant bacterial contamination load despite being clean–contaminated procedures, but considering the morbidity and requirement for at least one additional procedure in the event of mesh infection, the authors tend to refrain from performing even these minimally contaminating procedures concomitantly in most circumstances. Certainly, other "clean–contaminated" procedures such as gastrectomy, small or large bowel resections, appendectomy, biliary drainage procedures, or most bariatric operations other than a band would be considered by most to be an indication to use a bioprosthesis rather than a permanent synthetic mesh.

- Next, the medial edge of the anterior rectus fascia is incised at the lateral edges of the hernia defect, thereby exposing the vertical fibers of the underlying rectus muscle (**FIG 4A**). The rectus muscle is dissected and retracted anterolaterally to expose the firm, white surface of the posterior rectus fascia (**FIG 4B**).
- There are minimal, if any, adhesions between the posterior surface of the rectus muscle and the anterior surface of the posterior rectus fascia, except medially where the transfascial sutures from the originally fascial closure had been placed. The benefit of this retrorectus space is that it is virtually avascular to dissect and very easily mobilized.
- Care must be taken to preserve the inferior epigastric vessels (artery and vein) cranially near the xiphoid where they will course from medially near the xiphoid to the midrectus muscle anterior to the posterior rectus fascia before entering the rectus muscle. Caudally, the deep inferior epigastric vessels arise from the external iliac vessels medial to the internal inguinal ring and course cranially in the preperitoneal space caudal to the semicircular line and then on the anterior surface of the posterior rectus fascia before entering the rectus muscle with one or more branches. This inferior epigastric arcade is important to preserve because it provides the blood supply to the rectus muscles and equally important from the rectus muscles to the overlying skin and subcutaneous tissue via the "perforator vessels." One advantage of the rectorectus repair (in contrast to the wide onlay technique) is that mobilization of a lateral skin/subcutaneous flap (and the obligate transection of the important perforators) is not necessary, maximizing the blood supply to the skin edges and minimizing the subcutaneous "dead space."
- The retrorectus space should be mobilized to the lateral border of the rectus muscle, the cranial and caudal extent of the hernia defect/hernia sac (**FIG 5**). The anterior rectus fascia and the linea alba need to be preserved cranially and caudally to the hernia defect to allow for fixation of the prosthesis.
- The cranial edge of the intact midline fascia is grasped with a Kocher clamp and retracted anteriorly to allow cranial mobilization of a space (if possible preperitoneally) for at least 7 cm or up to the xiphoid (**FIG 6A**). This requires transection of the insertion of the posterior

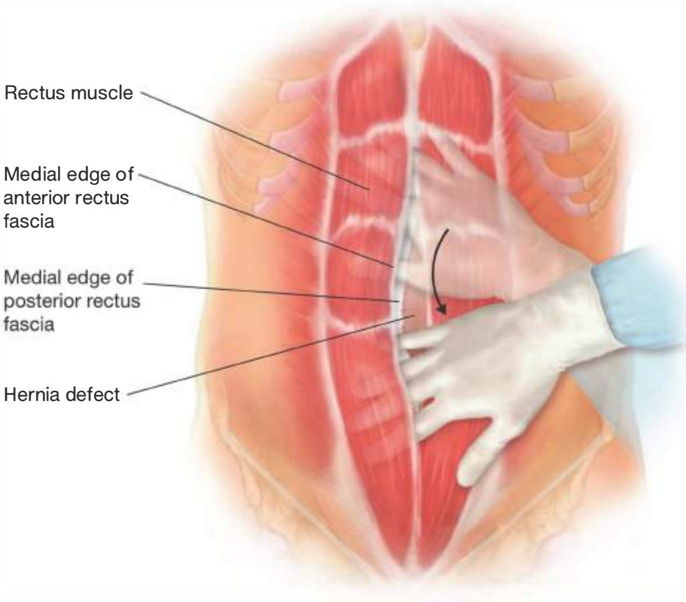

FIG 5 ● Extent of retrorectus space. Lateral dissection is carried out to the lateral edge of the rectus muscle, cranially if necessary up to and anterior to the costal margin, and caudally if necessary down to the pubis, also exposing Cooper's ligaments if extensive fixation is necessary.

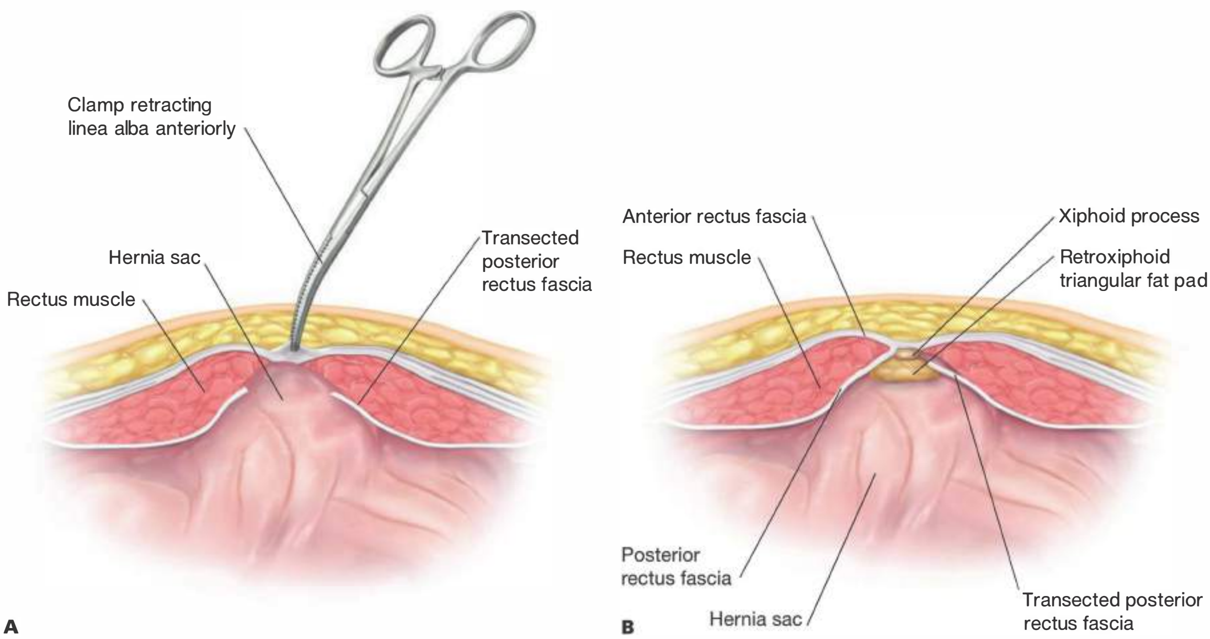

FIG 6 ● Cranial dissection of retrorectus space. **A.** The cranial dissection is aided by placing a clamp on the midline fascia at the cranial-most extent of the hernia defect. Next, the medial insertion of the posterior rectus fascia into the anterior rectus fascia is transected, being careful not to disrupt the continuity of the anterior rectus fascia with linea alba cranially. This can often be completed extraperitoneally. **B.** When it is necessary to mobilize fully up to the xiphoid, the medial fascial insertions of the posterior rectus fasciae to the lateral xiphoid are transected and the triangular fat pad posterior to the xiphoid is mobilized posteriorly off the posterior surface of the xiphoid, allowing creation of a subdiaphragmatic space 3 to 5 cm behind the xiphoid/distal sternum. *(continued)*

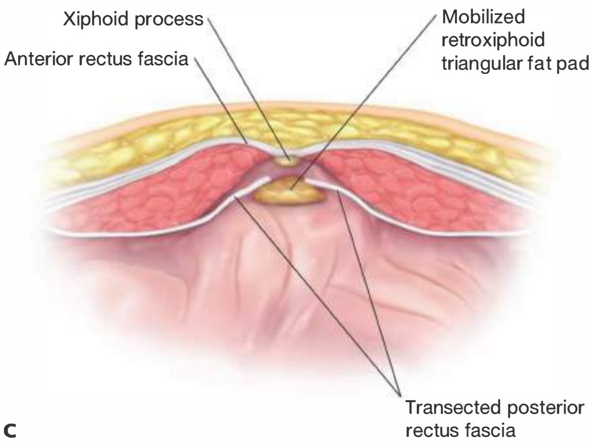

FIG 6 ● *(continued)* **C.** Fully mobilized retrosternal space, allowing the mesh to cross the midline behind the xiphoid.

rectus fascia at the medial edge of the rectus muscle bilaterally, being careful not to disrupt continuity of the anterior rectus fasciae with the linea alba; this maneuver may be performed totally in the preperitoneal space. If the prior celiotomy incision extends cranial to the edge of the hernia defect, the surgeon should palpate further cranially for areas of Swiss cheese defects or areas of fascial weakness; if found, then the retrorectus space needs to be extended beyond the upper most defect. This maneuver may require being intraperitoneal if the preperitoneal space was transgressed previously. If there is not, 7 cm of good, solid, anterior rectus/linea alba cranial to the defect or if the defect extends to the xiphoid, then the insertion of the posterior rectus fascia onto the anterior rectus fascia will have to be transected up to its junction with the xiphoid (**FIG 6B**). Also, the preperitoneal "triangular" fat pad posterior to the xiphoid needs to be mobilized posteriorly off the undersurface of the xiphoid for 5 cm cranially—this is easy and is an avascular plane; this maneuver will allow the prosthesis to extend under the xiphoid and distal sternum to maximize the cranial surface area for tissue ingrowth/fixation (**FIG 6C**).

- A similar maneuver is performed caudally (**FIG 7**). Caudal to the semicircular line, the posterior rectus fascia disappears, and further caudal mobilization of the retrorectus space now becomes preperitoneal. If the prior celiotomy incision did not extend caudal to the caudal extent of the hernia defect, then this entire maneuver can often be done extraperitoneally. If the prior fascial incision extends further caudally, the peritoneal cavity may need to be entered. Note, any redundant peritoneum and *all* the hernia sac should be preserved to allow the peritoneum to be closed deep to the prosthesis caudally. This space should be mobilized at least 7 cm, if not 10 cm, being certain again that the overlying fascia is neither weak nor has any Swiss cheese defects. If necessary, mobilize all the way to the pubis (and maybe even mobilize posterolaterally to Cooper's ligaments for additional bony points of fixation of the prosthesis if the musculofascial tissue of the anterior abdominal wall is weak or attenuated. Note, as discussed previously, the lateral mobilization of the retrorectus space here should be accomplished fully under vision because it is here that the deep inferior epigastric vessels are most frequently injured.
- Several caveats: *First*, the retrorectus space extends cranial and anterior to the costal margin; the rectus muscle does not insert on the costal margin but rather on the ribs 3 to 5 cm cranial to the costal margin. *Second*, the intercostal nerves that supply the rectus muscle and

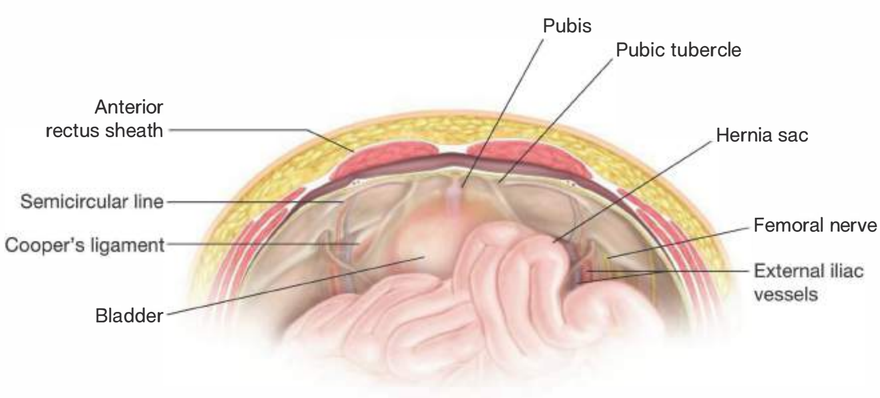

FIG 7 ● During caudal dissection of retrorectus space past the semicircular line, the posterior rectus fascia transitions to the peritoneum, and now, further caudal dissection is in the avascular preperitoneal space. Blunt dissection continues down to and posterior to the pubis if necessary, and lateral to expose Cooper's ligaments medial to the external iliac vessels. Care must be taken to protect the iliac vessels and especially the deep inferior epigastric artery and vein, which are at the lateral aspect of the rectus muscles posteriorly; this maneuver should be done under vision.

overlying skin course on/near the anterior surface of the internal oblique muscle lateral to the rectus muscle but perforate into the retrorectus space at the lateral-most border of the posterior rectus fascia—these nerves should be preserved. *Third*, if there has been loss of rectus muscle and the retrorectus space is narrow, the space can be extended to the space posterior to the internal oblique muscle but anterior to the transversus muscle. This will preserve the innervation of the rectus muscle by the intercostal nerves which run on/within the internal oblique muscle. A posterior component separation can be performed if necessary (see Part 2, Chapter 5).

- Full mobilization of the retrorectus space should extend 5 to 7 cm cranial to the hernia defect, 7 to 10 cm to the hernia defect, and to the lateral edge of the retrorectus space.

Reconstruction of the Continuity of the Posterior Rectus Fascia across the Midline

- Every attempt should be made to reapproximate the posterior rectus fascia in the midline, not only to isolate the retrorectus space from the viscera but also to serve as the deep fascial layer "closing" the hernia defect (**FIG 8**). This maneuver may be difficult at the cranial and caudal extent of the retrorectus space or with very wide hernia defects. If not possible to reapproximate the posterior rectus fasciae or to cover the exposed intraabdominal visceral with autogenous tissue (redundant sac, peritoneum, or rarely omentum), then consideration should be given to bridging this defect with an absorbable prosthetic such as polyglycolic acid (Vicryl® mesh, Ethicon, Inc or Dexon® mesh, Covidien, Inc) posterior to the synthetic mesh. Use of the expensive bioprosthetics for this "bridge" is not indicated, because this bridge will *not* be the stable, durable part of the hernia repair.

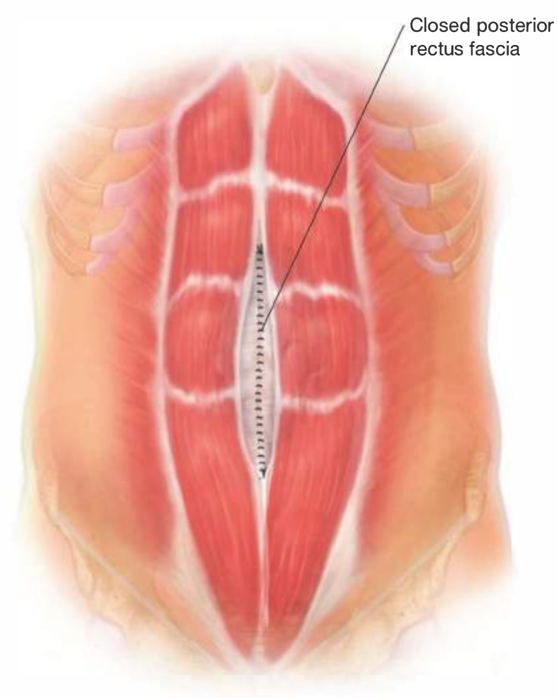

FIG 8 ● Closure of the posterior rectus fascia. The medial edges of the posterior rectus fascia are approximated in the midline, whereas the still-intact hernia sac is pushed posterior to this closure. If the peritoneal sac is disrupted and the posterior rectus fascia cannot be approximated in the midline, an inlay of absorbable synthetic mesh (Vicryl mesh, Ethicon, Inc) can be used to separate the intraperitoneal content from the permanent mesh to be placed in the retrorectus space.

Insertion of the Prosthesis

- This repair is best accomplished with a meshed prosthesis. We prefer a large-pore, lightweight type, such as ULTRAPRO™ (polypropylene, Ethicon, Inc), unless the patient is a laborer or a high-performance athlete, in which case we choose a heavyweight mesh, such as Prolene® mesh (Ethicon, Inc). This repair is designed for a meshed prosthesis and, because the repair is fully extraperitoneal, there is no indication for ePTFE or a "coated" mesh—transgrowth from both the anterior and posterior surfaces of the retrorectus space is encouraged.
- We position a 12 × 12–in sheet of meshed prosthesis diagonally—this increases the craniocaudal length available. This orientation allows a rapid and reliable fixation of each corner of the prosthesis to help in determining the appropriate sizing of the mesh.
- The mesh is fixed cranially and caudally. Cranially, a 1-cm horizontal mattress stitch is placed through the mesh just lateral to the midline after doubling back the corner of the mesh onto itself. We use a no. 1 polydioxanone suture for nonbony points of fixation. A suture passer is inserted through a stab wound in the skin into the retroxiphoid space (we prefer to use the more blunt, disposable Endo Close™ [Covidien, Inc] or the Reverdin needle rather than the non-disposable metal Carter-Thomason device). The surgeon's hand is positioned between the entry site of the suture passer and the peritoneum to prevent inadvertent puncture into the peritoneal cavity (**FIG 9A**). One end of the suture previously placed in the mesh is grasped by the suture passer and pulled back out the stab wound (**FIG 9B**); this process is repeated to withdraw the other end of the suture (**FIG 9C**) being certain to insert the suture passer through the fascia about 1 cm from the first pass such that when tied together, there is at least a 1.5 cm area of fascia incorporated in the knot. An identical suture fixation is performed on the other side of the midline.
- If the mesh extends posterior to the xiphoid, we use two permanent sutures (no. 1 polypropylene). After placing a horizontal stitch through the mesh, the suture passer is inserted through the most caudal part of the sternum

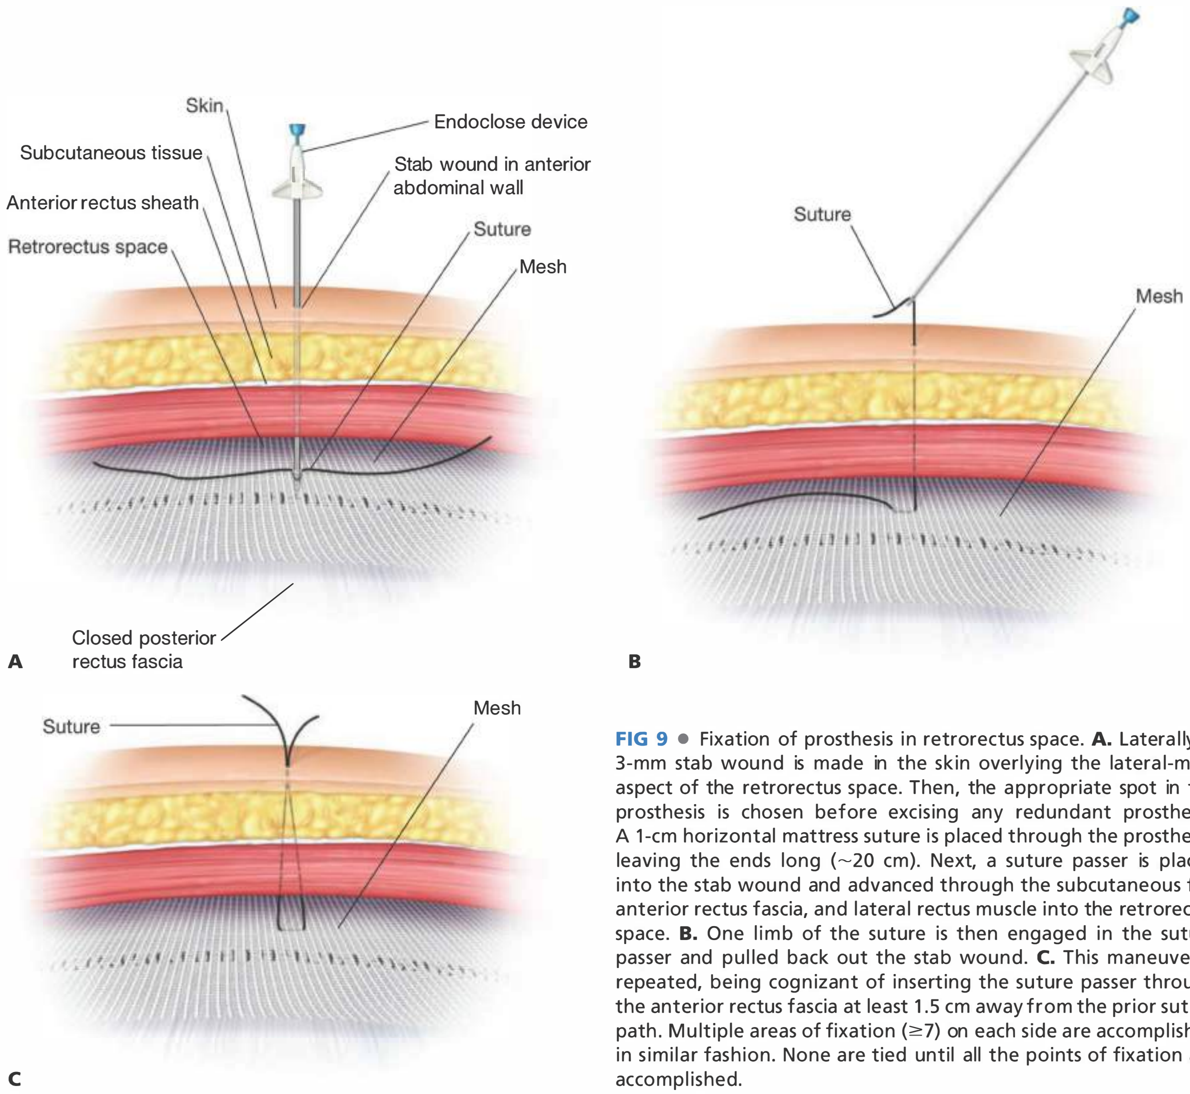

FIG 9 ● Fixation of prosthesis in retrorectus space. **A.** Laterally, a 3-mm stab wound is made in the skin overlying the lateral-most aspect of the retrorectus space. Then, the appropriate spot in the prosthesis is chosen before excising any redundant prosthesis. A 1-cm horizontal mattress suture is placed through the prosthesis, leaving the ends long (~20 cm). Next, a suture passer is placed into the stab wound and advanced through the subcutaneous fat, anterior rectus fascia, and lateral rectus muscle into the retrorectus space. **B.** One limb of the suture is then engaged in the suture passer and pulled back out the stab wound. **C.** This maneuver is repeated, being cognizant of inserting the suture passer through the anterior rectus fascia at least 1.5 cm away from the prior suture path. Multiple areas of fixation (≥7) on each side are accomplished in similar fashion. None are tied until all the points of fixation are accomplished.

rather than just through the cartilaginous xiphoid; this maneuver requires some force to push the suture passer through the bony sternum.

- The mesh is fixed at the caudal end of the retrorectus space. The mesh should be minimally taut but not under tension because some amount of mesh shrinkage is expected—more if the heavyweight/small-pore mesh is used.
- If the prosthesis extends to the pubis, a permanent suture is used for mesh fixation to the pubis, leaving about 3 cm of mesh that will extend posteriorly between the bladder and the pubis. A no. 1 polypropylene suture on a heavy needle is first passed through the mesh and then into the bone of the pubis and back out 1 to 2 cm from the insertion. This suture fixation is not to the periosteum but rather into the bony part of the pubis. The needle is then passed back through the mesh 1 cm from the other end to give 1 cm of mesh between the entry and exit points of the mesh. We use a minimum of four to five suture fixations through the pubis and pubic tubercle and, on occasion, two or three similar sutures to the medial aspect of Cooper's ligaments bilaterally. As another alternative, Mitek bone anchors (DePuy, Norwood, MA) may be used or a small passage through the pubis can be created using a bone drill. Use of a laparoscopic tacker is not recommended and should be avoided—the fixation is not durable enough.
- Once the prosthesis is sutured cranially and caudally, the fixation begins laterally. We place a Kocher clamp

on the medial edges of the anterior rectus fascia and bring the two sides in opposition to allow an accurate measurement of the lateral distance from the midline for the lateral point of mesh fixation. The mesh should be flat, without wrinkles. Start with the middle of the retrorectus space. The corners of the mesh should be the middle of the distance from the cranial and caudal extent of the repair. A 3-mm stab wound is then made on the anterior abdominal wall about 2 or 3 cm lateral to the lateral edge of the retrorectus space—this provides a bit more "lateral" pull and is easier to pass the suture passer into the retrorectus space. The mesh is folded over on itself to provide a two-layer fixation point in the mesh, and a horizontal suture is placed. The two sutures are pulled out the stab wound individually being certain that the two insertions of the suture passer are at least 1 cm apart on the fascia. The insertion of the suture passer should be done fully under vision to be certain that the inferior epigastric artery/vein complex is not injured, that the suture passer does not go through the posterior rectus fascia, and that an exposed nerve is not incorporated in the horizontal suture.

- Cranially and caudally, three additional transmural fixation sutures are placed per side.
- Prior to tying down the transmural sutures, the excess prosthesis is excised. As the sutures are tied down, the knot is pushed through the subcutaneous tissue to lie on the anterior surface of the fascia. The surgeon's hand should be placed in the retrorectus space to be certain that the mesh is pulled up firmly when the knot is tied.
- Once the mesh is fixed in place (**FIG 10A**), we put one or two closed suction drains into the retrorectus space anterior to the mesh but posterior to the rectus muscle. The drains exit the abdominal wall cranially rather than caudally where there are more skin bacteria (**FIG 10B**). The drains are removed the next day and are there only to evacuate any blood or fluid that forms in the first 24 hours postoperatively. Because this retrorectus space is compressed both anteriorly and posteriorly, seroma formation is rare.

Special Situations

- *Special situation 1*. If the medial aspect of the rectus muscle has been resected or has atrophied, the mesh can be placed lateral to the rectus muscle by developing a plane posterior to the internal oblique muscle and

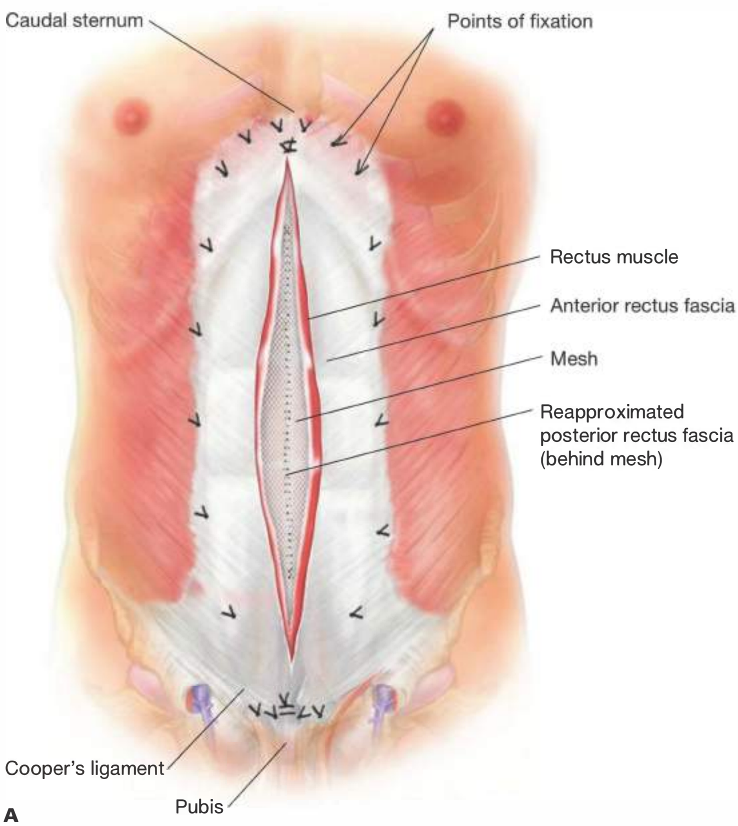

FIG 10 ● Circumferential fixation of the prosthesis. **A.** The prosthesis is fixed at the lateral, cranial, and caudal edges of the retrorectus space. If necessary, the prosthesis is sewn/fixed to the distal sternum and pubis. If the security/strength of fascial fixation is questionable cranially, the prosthesis can be sewn to the costal margin and caudally to Cooper's ligaments. The prosthesis should be flat and without wrinkles but should not be taut because some shrinkage is inevitable. *(continued)*

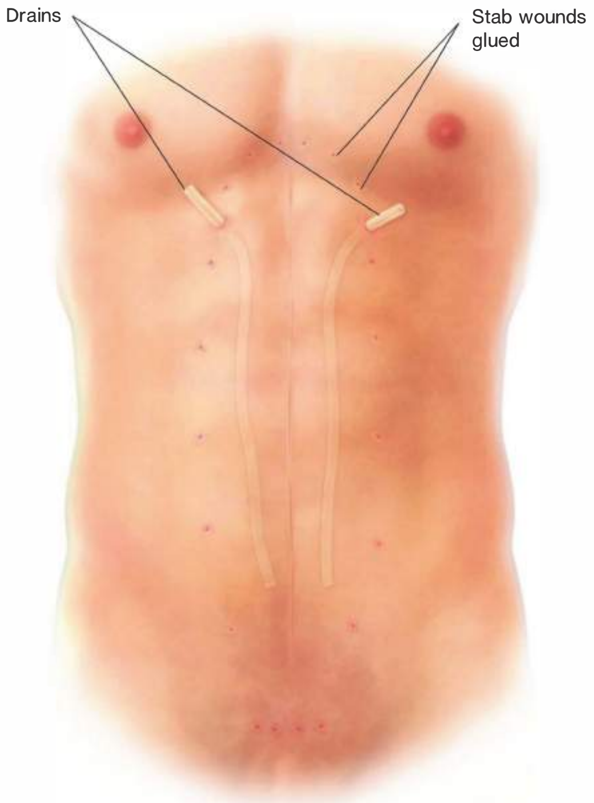

FIG 10 ● *(continued)* **B.** One or two closed suction drains are placed anterior to the prosthesis and brought out cranially.

anterior to the transversalis muscle (or even truly preperitoneal if that plane can be developed). In this case, the transmural sutures are passed much more laterally through the external oblique muscle/aponeurosis and internal oblique muscle.

- *Special situation 2*. If the retrorectus space extends anterior to the costal margin, we extend the mesh into this space to maximize overlap. On occasion, the mesh can be fixed to the costal margin for added support using a no. 1 polypropylene suture.

Closure of the Wound

- Once the mesh is secured, the medial borders of the anterior rectus fascia are reapproximated anterior to the prosthesis with a running no. 1 polydioxanone suture. Ideally, the rectus fasciae are sutured over the mesh, even if under moderate tension. If the fascia cannot be reapproximated, then consideration should be given to performing a components separation technique to allow autologous tissue closure over the mesh. We try not to bridge a fascial defect with a retrorectus repair (and thus exposing the mesh to the subcutaneous space) unless there are extenuating circumstances preventing either an intraperitoneal sublay (covered anteriorly with the peritoneum or the hernia sac or the ability to add a components separation technique to allow midline fascial closure) (see Part 2, Chapter 5).
- The subcutaneous tissue is closed with a running 2-0 polyglycolic acid suture and the skin with a dermal (subcuticular) 3-0 polyglycolic acid suture. The stab wounds are glued with Dermabond™ (Ethicon, Inc).

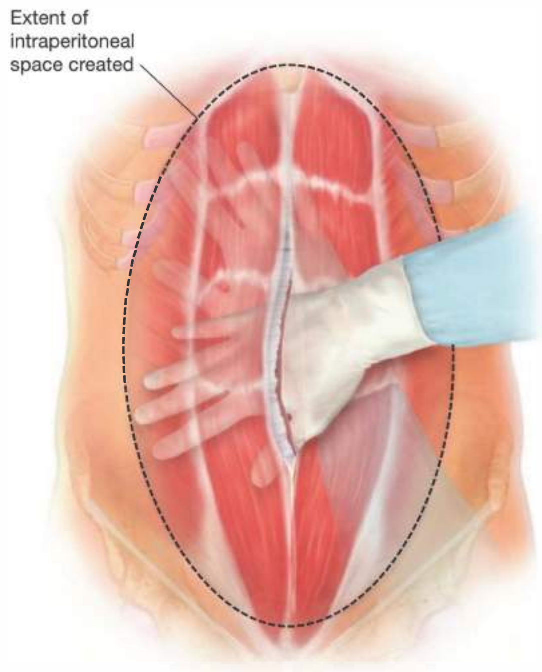
INTRAPERITONEAL SUBLAY REPAIR (ALSO REFERRED TO AS INTRAPERITONEAL ONLAY MESH)

Placement of Incision

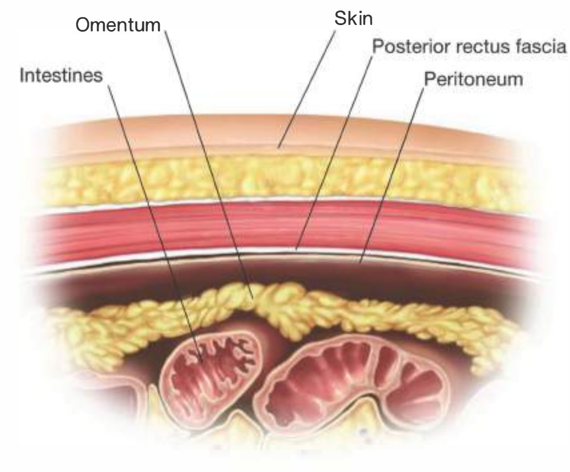
- The incision should be centered over the defect, resecting the prior incision and associated subcutaneous scarring. Because the placement of the prosthesis will be intraabdominal, the length of the incision needed will be determined by the amount of intraperitoneal adhesions and the ability to work through the incision created to place the prosthesis safely.

Creation of Space for Prosthesis

- Because the prosthesis will be placed intraperitoneally, there is no need to mobilize skin and subcutaneous flaps unless a concomitant components separation is planned; thus, the peritoneal cavity should be entered directly through the hernia sac (provided this can be done safely). The hernia sac should not be further mobilized or resected at this time; it will be used as an autogenous tissue barrier to close over the intraperitoneal prosthesis (as described later).
- If there are no concerns about obstructing adhesions (obstructive symptoms preoperatively), the dissection should free the intraperitoneal viscera off the posterior surface of the abdominal wall for 5 to 7 cm from the hernia defect circumferentially (**FIG 11**).
- If the hernia defect extends to the xiphoid, a space is created under the xiphoid by mobilizing the underlying triangular fat pad cranially for 5 cm.
- If the hernia defect extends to the pubis, then the preperitoneal space posterior to the pubis is dissected by mobilizing the space anterior to the bladder to allow fixation of the prosthesis to the bony pubis. For large hernias, this retropubic preperitoneal space can be further mobilized to allow a broader fixation of the prosthesis to Cooper's ligaments on both sides.
- Whenever possible, the omentum should be preserved and positioned between the posterior surface of the



A



B

FIG 11 ● Intraperitoneal mobilization. The posterior surface of the anterior abdominal wall is dissected free of any attachments of intraperitoneal content (bowel, omentum, liver) (see **B**). An intraperitoneal free space is dissected 5 to 7 cm cranial, lateral, and caudal past the edges of the fascial defect.

prosthesis and the intestine—this maneuver will minimize adherence of the bowel to either the prosthesis.

Choice of Prosthetic

- The prosthetic should allow transgrowth from abdominal wall but not adherence to the intraperitoneal contents. Several choices are available. Prostheses made from ePTFE have been used, and there will be no adherence of the viscera to its posterior surface, but there will also be no transgrowth into its anterior surface—therefore, we do not suggest using an ePTFE prosthesis. Several "composite-type" prostheses are available; these prostheses have two panels that are bound together—the anterior panel is a meshed synthetic prosthetic (usually polypropylene or polyester) that allows transgrowth, whereas the posterior panel is a thin layer of ePTFE that will prevent adherence of the intraabdominal viscera. The third type of prosthesis is a meshed synthetic prosthetic (polypropylene, Dacron, or polyester) with its underside coated ("protected") with a nonadhesive, proprietary barrier designed by the manufacturer to be hydrolyzed or reabsorbed in the first several days or weeks postoperatively; in so doing, this barrier is designed to prevent the intraabdominal viscera from adhering to the posterior surface of the synthetic mesh. In contrast, the anterior surface of the meshed prosthesis allows transgrowth from the posterior surface of the abdominal wall.

Placement/Fixation of the Prosthesis

- The prosthesis is fashioned to provide 5 to 7 cm of extension beyond the hernia defect circumferentially. The size of the prosthesis will vary depending on whether the fascial edges of the defect will be able to be sewn together or whether the defect will be bridged or patched; now is the time to determine this before mesh fixation.
- The mesh is sewn in place with multiple transmural sutures and not just by sewing the prosthesis to the posterior fascial layers of the abdominal wall. It is best to start with the four "corners" to size the prosthesis. A stab wound is made at least 7 cm lateral to the edge of the defect. Sutures are then passed through the abdominal wall using some form of suture passer. See the details for suture placement as described for the retrorectus repair (see **FIG 9**). The points of fixation require an intact fascia and not just muscle or fat through which the suture is passed.
- Attempts to fix the prosthesis to the undersurface of the abdominal wall from within the peritoneal cavity are not as reliable; such attempts are relatively blind, and although the posterior rectus fascia can be caught in the suture reliably, sutures placed lateral to the rectus muscle may only include the transversus abdominis and internal oblique fasciae (and not the external oblique fascial aponeurosis) which are not as strong or reliable for points for fixation.
- We place transmural sutures at 1- to 2-cm intervals circumferentially (**FIG 12**). As a general rule, the distance between the sutures should be roughly equivalent to the width of the horizontal mattress suture bites in the prosthesis.
- The goal of the suture fixation is twofold—first, to immobilize the prosthesis with a strong, stable anterior

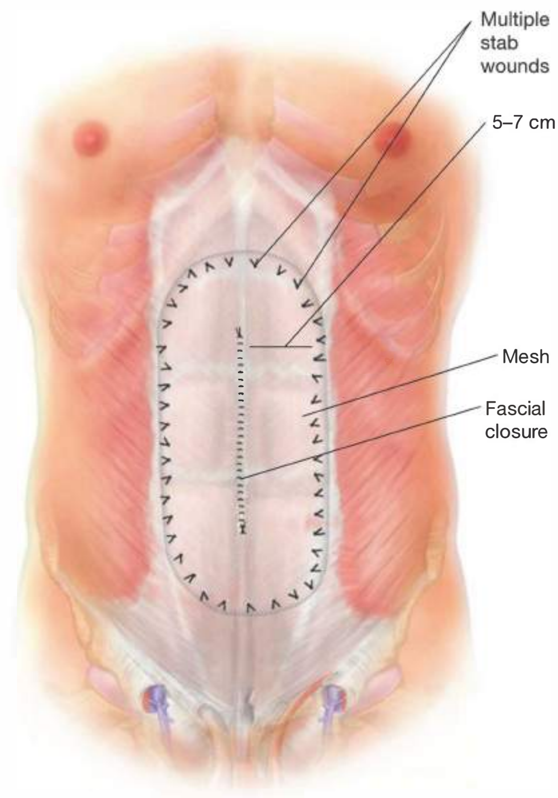


FIG 12 ● Placement of prosthesis. Using stab wounds and the suture passer (see **FIG 9**), multiple stab wounds are placed at 1.5-cm intervals for placement of transmural suture fixation. Because the prosthesis is intraperitoneal, many more areas of fixation are necessary to prevent intraperitoneal content from slipping anterior to the mesh between the points of fixation.

fixation and second, to obliterate completely any space between points of fixation where a loop of bowel can slip between the anterior surface of the prosthesis and the posterior surface of the abdominal wall. We stress that the transmural sutures should be placed close enough that there is *no* possibility that a loop of bowel can "herniate" between these transmural sutures. An alternative technique is to place several laparoscopic ports laterally to allow access after the wound is closed; then a laparoscopic tacker can be used to tack down the edges of the mesh between points of suture fixation, similar to the laparoscopic repair. We do not consider the use of a laparoscopic tacker alone without the use of multiple closely spaced transabdominal sutures to provide an adequately fixed, durable repair.

- For hernias that extend up to or within 5 cm of the xiphoid, the transmural fixation needs to pass directly through—not the xiphoid—but the distal sternum into the retrosternal intraperitoneal space. We use two permanent sutures in this region. These fixation sutures will fixate the prosthesis solidly and durably under the xiphoid, minimizing suture pullout. Technically, this may be accomplished in a number of ways. The Endo Close™ (Covidien Surgical) suture passer may be used, although it may become dulled or the tip bent and may need to be replaced. Suture with a CTX or larger needle can be partially straightened and passed through the distal sternum with some effort. The Reverdin needle is an excellent alternative, allowing passage of suture from the internal to external direction; the sharpness and heavy body of the instrument facilitate its use for this purpose. Again, avoid the too-sharp non-disposable metal Carter-Thomason suture passer.
- When the hernia extends caudally down to or within 5 cm of the pubis, the prosthesis should be sewn to the pubis. We use at least four separate no. 1 polypropylene sutures on a large, heavy needle. The needle should be passed through the bone of the pubis—not just the periosteum. If the tissues are too dense to allow passage of the needle, a penetrating towel clamp can be used to create a small passage through the bone or a bone drill may be needed. Alternatively, Mitek bone anchors may be used. Use of the laparoscopic tackers is not recommended—these limited points of fixation are not reliable. An additional 3 to 4 cm of the prosthesis can be positioned posteriorly between the bladder and the posterior surface of the pubis.
- Additional medial transabdominal fixation sutures can be placed circumferentially if there is concern about stability of the lateral fixation sutures.

Closure of the Wound

- We place one or two temporary, closed suction drains anterior to the prosthesis to encourage close apposition of the peritoneum to the prosthesis.
- The peritoneum and/or the preserved hernia sac is closed anterior to the mesh, providing an autologous layer of tissue on top of the mesh.
- The fascial edges of the hernia should be reapproximated. If there is tension, relaxing incisions or components separation should be contemplated to allow for fascial closure. To restore anatomic position of the abdominal wall musculature, close the fascial defect, and provide another layer of autogenous tissue over the prosthesis. Alternatively, a more "closed" type of components separation, either "laparoscopic" or "minimal incision," perforator-sparing type can be performed understanding that these approaches will only yield 3 to 4 cm of a medial advancement on each side (see Part 2, Chapter 5). If the edges of the fascia cannot be reapproximated, one can bridge the defect with an inlay of absorbable mesh of polyglycolic acid using Dexon™ (Covidien Surgical) with the aim of temporarily relieving the tension on the lateral fixation points. Use of second layer of a permanent synthetic prosthetic is not indicated because the hernia repair has already been accomplished with the intraperitoneal permanent prosthesis. Use of

the expensive bioprostheses is discouraged because of prohibitive cost (versus the temporary absorbable mesh) and the lack of defined efficacy either in relieving lateral tension or equally important as providing a durable, onlay-type patch repair.

- The incision is then closed with a running 2-0 polyglycolic suture and the skin with a running 3-0 polyglycolic acid dermal suture. The stab wounds are glued with Dermabond™ (Ethicon, Inc).

COMBINED RECTUS ROLLOVER/ COMPONENT SEPARATION WITH PROSTHESIS UNDERLAY

General Considerations

- This is a combination of several techniques to provide maximal medial reapproximation of the musculoaponeurotic walls. It is particularly useful for large midline defects when the abdominal wall musculature is largely intact. Closure of defects up to 15 cm in width are possible with this combination technique.
    - The rectus rollover is a modification of a components separation technique. The anterior rectus sheaths are incised vertically just medial to their lateral borders along their entire length. The anterior rectus sheaths are then dissected off the muscle to a point 2 cm lateral to the medial edge of the rectus muscles. During suturing, the sheath is rolled anteromedially (**FIG 13**).
    - The external oblique can be incised vertically just lateral to the rectus sheath as done for components separation (see Part 2, Chapter 5).
    - An underlay prosthesis is placed intraperitoneally, preperitoneally, or retrorectus and secured with interrupted, transabdominal, horizontal mattress sutures.
- Skin flaps are raised off the musculoaponeurotic walls bilaterally as for the wide onlay technique. Care must be taken to not incise or buttonhole the fascial layers, but no fat should remain on the musculoaponeurotic wall.
- A vertical incision is made in the anterior rectus sheath, about 1 cm medial to the lateral border (see **FIG 13**). The anterior rectus sheath is mobilized off the anterior surface of the rectus abdominis with electrocautery progressing in a medial direction to about 2 cm lateral to the medial border of the rectus muscles.
- A components separation division of the external oblique can then be created laterally, if needed, using a vertical incision of the external oblique about 1 to 2 cm lateral to the lateral border of the rectus sheath (see Part 2, Chapter 5).
- An underlay prosthesis is chosen based on the principles outlined earlier in this chapter. Sizing is to provide an overlap of at least 5 cm circumferentially; ideally, the prosthesis will be sutured just outside the lateral border of the rectus sheath. Horizontal mattress sutures are placed using a large needle such as a CTX or a suture passer. The width of the horizontal mattress sutures should be about 1.5 cm, and the spacing of the sutures should be the same.
- Once all sutures have been placed, the prosthesis is snugged up to the abdominal wall. If the prosthesis is placed intraperitoneally, the prosthesis is carefully examined to make certain no intraabdominal contents have slipped between the sutures; this is done repeatedly as the sutures are pulled up and tied.
- The fascia is then approximated in the midline using a running horizontal mattress suture; we prefer a no. 1 looped polydioxanone suture for this step. Bites are taken after medializing the anterior rectus sheath (**FIG 13**); they should reapproximate the rolled-over edges of the anterior rectus fascia in the midline. When completed, very near normal anatomy is restored, although the rectus muscles will not be approximated (**FIG 13**).

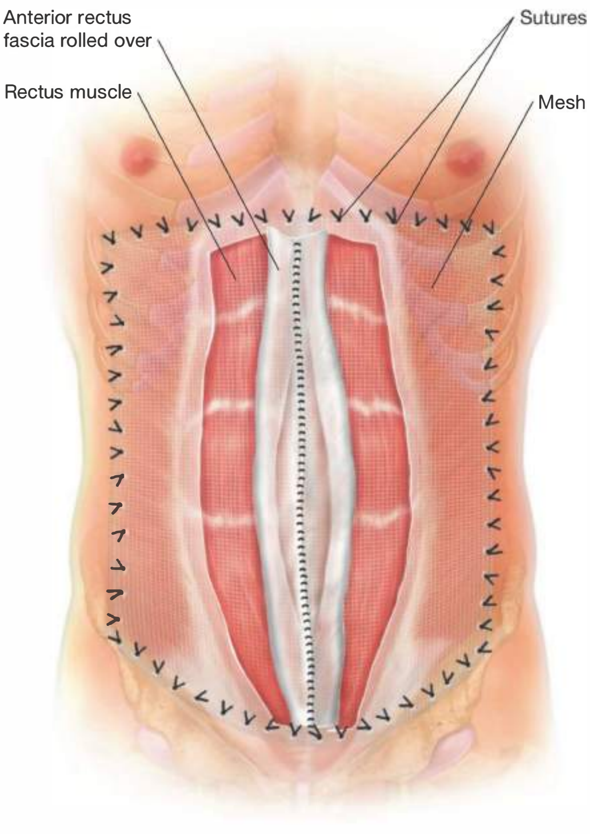

FIG 13 ● Completed intraperitoneal sublay with anterior rectus rollover fascial closure. Note medial edges of rectus muscles not approximated.

FLANK HERNIAS

General Considerations

- Flank hernias (after a flank incision, such as kidney/ureter or anterior spinal access procedures) are different functionally from most incisional hernias, as they have higher recurrence rates. Flank pseudohernias are bulges in the musculofascial components of the lateral abdominal wall secondary to denervation and should be noted prior to operation with a CT because surgical bolstering of pseudohernia have not yielded satisfactory results.
- Repair of a flank hernia is not as straightforward as repair of midline incisional hernias; the points of fixation of the prosthesis are not as reliable. Although onlays and sublays (intramural or intraperitoneal) have been described, we believe strongly that for these difficult hernias, an intramural, synthetic mesh-based repair is best because it provides the most durable and reliable fixation of the prosthesis.

Step 1: Patient Positioning

- If the hernia is located more medially and does not extend past the anterior axillary line, the patient is placed in a "modified lateral" position with the ipsilateral side rotated medially to allow free access to as far posteriorly as the posterior axillary line (**FIG 14A**).
- If the hernia extends further laterally, then a full lateral position (**FIG 14B**) is necessary to allow access to the posterior midclavicular line posteriorly.

Step 2: Development of Intramural Space

- The prior skin incision should be excised down to the hernia sac. Unless necessary, try to stay extraperitoneal.
- Next, a plane is developed posterior to the internal oblique muscle but anterior to the transversalis muscle (**FIG 15**). Attempts to stay in the preperitoneal space cranially can be difficult; caudally, this space is much easier to develop. The goal is to create a space with a large surface area in which to place a synthetic, meshed prosthesis. The space is mobilized to the costal margin cranially, as far laterally as possible (posterior axillary line), to the anterior superior iliac crest caudally and to the lateral edge of the rectus muscle medially.
- If the hernia extends to the lateral edge of the rectus muscle, then the retrorectus space can be entered and mobilized to the midline. The prosthesis lies between the very vascular internal oblique and transversalis muscles to maximize transgrowth. This space is better vascularized than the preperitoneal space.

Step 3: Fixation of Prosthesis

- Once the intramural space has been mobilized with at least a 7- to 10-cm margins from the hernia defect, the

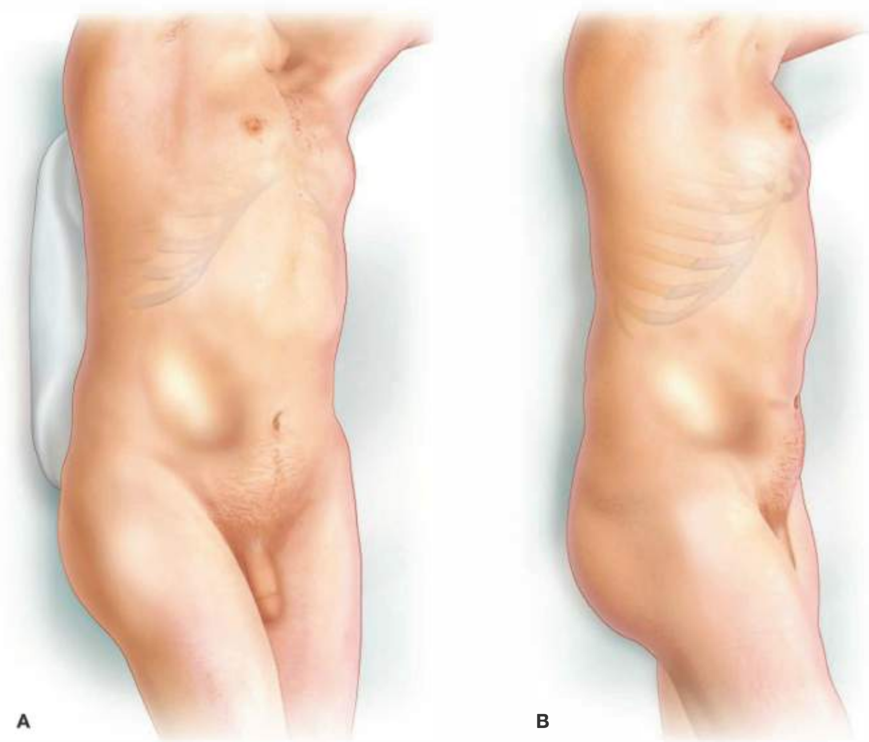

FIG 14 ● Positioning of patient for a flank herniorrhaphy. **A.** When the hernia/bulge does not extend lateral to the anterior axillary line, the patient is placed in a "sloppy" lateral position allowing access to the posterior axillary line. **B.** For defects extending to the midaxillary line, a true lateral position is necessary to allow access to the posterior midclavicular line.

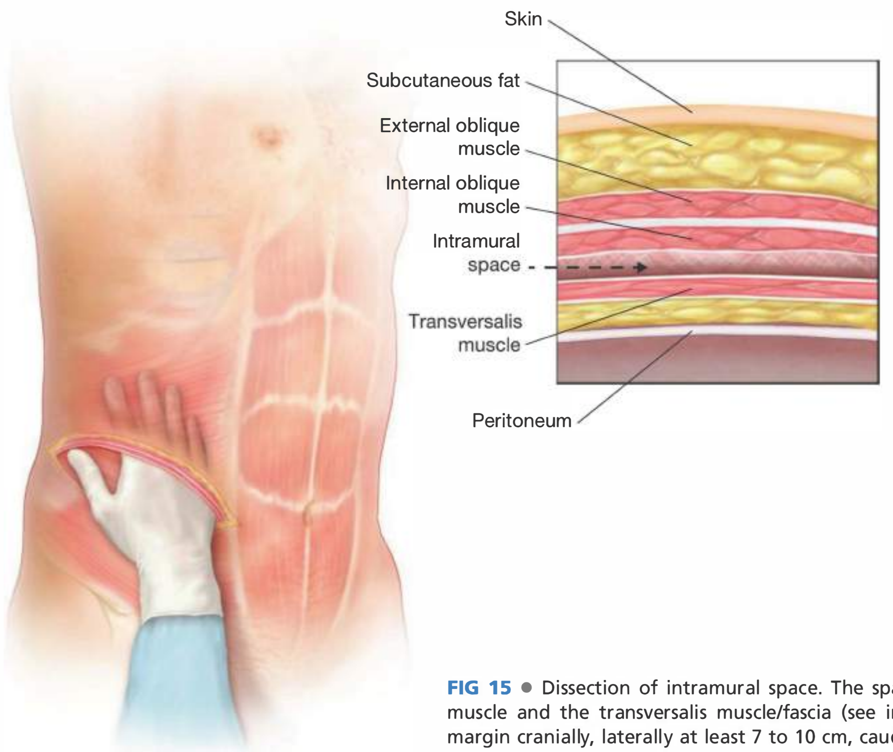

FIG 15 ● Dissection of intramural space. The space between the internal oblique muscle and the transversalis muscle/fascia (see insert) is created up to the costal margin cranially, laterally at least 7 to 10 cm, caudally to iliac crest, and medially to lateral border of the rectus muscle.

meshed prosthesis is fixed with transmural sutures. As described for ventral incisional hernia repairs previously, multiple horizontal sutures of no. 1 polydioxanone are placed along the edge of the prosthesis. Stab wounds are positioned at the extent of the space mobilized (**FIG 15**). Using a suture passer, the ends of the sutures are separately grasped and tied down onto the surface of the abdominal wall fascia. Because the mesh is placed intramurally, there is no concern for bowel becoming entrapped between these sutures, thus the number of sutures should be determined by the quality of the tissue. If the anterior fascia is weak or attenuated, the space needs to be developed further (see later "Special Situations").

Step 4: Closure of the Wound

- A closed suction drain is placed anterior to the mesh brought out cranially.
- The muscle and/or weakened fascial layers anterior to the mesh are reapproximated with a running absorbable suture; the subcutaneous tissue and skin incision are closed with absorbable suture. All the stab wounds can be glued with Dermabond™ (Ethicon, Inc).

Special Situations

- *Fixation to costal margin*: When the musculofascial tissue cranial to the defect is attenuated or the overlap is not at least 5 to 7 cm, the prosthesis can be sewn to the costal margin (**FIG 16**). We use no. 1 polypropylene sutures through and not around the rib; this provides a stable cranial fixation.
- *Fixation to iliac wing*: A more common problem is when the musculofascial tissue caudal to the defect is attenuated or retracted such that the overlap is inadequate; in this situation, we sew the edge of the prosthesis to the anterior iliac spine and the more medial "wing" of iliac bone with no. 1 polypropylene sutures; these sutures pass through the bone and not just in the periosteum (**FIG 16**). The sutures can be placed from within the space created for the prosthesis; but this maneuver takes a bit of force. For very young or large men, we have made an incision in the skin directly over the anterior iliac spine, dissected down to the bone, and used a bone drill through this bone and into the intramural space.
- *Inadequate tissue medially and caudally*: Often, the area medial to the anterior iliac spine is very attenuated. In this situation, we will dissect into the preperitoneal space down to Cooper's ligament and the pubic tubercle behind the inguinal canal. These bony areas can serve as very stable points of medial and caudal fixation of the prosthesis, again with no. 1 polypropylene sutures into and through the bone (**FIG 16**).

FIG 16 ● Fixation of prosthesis. The prosthesis is fixed to the anterior fascia at the edges of the intramural space created, again using multiple stab wounds and a suture passer. The prosthesis can also be sewn to the costal margin cranially and the iliac crest caudally for a more secure fixation. For large flank hernias extending medial to the lateral edge of the rectus muscles, the retrorectus space can be opened to communicate with the intramural space created laterally. The cranial and caudal edges of the fascial defect are then sewn together to cover the prosthesis.

PEARLS AND PITFALLS

Indications	■ Despite lack of systemic symptoms, an acute, nonreducible, incarcerated incisional hernia is an indication for urgent exploration/repair. ■ Review all previous operative notes—surprises in the operating room (OR) are usually not welcome. ■ When repairing a flank hernia, warn the patient that there may still be a bulge. Even with a "successful" repair, these patients can be the least happy postoperatively of all patients after repair of an incisional hernia. ■ Heavy laborers or high-performance athletes will do better with abdominal wall reconstruction (restoration of musculofascial continuity) rather than a laparoscopic patch repair. ■ For patients with lung disease or those with a history of pain intolerance, consider postoperative epidural analgesia or a "one-shot" intrathecal analgesia.
Choice of prosthetic	■ Currently, there are no biologic prosthetics that provide as good a long-term outcome as a synthetic prosthetic. ■ Large pore/lightweight, small pore/heavy weight, and ePTFE all have their advantages/disadvantages. There is little, if any, role for ePTFE for onlay or Rives-Stoppa sublay repair. A protected or "covered" meshed prosthesis of polypropylene, Dacron, or polyester with a layer of either a rapidly absorbable biologic barrier substance (to prevent visceral adherence) or ePTFE facing the viscera for an intraperitoneal repair is preferable to a pure ePTFE because there is no functional ingrowth into ePTFE. The classic role for ePTFE is when the prosthesis needs to be watertight—for example, in the very rare patient with ascites. ■ For laborers or serious athletes, the small-pore/heavyweight prostheses will give more support, but plan for 25%–30% shrinkage in size of the mesh. ■ If the patient has developed suture granulomas in the past to permanent sutures, avoid their use—suture granulomas predispose to superinfection.

Exploration of hernia defect	■ When an unexpected suture granuloma is encountered during the incision, consider aborting the procedure for worry of indolent, inactive bacterial colonization unless you can excise the entire area (i.e., the suture, the associated biofilm, and the cavity/wall are intact). Remove all foreign sutures, culture the area, and use a 2-week course of focused antibiotics postoperatively—we acknowledge that we have no evidence that this treatment is effective. ■ Always look for a Swiss cheese defect along the prior fascial incision distant from the presumed "isolated" hernia defect. ■ When performing a Rives-Stoppa, retrorectus sublay repair in a patient who has had a prior enterostomal takedown (e.g., after takedown of a Hartmann procedure), be aware that a knuckle of bowel may protrude through a defect in the posterior rectus fascia. ■ If the patient has had a recent history of recurrent partial small bowel obstruction, consider an intraperitoneal adhesiolysis in addition to the hernia repair. ■ Weeks to several months after a prior incisional herniorrhaphy, point tenderness laterally may be secondary to a suture granuloma at a fixation point. If possible, inject a local anesthetic to "buy time" and wait for the suture to be reabsorbed. If symptoms persist, locally explore that area and remove the suture.
Early postoperative seroma	■ Should a symptomatic seroma develop within the first postoperative month, repeated percutaneous aspiration may prevent rupture through the incision and subsequent risk of superinfection of the prosthesis. If the seroma persists, then consider a percutaneous drain. Nonresolving "seromas" usually represent the development of a pseudobursa lined with mesothelial cells that produce fluid—if large and symptomatic, these require operative excision of the entire lining. If the seroma is asymptomatic, consider not intervening. ■ When placing lateral fixation sutures, it is possible to encircle a somatic nerve—the resulting early (1 day postoperatively) and persistent pain will follow the dermatome or the distribution of the nerve—for example, intercostal, genitofemoral, or circumflex iliac nerve—and may require early removal of the offending suture, even prior to discharge.
Placement of fixation sutures	■ For intraperitoneal sublay repairs, the surgeon should ALWAYS have his/her hand between the posterior surface of the prosthesis and the abdominal viscera when the sutures are tied. Likewise, there should be NO laxity or space between fixation sutures or tacks.

POSTOPERATIVE CARE

- Most patients will not need a nasogastric tube, but in extended complex repairs, especially with an accompanying adhesiolysis, gastric decompression may be advisable.
- The timing of removal of subcutaneous drains is controversial—drains serve as sites of potential bacterial contamination, yet drains may minimize formation of seromas/pseudobursa. When placed intraperitoneally on the anterior surface of prosthesis or in the retrorectus space, they should be removed early (1st postoperative day). When placed subcutaneously after an extensive, subcutaneous flap mobilization, one must weigh the risk of infection versus that of seroma when deciding to remove the drains. No evidence-based suggestions can be offered.

OUTCOMES

- Recurrence rates with these types of elective repair for anterior abdominal wall hernias (midline or transverse incisions) should be less than 10% to 15% range. Many factors adversely affect recurrence rates, such as multiple prior repairs, hernia size, impaired healing (steroid use, active smoking, chemotherapeutic agents, obesity, etc). "Recurrences" for flank hernias are greater—note the recurrence to the patient may be a "bulge" rather than a true musculofascial/prosthetic defect—preoperative counseling of this possibility and intraoperative planning of the appropriate tension and secure placement of fixation of the prosthesis will minimize this possibility.
- Early or late (even years later) infection of the prosthesis occurs in ~3% of patients. Prior wound infections, usually with *Staphylococcus* species and especially methicillin-resistant *Staphylococcus aureus* (MRSA), appear to increase the risk of prosthetic infection. Whether preoperative clearance of nasal, vaginal, and rectal MRSA colonization is effective is unproven.
- Postoperative, subcutaneous wound infections require immediate, aggressive treatment to prevent underlying infection of the prosthesis, even if there is autogenous tissue between the prosthesis and the subcutaneous space.
- A nonreducible bulge/mass that develops directly under the incision with the first 6 weeks is likely a seroma and often does not require further investigation; ultrasonography will differentiate seroma from recurrence. Not all seromas require intervention, and many will reabsorb over time. Cognizance of this possibility will prevent unnecessary aspiration or especially placement of a drain, both of which can introduce bacteria and secondary infection. Fever, pain, increase in size, or nonresolution warrant aspiration.

COMPLICATIONS

- Bleeding/hematoma—usually contained
- Seroma—appears within first several weeks postoperatively; if persistent for weeks or months, suspect formation of a mesothelial-lined pseudobursa. These are more common with an onlay prosthesis, especially ePTFE or when the herniorrhaphy is combined with an abdominoplasty.

- Subcutaneous wound infection—~2% to 5% but depends on extent of lateral dissection
- Skin necrosis at medial edge of incision after wide lateral mobilization of a skin/subcutaneous flap; with an abdominoplasty, minor wound problems may approach 40%.
- Prosthetic infection, both early (first 2 months) or late (months to years later)—3%
- Recurrence—approximately 10% to 15%; often, the recurrence is at the cranial or caudal end of the prior hernia defect
- Radiculopathy from a somatic nerve trapped by a fixation suture, though rare, can complicate an abdominal wall reconstruction.
- Suture granuloma at fixation site
- Small bowel obstruction from the intraperitoneal part of the hernia mobilization and prosthetic placement of the prosthesis; the obstruction is either related to adhesions or rarely between adjacent fixation points if the space left was too large or too loose. In theory, the fixation suture can trap a loop of bowel within the suture—this should lead to a very early obstruction 1 or 2 days postoperatively.
- Unrecognized enterotomy at the time of hernia repair

Chapter 4

Incisional Hernia: Laparoscopic Approaches

Todd Heniford Kristopher Williams

DEFINITION

- Incisional hernia is defined as any abdominal wall defect occurring at the site of previous operation or scar. Laparoscopic incisional hernia repair uses prosthetic mesh reinforcement, much like as originally described by Stoppa,[1] applied through minimally invasive operative techniques with reliable success.[2]
- Incidence of incisional hernia following laparotomy exceeds 20% with over 2 million laparotomies performed in the United States annually, a factor contributing to the estimated 348,000 ventral hernia repairs in 2006.[3,4]
- Recurrence rates for primary suture hernia repair have been reported to be as high as 54%,[5] which have been reduced by more than half with the use of mesh reinforcement.[6,7]

DIFFERENTIAL DIAGNOSIS

- Diastasis recti
- Seroma
- Hematoma
- Abdominal wall abscess
- Hypertrophic scar
- Desmoid
- Abdominal scar endometrioma (at sites of previous cesarean or hysterectomy incisions)
- Soft tissue sarcoma

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed general health history should be obtained including past medical history, current medications, allergies, social habits (alcohol, illicit drug use, smoking history) as well as previous adjuvant treatments, which may impact any attempt at operative repair (e.g., previous pelvic or abdominal radiation). Consideration of other common abdominal pathology, such as symptomatic cholelithiasis or colon cancer, may need evaluation prior to hernia repair and results should be documented.
- A detailed history regarding obstructive symptomology (nausea, vomiting, passage of flatus, bowel frequency, abdominal pain) the patient may have experienced in the recent or distant past should be recorded.
- For all patients undergoing evaluation of incisional hernia, medical records should be obtained and reviewed, emphasizing surgical history and operative reports from previous pertinent surgeries and hernia repairs. Attention should be directed toward specifics of previous abdominal operations, especially hernia repairs: anatomic location of initial hernia defect, previous attempts at hernia repair, presence and type of previously placed mesh, location of any previously placed mesh (intraperitoneal, preperitoneal, retrorectus, fascial onlay, etc.), method of mesh fixation, and previous operative complications. Also, the extent of previous skin and subcutaneous dissection and the presence and extent of a components separation can be very helpful.
- The presence of comorbidities known to be associated with increased risk of postoperative wound complications or recurrence (current or smoking history, obesity, diabetes, immunocompromised status, cirrhosis, chronic obstructive pulmonary disease [COPD], current or chronic infections such as urinary or pulmonary infection, history of previous mesh or other methicillin-resistant *Staphylococcus aureus* [MRSA] infections), as well as any history of previous or current wound infections and any current abdominal wall wound issues should be noted.
- A complete physical exam should be performed paying particular attention to the existence and location of abdominal scarring, nonhealing wounds, erythema that may indicate deeper pathology, identification of any abdominal wall defects (either incisional or primary), presence and nature of hernia contents within defects, reducibility of hernia contents, and tenderness to palpation of noted defects. Fascial defect size should be estimated to aid in preoperative planning.
- Other physical findings or review of symptoms points may alert a surgeon to medical issues that require workup prior to surgery, such as heart failure, COPD, vascular disease, liver or kidney disease.
- A thorough examination should be performed looking for the existence of other potential hernia sites (umbilical, inguinal, femoral, parastomal, etc.), which may be addressed at the time of surgery. By neglecting other potential hernias, the opportunity to repair them at the same time as the primary hernia may be lost.
- The presence of a gastrointestinal stoma, active wound infection, or chronic draining sinus tracts should also be taken into account, as these situations influence operative planning, risk counseling, and may influence an open versus a laparoscopic repair. A laparoscopic repair with synthetic mesh placement is not appropriate for an actively infected field.
- The presence of peritoneal signs (abdominal rigidity, guarding, rebound tenderness) should alert the surgeon to the likelihood of intraabdominal issues and may mandate an emergent laparotomy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Although physical exam is the gold standard of diagnosis, obese body habitus, abdominal scarring, and the presence of previously placed mesh may preclude physical diagnosis of an incisional hernia. For these reasons, computed tomography (CT) is a valuable tool for diagnosis and operative planning in cases of a suspected incisional hernia (**FIG 1**).

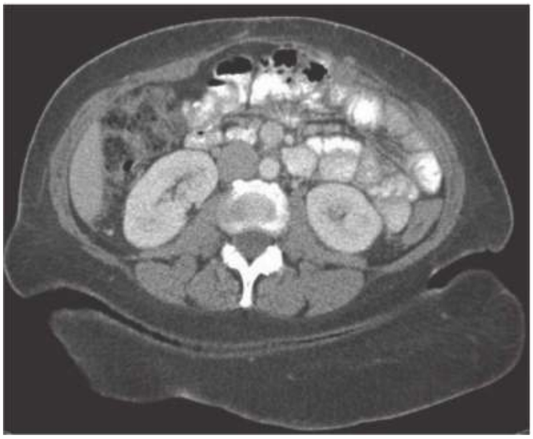

FIG 1 ● CT incisional hernia. A 51-year-old female with multiple gastric revisions since undergoing original gastric bypass, eventually resulting in completion gastrectomy. CT shows 7-cm incisional hernia defect containing normal-caliber small bowel with intraluminal contrast.

- Advantages of CT imaging for the evaluation of incisional hernias are multifactorial: accurate diagnosis in cases of obscure or small defects; proper identification of hernia contents (small bowel, colon, solid organs, omentum, etc.); definition of defect size; location of previously placed mesh; distinction from other or concomitant potential diagnoses (seroma, abscess, hematoma, etc.); identification of bowel incarceration; obstruction or possible ischemia, necrosis, or perforation; and planning of where to enter the abdomen safely.
- When feasible, it is helpful for the operating surgeon to review the actual CT images, as the information discussed earlier may not be included in a radiologist's reading of the films. It is also helpful to have CT images available to be viewed intraoperatively as they can serve as a reference during the operative procedure.
- Colon cancer screening with colonoscopy or other appropriate means is often considered for those patients who have reached appropriate age for screening, have a significant family history, or other colonic symptoms prior to hernia repair.

SURGICAL MANAGEMENT

Preoperative Planning

- For elective procedures, in the weeks leading up to repair, attempts should be made at optimization of preoperative patient factors associated with increased risk of postoperative wound complications: smoking cessation, evaluation and maximization of nutrition status, tight blood glucose control, weight loss in the obese, or elimination of open wounds through local wound care.[8]
- Appropriate intravenous antibiotic prophylaxis should be administered prior to incision and repeated as needed to provide adequate prophylactic coverage depending on length of procedure and drug half-life.[9]
- Venous thromboembolism prophylaxis should be provided, such as lower extremity serial compression devices or subcutaneous prophylactic dose heparin prior to induction of anesthesia, assuming no contraindications.[9]
- Following induction of anesthesia, the abdominal wall is reexamined to confirm the borders of the defect in question and to identify the presence or location of previous mesh, signs of infection, or other issues.
- Intraoperative urinary and gastric decompression are recommended.
- Iodophor-impregnated adhesive skin drape may be used to minimize mesh contact with skin surfaces and therefore reduce the risk of mesh infection, although this has not been proven in randomized clinical trials.

Positioning

- The patient should be positioned supine with arms adducted and tucked at sides of body with adequate padding of pressure points to avoid neurologic pressure injury. This allows movement of the surgeon and the assistant on each side of the table during the operation (**FIG 2**).
- Semilateral or lateral decubitus position may be favored for repair of flank or lumbar hernias.
- The patient should be secured to the operating table to allow steep positioning or rolling of the table as required during the procedure.
- Laparoscopic monitors should be positioned over the working space to allow direct vision by both the primary surgeon and assistant.

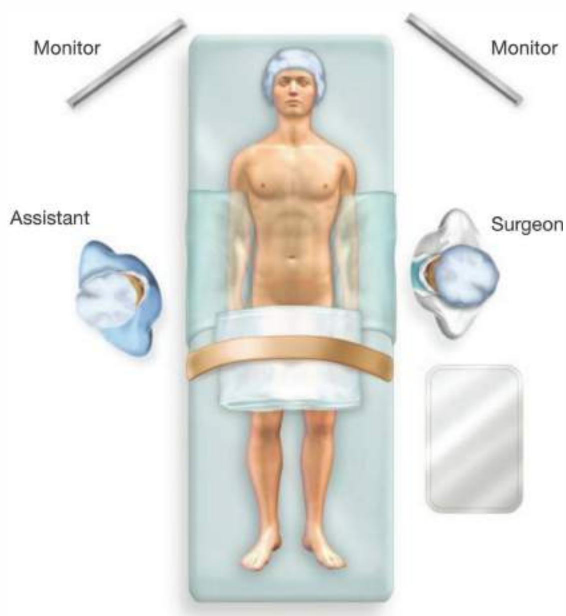

FIG 2 ● Patient positioning. The patient is placed supine on the operating table with arms adducted and monitors positioned toward the head of the table. The surgeon stands on either side of the patient, depending on hernia location, with the assistant directly opposite.

INITIAL ACCESS

- A safe window of intraperitoneal access is usually available in areas distant from site(s) of previous surgery, although an open, "cut-down" technique can be performed near or within a hernia if the surgeon prefers.
- Often, safe entry is found just inferior to the tip of the 11th rib, between midclavicular and anterior axillary lines (**FIG 3**).
- Open cut-down technique is most often performed with identification of individual abdominal wall layers as each is entered, but some surgeons use a port that allows visualization of the abdominal wall layers with the laparoscope as the trocar is slowly advanced into the abdomen.
- Pneumoperitoneum is established at 12 to 15 mmHg.

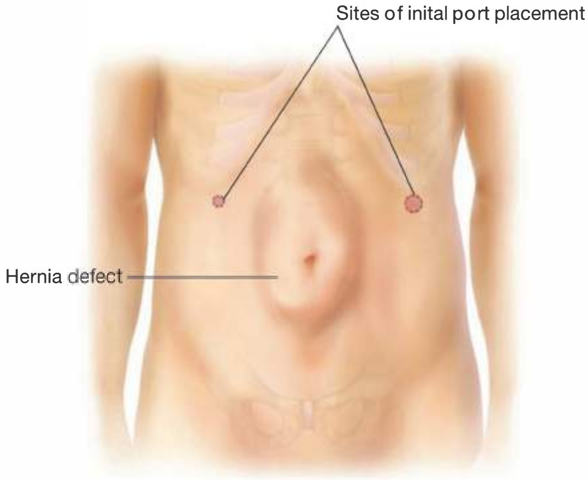

FIG 3 ● Initial port placement. Safe areas of initial trocar placement via the cutdown technique are often found just inferior to the 11th rib between the midclavicular line and the anterior axillary line.

PLACEMENT OF WORKING PORTS

- Using an angled (30- or 45-degree) scope, a brief general inspection of the abdominal cavity checking for organ injury, which may have occurred during initial access, is performed.
- Working port placement is based on target defect location, optimization of working space, and triangulation of working instruments, if possible. Ports that are too far caudal or cephalad may limit freedom of motion of the port due to the hip or rib cage (**FIG 4**).
- Ideal port placement allows sufficient working space between ports and target defect. The distance between individual ports should allow a range of motion that prevents ports from colliding or limiting motion. Ports should not be too close to the hernia defect as this limits visualization for mesh placement or mesh fixation.
- Additional 5-mm trocars are placed under direct visualization (**FIG 5**).
- Often, two 5-mm trocars are placed laterally on same side as initial access port, usually between anterior and midaxillary lines.
- One or two 5-mm trocars can be placed on the contralateral side of initial access port for adhesiolysis or to facilitate mesh fixation.

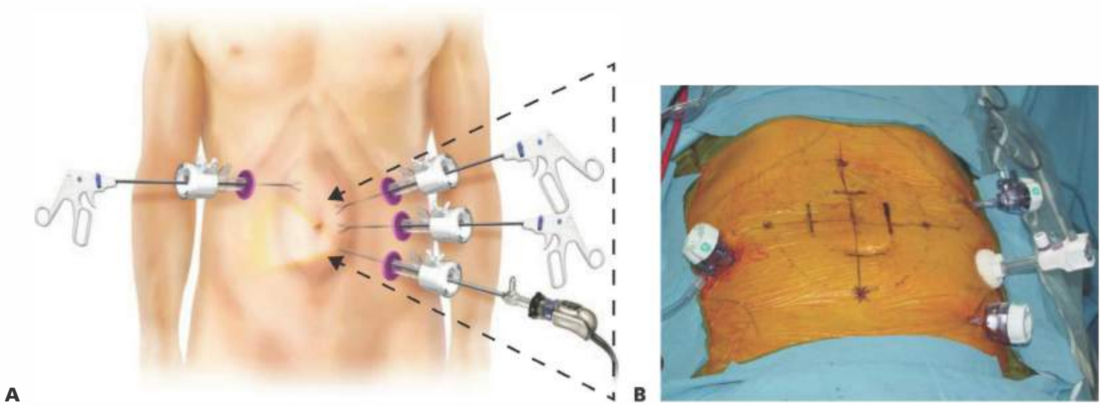

FIG 4 ● Working port triangulation. Figure **A** shows diagrammatic representation of working triangulation to target defect. Figure **B** is an intraoperative view of working ports.

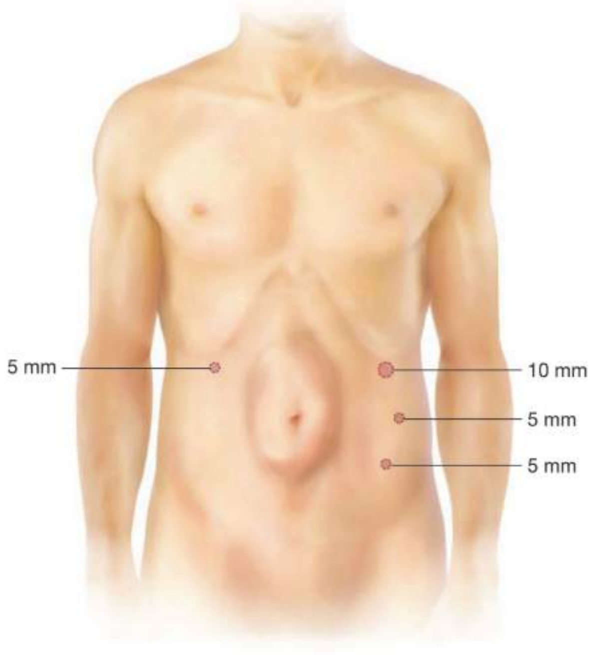

FIG 5 ● Port sizes and position. Positioning of initial 10-mm port and 5-mm working ports for midline periumbilical incisional hernia. Two 5-mm ports are placed on the ipsilateral side of initial access and a single 5-mm port is placed on the contralateral side.

LYSIS OF ADHESIONS AND DEFINITION OF HERNIA DEFECT

- Pneumoperitoneum assists in dissection as countertraction is provided by weight of dependent omentum and bowel to expose safe tissues planes (**FIG 6**).
- Meticulous lysis of adhesions is performed using sharp dissection with minimal judicious electrocautery to avoid thermal spread and bowel injury (**FIG 7**).
- The majority of operative time is often spent performing the adhesiolysis. An enterotomy can increase the risk of mesh infection and, in cases of gross spillage, placement of prosthetic mesh is contraindicated. A bowel injury may result in the need for conversion to an open procedure, may necessitate the use biologic mesh or hernia closure without mesh, or the need for staged repair.
- Freeing the adhesions along the entire length of incision often allows the surgeons to identify all defects

FIG 6 ● Lysis of adhesions. Pneumoperitoneum assists in dissection.

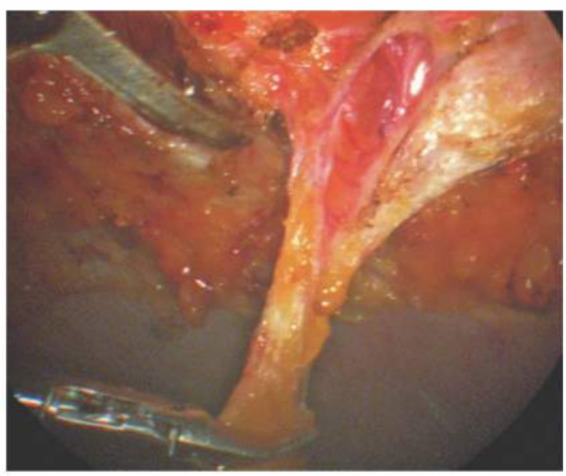

FIG 7 ● Lysis of adhesions. Meticulous adhesiolysis performed to expose entire length of incision.

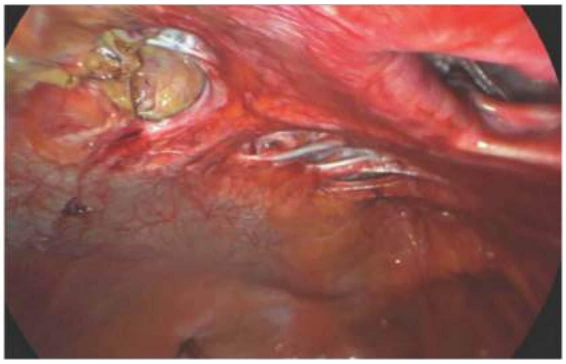

FIG 8 ● Swiss cheese defect. Multiple defects can be seen following complete exposure of incision length.

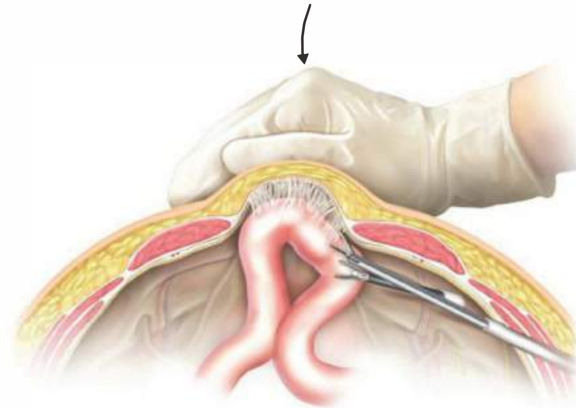

FIG 9 ● External manual reduction. External pressure applied to abdominal wall can aid in intraoperative reduction of hernia contents.

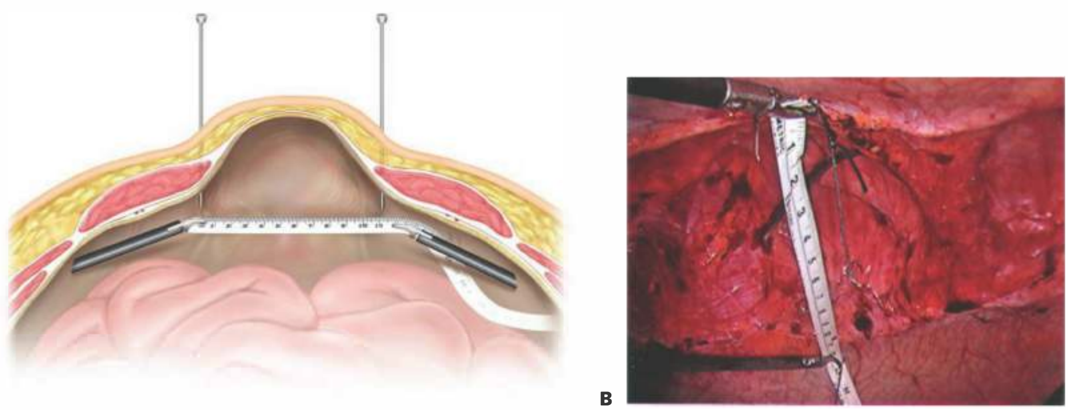
("Swiss cheese" or buttonhole abdominal wall defects), which otherwise may have gone unnoticed and therefore unrepaired (**FIG 8**).

- Hernia contents can be reduced by applying gentle traction using nontraumatic graspers.
- Simultaneous external manual compression of the hernia sac is helpful in reducing contents (**FIG 9**).
- The hernia sac is left in situ.
- The hernia defect edges are measured externally and marked on patient's skin.
- Length and width of the abdominal wall defect is precisely measured intraabdominally using a narrow plastic disposable ruler introduced through a port.
- A spinal needle is used to penetrate the abdominal wall along the internally visualized defect edges to accurately define boundaries (**FIG 10**).
- The falciform ligament and umbilical ligaments may be taken down to allow flush placement of mesh against anterior abdominal wall.



A B

FIG 10 ● Measurement of defect. Figure **A** shows diagrammatic representation of defect measurement using a narrow disposable ruler and spinal needles to define exact borders. Figure **B** shows intraoperative defect measurement.

MESH PREPARATION AND INTRAPERITONEAL INTRODUCTION

- An appropriately sized sheet of mesh is chosen and tailored to overlap defect edges by minimum of 4 to 6 cm circumferentially. Proper mesh to fascia overlap allows for even distribution of intraabdominal forces across peritoneal surface of the mesh and aids in holding the mesh in place according to Laplace's law (**FIG 11**).[10]
- Use of a mesh product constructed with a visceral adhesion barrier to prevent the formation of future adhesions is highly recommended.

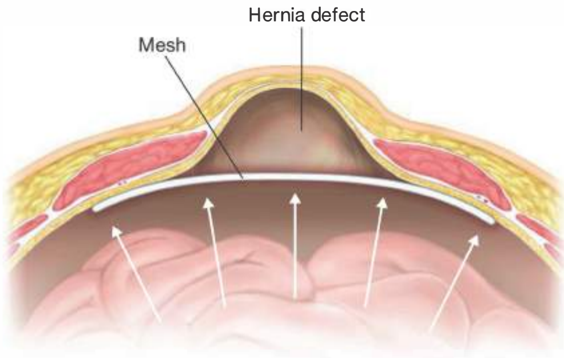


FIG 11 ● Intraabdominal forces on mesh. The intraperitoneal mesh is held in place by the intraabdominal forces acting to push the mesh against the abdominal wall as long as sufficient mesh/defect overlap of 4 to 6 cm is obtained.

- For large single defects, greater mesh to fascia overlap is recommended to resist intraabdominal forces acting to push the mesh through the defect.
- It may be necessary to sew multiple sheets of mesh together in order to fashion a single sheet large enough to provide adequate defect coverage (**FIG 12A**).
- Size 0 or 1 permanent, monofilament sutures are placed at the midpoints of each side of the tailored mesh (**FIG 12B**).
- Corresponding points of reference are marked on the external abdominal wall to allow proper orientation once the mesh is placed intraabdominally (**FIG 13**).

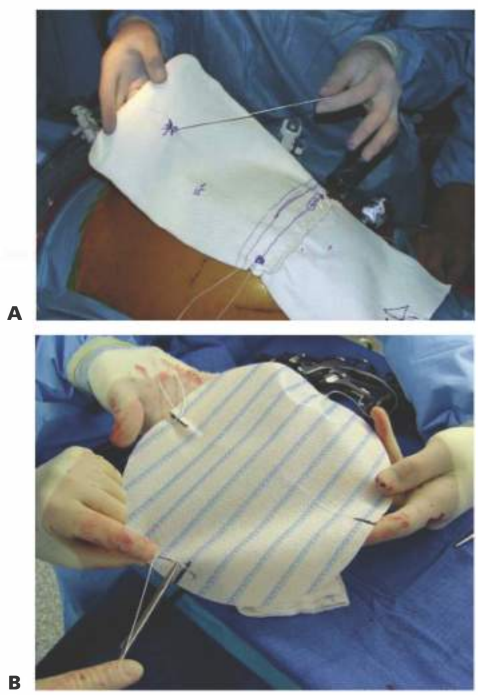

FIG 12 ● Tailoring of mesh. Mesh is fashioned to provide 4 to 5 cm of mesh/defect overlap and permanent sutures are placed at the midpoints of mesh edges. Multiple pieces of mesh may be stitched together to obtain a final mesh of sufficient size as seen in Figure **A**. Figure **B** shows the placement of midpoint sutures along the edges of the mesh.

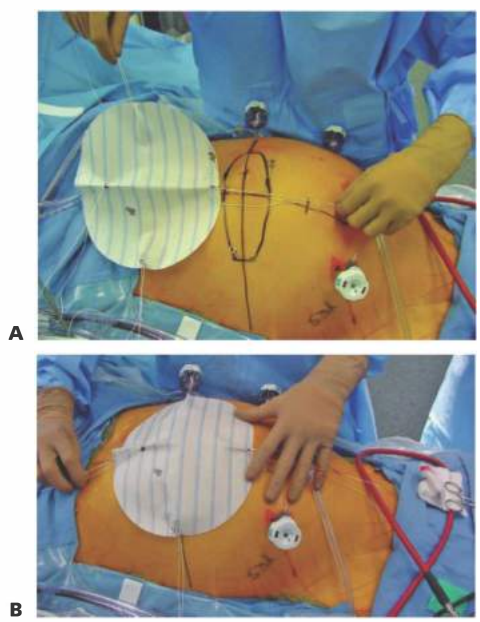

FIG 13 ● Orientation of mesh. Figure **A** shows how the external abdominal wall is marked to ensure proper orientation of mesh placed inside the abdominal cavity. Figure **B** shows the mesh overlying the marked external abdominal surface.

FIG 14 ● Rolling of mesh. Mesh is rolled in a scroll-like fashion from opposite sides inward to allow passage through trocar site.

- Mesh is then rolled from opposing edges in scroll-like fashion (which facilitates intraabdominal unfolding) and compressed to allow passage through trocar site (FIG 14).
- Using a grasper from the contralateral port site, the rolled, compressed mesh can then be pulled intraabdominally (FIG 15).
- Using two graspers, the mesh is unfurled within the peritoneal cavity. This is simplified by holding the center of the mesh with one grasper while pushing the rolled edge with second grasper.

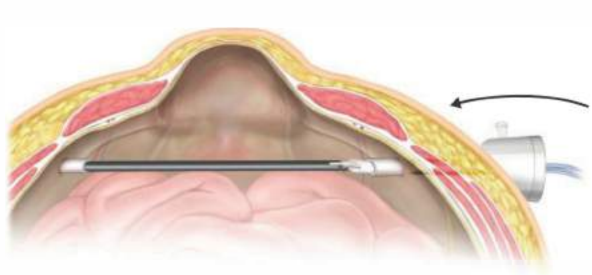

FIG 15 ● Introduction of mesh. Rolled mesh can be pulled intraabdominally from the contralateral 5-mm port site.

FIXATION OF MESH

- The mesh is properly oriented based on previously marked points of reference.
- Previously placed sutures (at midpoints along edges of mesh) are brought through the abdominal wall using a suture passer device under direct laparoscopic vision. Through the same skin incision, the suture passer enters the fascia in two locations a centimeter apart to create a fascial bridge between the tails of suture resulting in a full-thickness abdominal wall "bite" (FIG 16).
- It is recommended that the first suture to be passed transfascially be the one closest to a structure of potential concern (xiphoid, pubis, iliac crest, costal margin, stoma, etc.) to allow for optimal view of the structure(s) in question.
- Each suture is passed with identical technique.
- The transfascial sutures are pulled taut to confirm accurate mesh positioning, defect coverage, and to ensure that the mesh is taut against the abdominal wall at the time of fixation. Repositioning of previously marked reference points may be required to ensure proper mesh placement. It is very important that the mesh be tightly stretched across the abdominal wall; if the mesh is loosely applied, it will balloon out into the defect and result in the appearance of a recurrence.
- The initial two transfascial sutures are tied.
- The position of the mesh is rechecked prior to tying the remaining sutures.
- Using a 5-mm laparoscopic tacking device, the mesh perimeter is stretched out and secured into place by placing

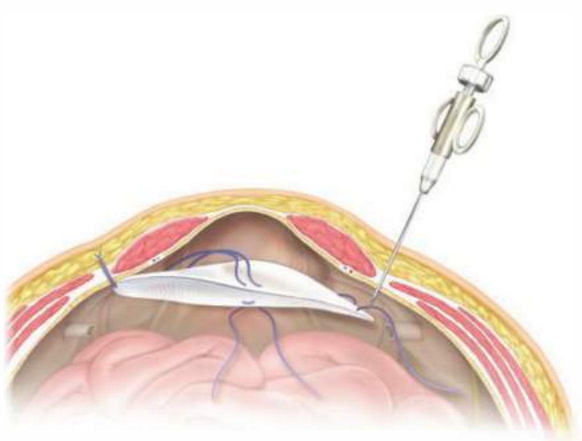

FIG 16 ● Suture passer technique. Previously placed permanent sutures along the mesh edges are brought through the abdominal wall using a suture passer device.

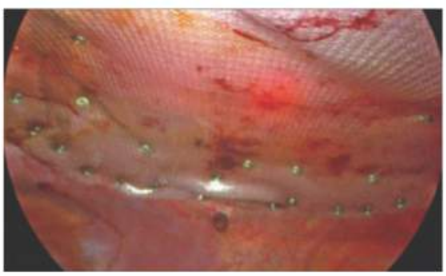
tacks no further than 1 cm apart to prevent bowel herniation between the mesh and abdominal wall. The tacks are also close enough to the mesh edge to prevent folding of the mesh. Placement of tacks is facilitated by external manual palpation of the tip of the tacking device (**FIG 17A**).

- A second row of tacks placed just inside the first row ("double crown" technique) is used by some surgeons to ensure there is no sagging of the mesh and to eliminate "dead space" between the mesh and abdominal wall (**FIG 17B**).

A



B

FIG 17 ● Tacking technique. Accurate placement of tacks is facilitated by external palpation of the tacker tip as seen in Figure **A**. Figure **B** shows completed defect coverage with two rows of tacks in place to eliminate sagging of the mesh.

- Additional full-thickness 0-0 transfascial sutures are placed every 4 to 8 cm circumferentially using the suture passer device (**FIG 18**). Larger defects require additional suture fixation to limit the mesh from eventrating into the fascial defect.
- After individual sutures are tied, the subcutaneous tissues and skin overlying the transfascial suture knots should be released using upward traction with a hemostatic clamp to avoid dimpling of the skin.
- Laparoscopic inspection of the abdominal cavity is performed to ensure adequate defect coverage (proper mesh position, attachment, and mesh/fascia overlap), hemostasis at areas of adhesiolysis, and that no bowel injury occurred.

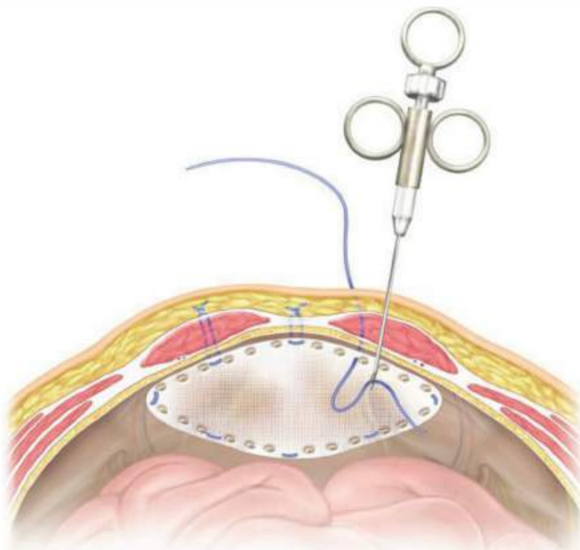


FIG 18 ● Full-thickness suture technique. Additional full-thickness transabdominal sutures are placed every 4 to 6 cm along the edge of the mesh using the suture passer device.

CLOSURE

- Fascia for all size 10-mm or larger port sites is closed with an adequate absorbable suture either externally or by using the suture passer device and laparoscopic visualization.
- Skin incisions overlying all port sites are often closed with size 4-0 absorbable suture and covered with sterile dressings or skin adhesive.

PEARLS AND PITFALLS

Preoperative imaging	■ Preoperatively, review CT images as available. ■ Images should be available for reference during procedure.
Port placement	■ Improper triangulation of working ports to target defect leads to inefficient working space and increases level of procedural difficulty. ■ Placing ports too close to the hernia leads to added difficulty in mesh placement and may result in mesh covering working ports.

Bowel injury during procedure	■ Gross contamination or large enterotomies likely requires conversion to open procedure and possibly the need for a staged repair or the use of biologic or biosynthetic mesh. ■ If little or no contamination is present and the enterotomy is small, primary laparoscopic repair may be acceptable with either immediate (no contamination) or delayed (significant contamination) herniorrhaphy.
Mesh placement	■ Inadequate fixation of mesh edges risks folding of mesh and subsequent recurrence. ■ Insufficient mesh/defect overlap (4 to 5 cm) or lack of appropriate fixation may lead to repair failure. ■ Not fixating the mesh so that it is taut across the abdominal wall risks eventration of mesh into the hernia sac after desufflation.
Unrecognized bowel injury	■ Examination of patients to diagnose an unrecognized bowel injury early in the post-operative course
Failure to close larger port sites (10 mm or greater)	■ Risks future port site hernia and possible bowel incarceration

POSTOPERATIVE CARE

- Patients are monitored postoperatively as for standard laparoscopic procedures and either discharged same day or admitted, depending on presence of significant comorbidities, recovery from anesthesia, and adequate pain control.
- Pain control measures should be initiated in the immediate postoperative period and continued 1 to 4 weeks following surgery as dictated by clinical assessment during follow-up.

OUTCOMES

- In a large series of 850 laparoscopic ventral hernia repairs performed spanning 9 years and an average of 20.2 months of follow-up, an overall complication rate (13.2%) was observed; the most common of which being prolonged ileus (3%) and seroma (2.6%). A recurrence rate of 4.7% was seen and was associated with large defect size, obesity, previous open repairs, and postoperative complications.[2]
- In the largest quality-of-life outcomes study to date comparing laparoscopic and open ventral hernia repairs from a multinational, prospective, self-reported database at 1-, 6-, and 12-month follow-up, laparoscopic repair was associated with decreased quality of life (pain and movement limitation) in the short term (1-month follow-up) but was equivalent to open repair at 6 and 12 months. An overall recurrence rate of 5.7% was observed at 1 year; 5.2% recurrence for laparoscopic versus 6.0% for open. There was also no difference in overall complications (deep venous thrombosis [DVT], ileus, urinary problems, pneumonia, fistula formation, and reoperation). However, laparoscopic ventral hernia repair was associated with decreased hospital length of stay of almost 2 days and fewer surgical site infections compared to open repairs (0.3% for laparoscopic versus 3.0% for open).[11]
- Laparoscopic incisional hernia repair has proven to be a safe and effective option for hernia repair and may actually be favored in certain patient populations, such as the morbidly obese, due to decreased rates of wound complications as compared to open ventral hernia repair.[12]

COMPLICATIONS

- Prolonged postoperative ileus
- Seroma
- Hematoma
- Prolonged transfascial suture site pain
- Mesh infection
- Bowel or bladder injury
- Recurrence
- DVT
- Cardiac or pulmonary problems
- Anesthesia complications

Chapter 5 Incisional Hernia Repair: Abdominal Wall Reconstruction Options

Michael J. Rosen

DEFINITION

- The field of abdominal wall reconstruction has seen significant advances in the past decade. A resurgence in the concept of recreating a functional dynamic abdominal wall through reconstructing the linea alba and restoring normal anatomy of the abdominal wall unit has fostered several innovative techniques to achieve these goals. The foundation for much of our understanding of abdominal wall reconstruction can be linked to pioneering surgeons such as Oscar Ramirez, Renee Stoppa, and Jean Rives. These reconstructive surgeons brought forth the concepts of performing fascial releases of the anterior abdominal wall compartments to provide advancement of the midline fascia. Although each of these surgeons and several of the newer techniques that will be described in this chapter differ in the exact mechanism in which fascial advancement is obtained, the underlying concept of achieving fascial advancement to reconstruct the midline is a constant.
- When considering which approach is indicated for reconstructing the abdominal defect that the surgeon is faced with, it is helpful to provide general categories of the various abdominal wall reconstructive techniques. In the authors' opinion, the most clinically relevant classification scheme is based on preservation of the anterior abdominal wall neurovascular blood supply and the need to raise large lipocutaneous flaps to gain access to the lateral abdominal wall. In general, minimally invasive approaches preserve the abdominal wall blood supply and avoid large skin flaps. Examples of such techniques include endoscopic component separation, posterior component separation, and periumbilical perforator sparing approaches, whereas, the standard open approach does not typically preserve the anterior abdominal wall blood supply.
- This chapter will focus on some of the more advanced reconstructive techniques to repair large abdominal wall defects. Prior to discussing each of these approaches, it is imperative to understand that not all ventral hernia repairs will require these approaches. In fact, most abdominal wall defects less than 10 to 15 cm in maximal width can be repaired using a standard Rives-Stoppa-Wantz approach. This technique will be described in detail in another chapter in this textbook. In the authors' opinion, this approach should always be initially considered prior to moving on to more advanced techniques.

DIFFERENTIAL DIAGNOSIS

- When planning an abdominal wall reconstruction, the most important first step is to clarify patient's expectations for a successful outcome as well as the surgeon's. Not all defects, particularly in the setting of contamination or infection, can or should be repaired in a single setting. Often, the initial attempt at clearing the infectious source or reconstructing the gastrointestinal (GI) tract takes precedence and formal reconstruction should be delayed. In these cases, the patient should understand that they will likely have a ventral hernia at the end of the procedure that eventually will need to be repaired.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Basic cardiac and pulmonary risk stratification are essential.
- Skin preparation is critical, and an experienced wound care nurse is invaluable. Treating any subcutaneous cellulitis or breakdown can significantly improve soft tissue coverage at the time of formal reconstruction.
- Optimization of nutritional status is also important. This can include supplemental, enteral, or parenteral feeding when necessary. It is also important to point out that patients with an ongoing infectious nidus, particularly infected synthetic mesh, can be very difficult to obtain a positive nitrogen balance.
- Many patients with large ventral hernias also suffer from morbid obesity. The ideal approach to managing obesity in the setting of a complex ventral hernia is challenging. No doubt, substantial weight loss prior to surgical intervention is optimal. However, the best approach is unclear, but options include medically supervised weight loss or bariatric surgery. This can be particularly challenging in symptomatic incarcerated hernias in which there is little time to achieve or obtain clearance for weight loss surgery.
- Preoperative smoking cessation is mandatory in our practice prior to complex abdominal wall reconstruction. Smoking has been clearly linked to impaired wound healing and in the author's opinion is an absolute contraindication to complex abdominal wall reconstruction.
- Obtaining and reviewing all old operative records is extremely important. Understanding what type of mesh and in what layer in the abdominal wall it was placed can help guide your approach. In addition, it is important to clarify if one of the lateral abdominal wall muscles were already released because it can lead to lateral abdominal wall laxity if it is rereleased. Likewise, the surgeon might choose another muscle to release to access an undissected plane.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Routine radiologic imaging with an abdominal–pelvic computed axial tomography (CAT) scan is particularly useful in complex ventral hernia repairs. These scans can provide valuable information as to the size of the defect and presence of loss of domain, the absence or destruction of important components of the abdominal wall, and the presence of remnant prosthetic materials.

- More advanced radiologic imaging such as magnetic resonance imaging (MRI) or angiogram to look for periumbilical perforator vessels is not routinely performed in our practice.
- Preoperative antibiotic and deep venous thrombosis prophylaxis is routinely given. Typically, a first-generation cephalosporin will suffice, but in cases of prior or active methicillin-resistant *Staphylococcus aureus* (MRSA) infection, Vancomycin is added.
- Nasogastric tube decompression and Foley catheters are routinely inserted.
- Perioperative anesthesia management is critical to success in large abdominal wall reconstructions. It is important that the patient remains completely relaxed during the procedure as this greatly improves exposure of the abdominal wall. In addition, in larger abdominal wall reconstruction, there is often some level of compartment syndrome at the conclusion of the procedure. It is important to keep these patients intubated for a 24- to 48-hour period until their airway pressures normalize.

SURGICAL MANAGEMENT

- As with any hernia repair, it is critically important that the surgeon has a firm understanding of the anatomy of the abdominal wall prior to manipulation. The abdominal wall is basically composed of the two rectus muscles running longitudinally and the three lateral muscles on each side of the abdominal wall. Each performs a valuable function for the abdominal wall, and any disruption can cause impairment in core physiology. Understanding the neurovascular anatomy of the anterior abdominal wall is particularly important for optimizing the results of each of these approaches. The rectus muscle receives its innervation from the T7–T11 intercostal nerve routes. These nerves run above the transversus abdominis and below the internal oblique muscles in the lateral abdominal wall. They penetrate the linea semilunaris and segmentally innervate the rectus muscle. It is very important to preserve these nerves in any reconstruction; otherwise, the rectus muscle will atrophy and prevent any hope for a functional abdominal wall (**FIG 1**). One important consideration for a posterior component separation is that the transversus abdominis muscle actually forms the posterior sheath of the rectus muscle in the upper two-thirds of the abdomen.
- The blood supply of the anterior abdominal wall is slightly more complex (**FIG 2**). The rectus muscle receives its blood supply both laterally from the intercostal vessels and from a superior and inferior branch of the inferior epigastric vessel. The blood

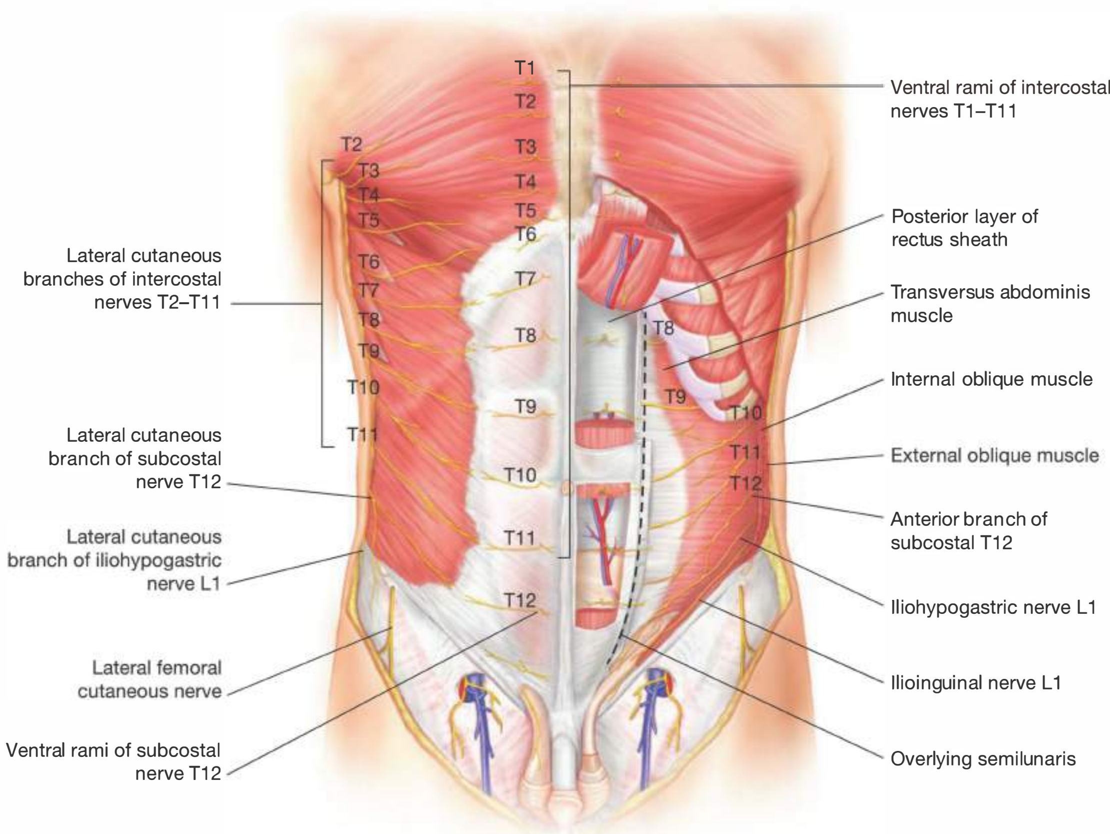

FIG 1 ● Innervation of the anterior abdominal wall. Note the intercostal nerves run in the lateral abdominal wall in between the internal oblique and transversus abdominis muscle.

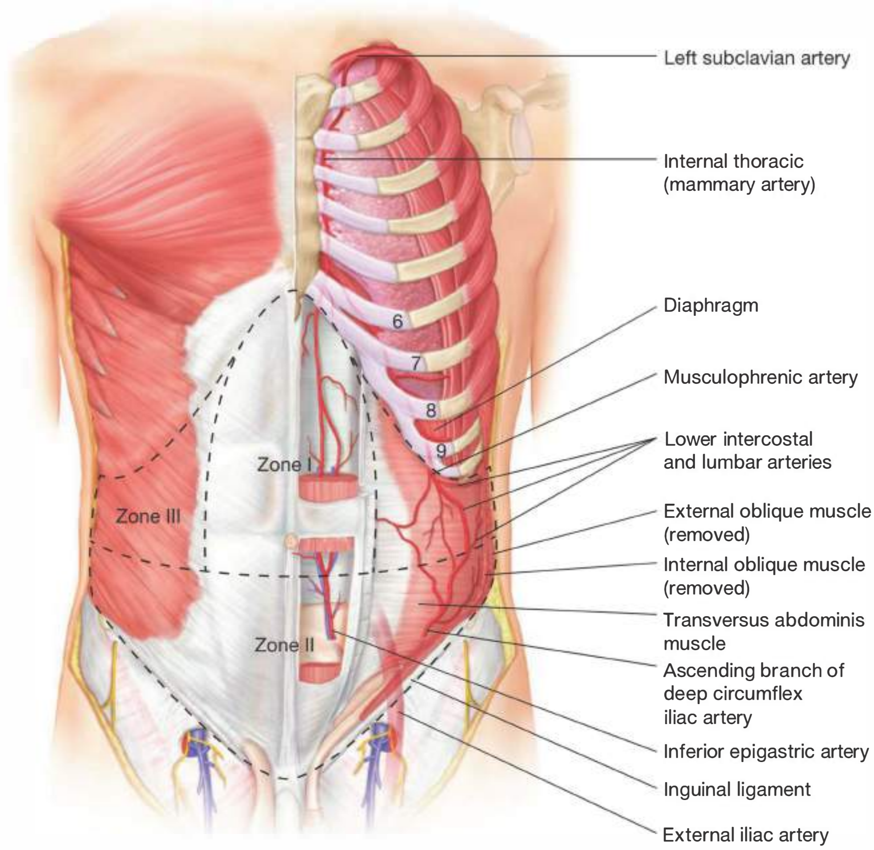

FIG 2 ● Blood supply to the anterior abdominal wall. Note location of the medial row of perforators off the inferior epigastric providing blood supply to the medial aspect of the skin.

supply to the skin and subcutaneous tissues of the midline is also important to understand to limit ischemic problems during reconstruction. The skin does receive some limited supply from the lateral intercostal vessels, but the majority comes from deep inferior epigastric perforator vessels. These vessels typically lie within 5 cm cephalad and caudad to the umbilicus. This relationship is particularly useful when performing a periumbilical perforator sparing component separation.

Positioning

- Regardless of the abdominal wall reconstructive technique chosen, some basic technical aspects remain constant. A wide surgical preparation including the entire abdomen, lower chest, and upper legs is performed with a chlorhexidine solution. All stoma sites are oversewn to minimize spillage. An iodine-impregnated dressing is routinely applied to cover the entire abdominal wall.

TECHNIQUES

INCISION

- The surgical incision is typically performed in a midline fashion and all other old scars or skin ulcerations are completely excised.

ADHESIOLYSIS

- The abdominal cavity is entered and a complete adhesiolysis is performed to free up the entire abdominal wall all the way to the gutters. This step is critical, as the abdominal wall will be limited in its mobility if it remains fixated to the viscera.

CONCOMITANT PROCEDURES AND REMOVAL OF ALL FOREIGN MATERIAL

- Any concomitant GI surgery is completed and all prior synthetic material is removed from the abdominal wall. In our opinion, removing prior synthetic material allows the new prosthetic to actually grow into the abdominal wall and reduces seromas and mesh infections. After the intraperitoneal portion of the procedure is completed, a countable towel is placed over the abdominal viscera to prevent inadvertent injury during dissection of the abdominal wall.

POSTERIOR COMPONENT SEPARATION TECHNIQUE

- A posterior component separation is basically an extension of the standard Rives-Stoppa-Wantz repair.
- The initial procedure begins in a similar fashion. The linea alba is identified and grasped with Kocher clamps. To avoid confusion and misidentification of appropriate planes, the clamps must be placed on the medial edge of the rectus muscle and not on the hernia sac. If the clamps are on the hernia sac, the dissection will proceed in a subcutaneous plane. Next, an incision of the posterior sheath is made approximately 1 cm off the linea alba. It is important to identify the rectus muscle, which will avoid creating a subcutaneous or preperitoneal plane of dissection (**FIG 3**).
- The posterior rectus sheath is then separated off the rectus muscle using electrocautery, carefully preserving the inferior epigastric vessel. This dissection plane is facilitated by placing upward traction on the rectus muscle and medial traction on the posterior sheath with Kocher clamps. Typically, small posterior branches off the epigastric vessels can be coagulated.
- The lateral extent of this dissection continues until the perforating intercostal nerves and vessels are identified. These nerves as mentioned are critical to preserve to maintain a functional innervated rectus muscle. They also are the landmark of the linea semilunaris, that is, the lateral extent of the rectus muscle. In a standard Rives-Stoppa-Wantz repair, the dissection is completed at this point (**FIG 4**).
- If more advancement is needed to provide mobilization for the posterior sheath or anterior sheath, or provide a larger compartment for an adequate-sized piece of mesh, then a posterior component separation is performed.
- This dissection is usually started in the upper third of the abdomen. In this location, the transversus abdominis muscle actually forms the posterior sheath and does extend medial to the linea semilunaris. The incision is begun approximately 0.5 cm medial to the intercostal nerves. The initial incision should involve the fascial covering of the muscle, and it is extended throughout the length of the posterior rectus sheath. When performing this release, it is always important to confirm that it is not disrupting the intercostal nerves.
- Next, the transversus abdominis muscle is released medial to the linea semilunaris. This is facilitated by the use of a right-angle clamp in the upper third of the abdomen under the muscle (**FIG 5**). Below this muscle is the peritoneum and can be quite thin on the medial side.
- As the dissection continues caudally, the muscle belly of the transversus abdominis is replaced with a fascial layer. This layer is also incised, leaving the transversalis fascia and peritoneum in the lower third of the abdomen (**FIG 6**).
- Once the entire transversus abdominis is released, the dissection is continued laterally. Again, this dissection plane is below the transversus abdominis muscle and above the peritoneum/retroperitoneum. The lateral extent of this

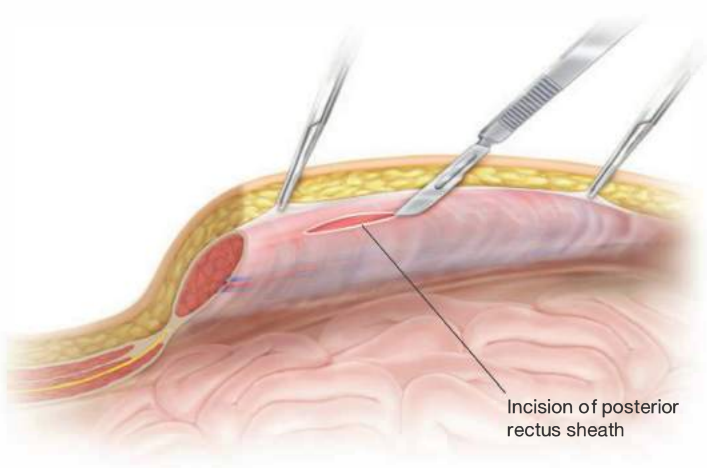

FIG 3 ● The posterior rectus sheath is incised 1 cm lateral to the linea alba to gain access to the retrorectus space.

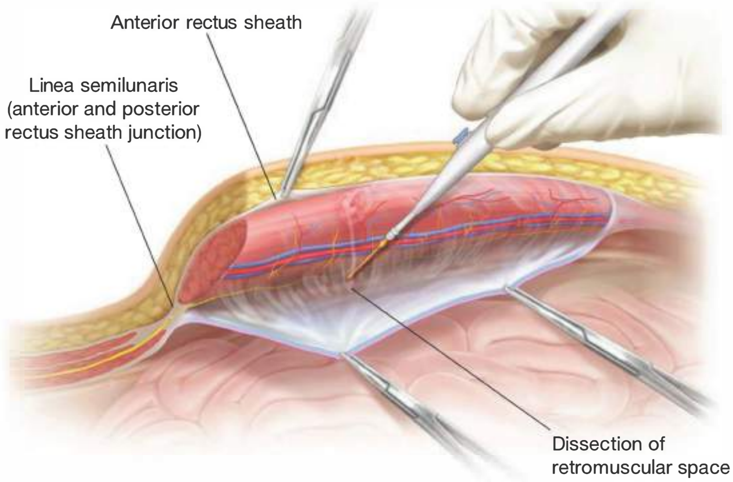

FIG 4 ● The posterior rectus sheath is separated off the rectus muscle until the lateral edge of the rectus is identified by the presence of the perforating intercostal nerves.

dissection is the lateral edge of the psoas muscle. This plane can be extended cephalad to the costal margin, sweeping the peritoneum off the diaphragm.

- The posterior sheath is incised at its insertion into the linea alba to connect each side of the abdomen. This is continued at least 5 cm above the incision and typically can be performed to the xiphoid process. In upper abdominal hernias, the insertion of the posterior sheath is released from the xiphoid, and the dissection is continued to the fatty triangle underneath the sternum and toward the central tendon of the diaphragm.
- Inferiorly, the bladder is separated off the anterior abdominal wall. In suprapubic hernias, the pelvis is exposed, including the pubis, Cooper's ligaments, and the space of Retzius.
- The posterior sheath, peritoneum, and transversalis fascia are reapproximated in the midline, completely excluding the mesh from the bowel. Any fenestrations are sutured closed. In cases of large defects of the posterior sheath, Vicryl mesh can be used.
- It is very important that the posterior sheath is closed safely because bowel can herniate through the posterior closure and become incarcerated below the mesh.
- A large sheet of unprotected medium-weight large-pore polypropylene mesh is typically placed in the retrorectus space.
- Several transfascial sutures are placed at the lateral edge of the mesh. The sutures are placed under tension so as to allow the midline closure to be off weighted. These sutures also set the tension on the mesh that prevents buckling when the midline is closed over the mesh (**FIG 7**).
- Drains are placed over the mesh and below the rectus muscle and removed when less than 30 mL per day of output.
- The midline fascia is reapproximated with running or interrupted slowly absorbable monofilament sutures. The skin is closed in layers.

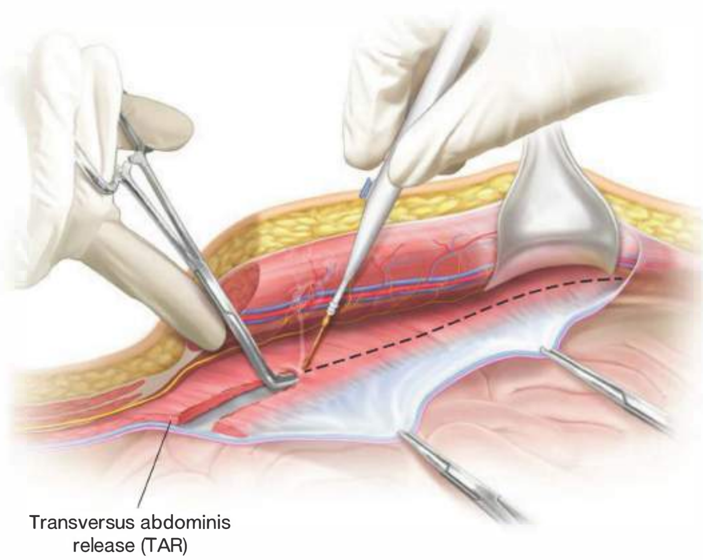

FIG 5 ● The transversus abdominis muscle is incised to expose the peritoneum below. Note the intercostal nerves are preserved as this release occurs medially.

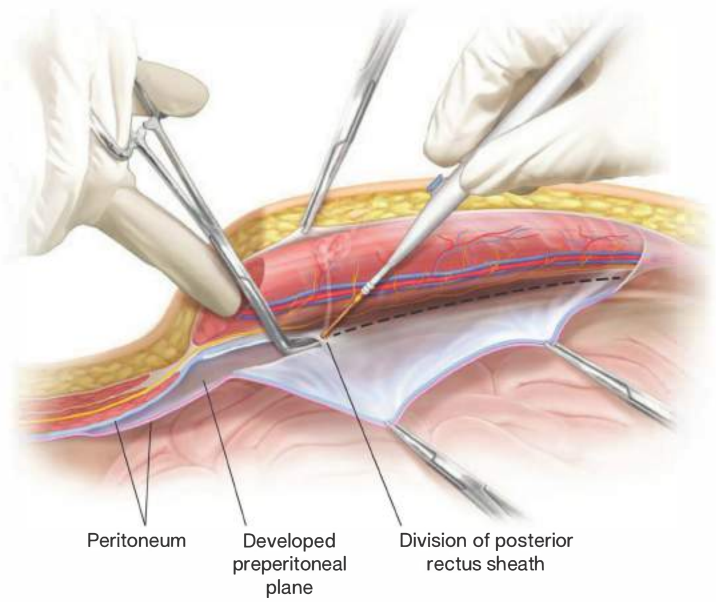

FIG 6 ● In the lower third of the abdomen, the transversus abdominis is mainly fascia and is released to expose the peritoneum.

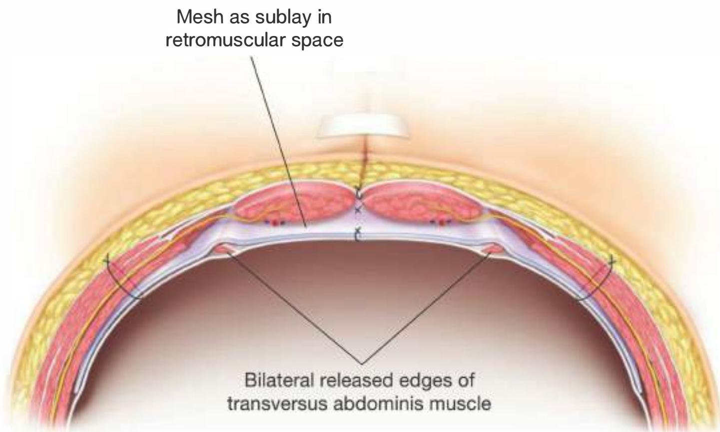

FIG 7 ● Mesh is placed as a sublay with lateral transfascial sutures and the midline closed without buckling of the mesh.

COMPONENT SEPARATION TECHNIQUE

- Anterior component separation is typically performed if the skin will require undermining to gain advancement for closure. In addition, if the retrorectus space or the preperitoneal or retroperitoneal space cannot be accessed, an anterior component separation can be performed with intraperitoneal mesh placement.
- Placing Kocher clamps on the linea alba provides medial retraction, whereas rake retractors are placed on the dermis and retracted superiorly. Using electrocautery, the subcutaneous tissues are undermined to the lateral abdominal wall.
- These lipocutaneous flaps are created to the inguinal ligament and several centimeters above the costal margin. In a standard open component separation, all of the medial row perforator vessels are sacrificed. Therefore, the skin flap is supplied by the intercostal vessels approaching laterally.
- The release is performed by incising the external oblique muscle. It is imperative that this incision does not violate the linea semilunaris. This can occur if the release is begun too medially and will result in a full-thickness defect in the lateral abdominal wall, which is very challenging to repair. There are no clear anterior anatomic landmarks to define the linea semilunaris or the external oblique. It is helpful to grip the rectus muscle in between the thumb and fingers and feel the indentation at the lateral extent of the rectus muscle (**FIG 8**). The incision in the external oblique should be placed approximately 2 cm lateral to the identified linea semilunaris.
- A 1-cm incision is made parallel to the linea semilunaris. The orientation of the muscle fibers below should be confirmed. If the fibers are oriented in a vertical direction, it is likely that the anterior rectus sheath has been incised.

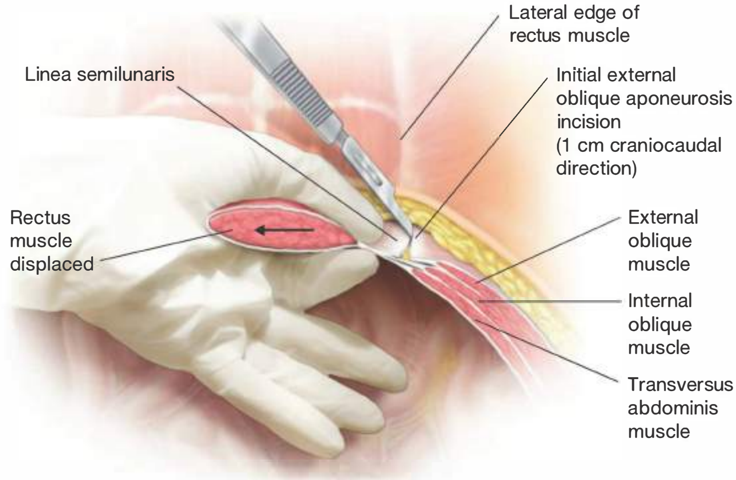

FIG 8 ● Bimanual palpation to confirm the linea semilunaris location.

To confirm, a right-angle clamp can be placed below the external oblique muscle and passed medially. If in the correct plane, the tip of the instrument will not be able to traverse the linea semilunaris. If the incision was erroneously placed on the anterior rectus sheath, the clamp will not meet resistance, and the incision should be closed and the dissection continued laterally.

- The external oblique is then released from the inguinal ligament to 3 to 4 cm above the costal margin. This can typically be performed with electrocautery (**FIG 9**). It is important to avoid injuring the internal oblique fascia or muscle complex below to avoid bulging and herniation.
- A component separation is more than a fasciotomy of the external oblique muscle. After the muscle is released, the external oblique muscle is dissected in the avascular plane in between the external and internal oblique to the posterior axillary line. This dissection allows the rectus complex to slide medially.
- A component separation should typically be performed bilaterally to allow for equal redistribution of forces on the eventual repair. In certain circumstances, such the presence of a stoma or a prior transverse incision, unilateral releases can be performed.
- If further advancement is necessary, the posterior rectus sheath can be separated off the rectus muscle. This incision is made approximately 1 cm lateral to the linea alba on the posterior rectus sheath. The posterior rectus sheath can be separated off the rectus muscle to the linea semilunaris if necessary.
- An appropriately sized mesh is placed as a sublay. Typically, this is placed in the intraperitoneal position. Depending on the indications of the case, a synthetic or biologic mesh might be appropriate.
- One of the major drawbacks of the anterior component separation is skin flap ischemia and wound breakdown. There are several techniques to minimize this risk. First, the skin flap should only be created as far lateral as needed to access the external oblique release and not all the way to the posterior axillary line. Second, redundant skin should be readily excised. This will limit the dead space and remove the most ischemic area. In certain cases, this can require a formal panniculectomy. However, most cases can just be performed using a vertically oriented elliptical incision. Some authors have advocated quilting sutures, securing the flaps to the anterior abdominal wall.

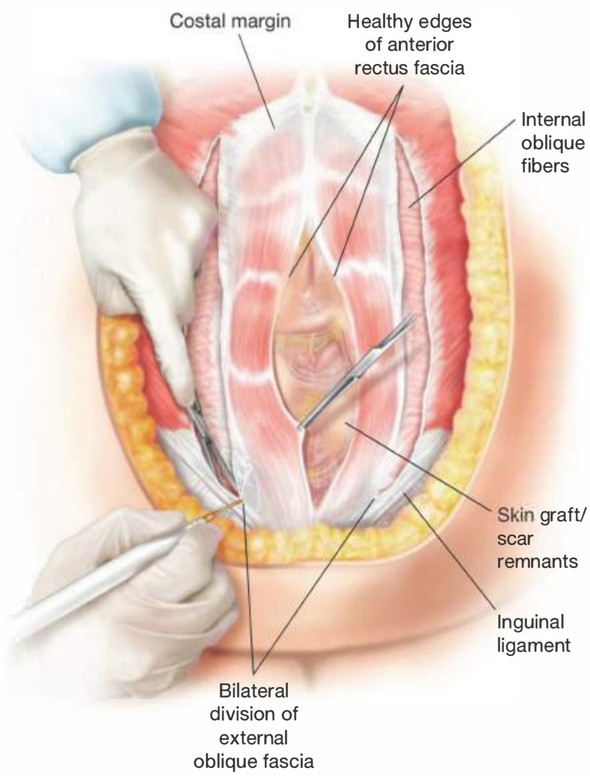

FIG 9 ● Bilateral open component separation procedure completed.

PERIUMBILICAL PERFORATOR SPARING COMPONENT SEPARATION

- The rationale for preserving the periumbilical perforator vessels is to decrease the risk of skin flap necrosis, infection, and dehiscence. This technique takes advantage of the fact that the majority of the perforator vessels supplying the medial aspect of the skin originate within 5 cm of the umbilicus. This approach might be particularly useful in high-risk patients such as those with obesity, diabetes, or concomitant stomas.
- The periumbilical approach is indicated in any patient undergoing a component separation. However, in cases that require extensive subcutaneous skin dissection, it is often not feasible to perform. When removing an infected onlay mesh, or if significant skin advancement is necessary, a standard anterior open component separation as previously described is indicated.
- The periumbilical component separation technique is performed by creating subcutaneous tunnels to access the anterior aspect of the external oblique muscle.
- The dissection is begun in the epigastric area. A lighted retractor can be very helpful to minimize the size of the tunnel while providing exposure (**FIG 10**). The skin and subcutaneous tissues are dissected off the anterior rectus sheath to a point 2 cm lateral to the linea semilunaris. This can be confirmed by manual palpation as described in the anterior open release. Once this lateral point is reached, the dissection continues inferiorly. The dissection should extend to a point several centimeters above the umbilicus.
- The suprapubic dissection is carried out in a similar fashion. Once the lateral extent is reached, the tunnels are connected in the lateral abdominal wall.
- It is important to understand that there is a fairly large amount of subcutaneous tissue that remains attached to the midline (**FIG 11**). If the periumbilical perforator vessels are skeletonized, they often will thrombose.
- Once the tunnels are connected and the external oblique identified, it is incised similar to a standard open component separation. It is also separated off the underlying internal oblique muscle.
- Additional advancement can be obtained from division of the posterior rectus sheath. If feasible, the mesh can be placed in this retrorectus space, with the lateral limit being the linea semilunaris.
- If not feasible, an appropriately sized mesh can be placed intraperitoneally.
- The midline fascia is then reapproximated and the skin closed. Drains should be placed in the lateral tunnels.

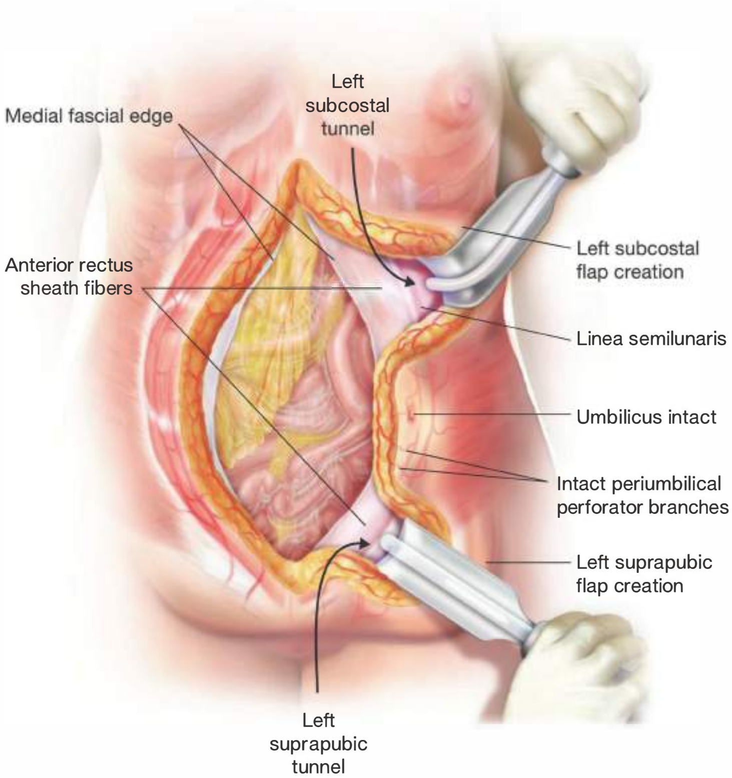

FIG 10 ● Use of lighted retractor to begin tunnel to the lateral abdominal wall while preserving the periumbilical perforator vessels.

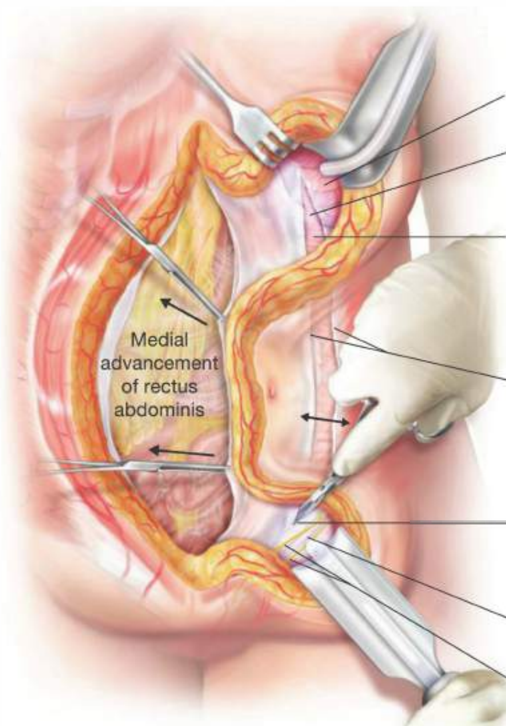

FIG 11 ● Completed periumbilical release with intact medial row of perforator vessels.

PEARLS AND PITFALLS

Operative planning	■ One of the most common pitfalls associated with abdominal wall reconstruction is underestimating the limitations of what each of these procedures can accomplish. In patients with massively large defects more than 30 cm in width and damaged, fibrotic, fixed abdominal walls, there is little hope for a definitive repair. It is critically important that both the patient and the surgeon have reasonable expectations as to what abdominal wall reconstruction procedures can actually achieve. ■ Preoperative optimization of the patient is one of the most important steps in predicting a successful outcome. Weight loss is encouraged; optimization of diabetes control and smoking cessation are mandatory.
Difficult anatomy	■ The xiphoid and suprapubic region can be difficult to achieve maximal advancement and should be avoided early in one's experience. ■ In many cases of complex abdominal wall reconstruction, the umbilicus must be resected. Patients must be aware of this issue preoperatively.
Avoid denervation	■ Understanding the anatomy of the anterior abdominal wall is very important to ensure a successful outcome. Special consideration should always be given to the innervation and blood supply to the abdominal wall musculature and skin during manipulation.
Inability to reapproximate the midline	■ Although it is always optimal to bring the midline together and reconstruct the linea alba, it is not always safe or feasible. If excessive tension results and the patient manifest hemodynamic instability or respiratory embarrassment, the closure should be aborted and a bridged repair is appropriate. ■ These advanced reconstructive procedures are not simply fasciotomies. Much of the advancement achieved is a result of separating the muscle layers from each other to provide advancement.

POSTOPERATIVE CARE

- Abdominal wall reconstruction is a major surgical procedure that results in a significant physiologic impairment to the patient. Because many patients undergoing abdominal wall reconstruction have multiple comorbidities, careful perioperative management is important to maximize outcomes.
- Reestablishing the midline in a large defect can have early consequences to respiratory mechanics. If the plateau pressures rise by greater than 6 mmHg after fascial closure, patients remain intubated overnight. Airway pressures are reassessed in the morning to plan for extubation.
- Epidural catheters are routinely used in patients undergoing major abdominal wall reconstruction. These catheters are typically maintained for up to 5 days, depending on return of bowel function and level of pain.
- Early resumption of oral intake is highly discouraged in this patient population. Because most of these patients have increased intraabdominal pressure after the reconstruction, some form of ileus is common. To avoid retching and potential breakdown of the repair, we avoid initiating a diet until the return of flatus. However, routine nasogastric tube decompression is not necessary.
- Most patients undergoing complex abdominal wall reconstruction are hospitalized for 5 to 7 days. Depending on the complexity of the procedures, some patients remain in the intensive care unit for several days.
- Patients are encouraged to ambulate early.
- Because these procedures create significant dead space, drains are placed. Drains should be removed when the output is less than 30 mL per day. In patients with subcutaneous drains, these may remain for several weeks.
- Perioperative antibiotics are continued for up to 24 hours, unless otherwise indicated.
- Most patients are allowed to return to activity within 6 weeks of surgery and unrestricted activity at 3 to 6 months, depending on the case. Abdominal binders are continued for the first 6 weeks and then as needed for comfort.

OUTCOMES

- There are very little comparative studies evaluating the outcomes of each of these approaches head-to-head. In fact, it is likely that these studies will never be completed, as the heterogeneous nature of the patients who develop incisional hernias precludes any one approach ever being ideal. Most series are from single centers with high-volume abdominal wall reconstructive practices. In the selected references, each article provides reasonable outcomes as to the expectations for each procedure.

COMPLICATIONS

- Wound morbidity is common after complex abdominal wall reconstruction.
- Wound cellulitis should initially be treated with broad-spectrum antibiotics. In most cases, the skin does not need to be opened. If the erythema does not improve within 24 to 48 hours, the incision should be opened, cultured, and drained. In cases with clinical signs of sepsis, the surgeon should have a low threshold to perform an abdominal pelvic computed tomography (CT) scan.
- Skin necrosis should be treated with early debridement and wound care. In certain cases, delayed primary closure can be performed.
- Seromas are very common after abdominal wall reconstruction and most do not require any intervention. If they are symptomatic, they can be drained under sterile conditions.

Chapter 6

Parastomal Hernia

Melissa M. Alvarez-Downing   Susan M. Cera

DEFINITION

- Parastomal hernia is defined as an incisional hernia which occurs at the site of or immediately adjacent to an existing ostomy.

DIFFERENTIAL DIAGNOSIS

- Abdominal wall mass (tumor, hematoma, abscess)
- Eventration of the abdominal wall

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be obtained to determine the time frame of onset, severity of symptoms, and degree of size change. Patients should also be questioned about their satisfaction with stoma site location because relocation is an option for repair of parastomal hernia.
- The most common symptoms associated with an uncomplicated parastomal hernia include bulging near the stoma that worsens with activity and difficulty of adherence of the stoma wafer due to irregularities and bulging of the skin surface. The result is frequent leakages and skin excoriation. In addition, patients complain of the associated expense of increased appliance/wafer usage. Occasionally, wafer leakage may be the presenting complaint and parastomal hernia should be included in the differential diagnosis.
- Other symptoms associated with a complication of the parastomal hernia (obstruction, incarceration, and strangulation) include abdominal pain, decreased ostomy output, cramping, nausea, or vomiting.
- Characteristic findings on physical exam will render the diagnosis of parastomal hernia in most patients. Examination should be performed with the stoma wafer off with the patient in both the supine and standing position. The patient should be asked to perform a Valsalva maneuver. A characteristic bulge adjacent to the stoma site will be present and confirmed with digital palpation (**FIG 1**). A search for concomitant hernias should be undertaken, especially at previous laparotomy scars, because these can occur in up to 41% of patients.[1]
- Abdominal tenderness or skin discoloration associated with a nonreducible hernia is indicative of incarceration and/or strangulation and requires urgent/emergent intervention.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Computed tomography (CT) scan of the abdomen and pelvis performed with intravenous (IV) and oral contrast can confirm the presence of a hernia and help guide operative intervention (**FIG 2A,B**). Having the patient perform Valsalva during the CT may unmask a hernia and/or reveal the true extent of the hernia. The use of oral contrast will assist in identification of partial or complete obstruction associated with the hernia. The CT scan will also aid in the identification of other associated hernias, that is, at the site of previous laparotomy scars. The size of the neck of the hernia is important and is especially useful in determining the size of the mesh needed in cases where it will be used in the repair. Knowing the contents of the hernia sac (omentum, small bowel, large bowel) preoperatively aids in minimizing bowel injury during surgery because the peritoneum of the hernia sac and bowel serosa can appear similar during dissection. In addition, the planes between the hernia sac and intestine are often distorted by adhesions.
- If the stoma was created for inflammatory bowel disease, thorough evaluation of the entire gastrointestinal (GI) tract to evaluate for active disease that may necessitate surgical intervention at the time of the hernia repair is warranted. In addition to endoscopic exams (see below), radiologic testing may include barium small bowel follow-through and capsule endoscopy.

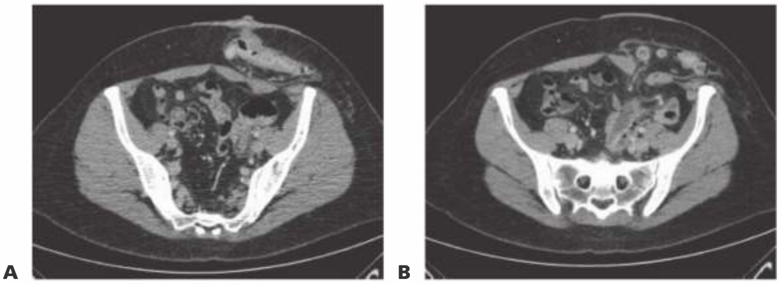

FIG 2 ● **A,B.** CT images demonstrating a parastomal hernia with bowel present in the hernia sac at and below the level of the colostomy.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients should be counseled that parastomal hernia is the most frequent complication following the construction of a stoma and can occur in up to 50% of patients because the stoma itself creates a weakened area in the abdominal wall.[2]
- Patients should also be counseled on the various techniques/options available for treatment. Nonsurgical options are appropriate for asymptomatic patients and include use of a hernia belt (secured to the stoma wafer) or an abdominal binder. Surgical intervention is reserved for an enlarging hernia or those associated with symptoms or decreased quality of life because of inadequate stoma pouching. If surgical intervention is considered, the choice of procedure should be tailored to the individuals' life expectancy, operative risk/benefit analysis, degree of physiologic function (which often corresponds to the degree of weakness of the abdominal wall and ability to successfully sustain repair), and risk of recurrence.
- Type of surgical technique chosen is based on patient factors, surgeon experience, and safety of laparoscopic approach.
- Risk of initial occurrence and recurrence after repair is associated with obesity and/or weight gain, smoking, emergent intervention, poor nutritional status, immunosuppression, infection, and persistent underlying malignancy or inflammatory bowel disease.
- Informed consent should include a possibility of conversion to open in laparoscopic procedures and possible placement of a mesh, particularly in large hernia repairs.
- If stoma relocation is planned, preoperative stoma marking for a new stoma site is an important step. Consultation with a stoma nurse is advised. Stoma relocation may include placing the stoma in either of the upper quadrants as opposed to the lower quadrants because less tangential pressure is generated in the upper abdominal wall. This type of placement is also beneficial in morbidly obese patients with a large abdominal wall pannus. Additionally, it is important to explain to patients that the new ostomy site is associated with the same risk of hernia formation.[3]
- In morbidly obese patients, preoperative weight loss can assist with durability of parastomal hernia repair.
- Colonoscopy/ileoscopy should be performed to ensure no concomitant lesions are present, which would require simultaneous surgical resection. This can be performed the day prior to planned hernia repair so that the patient can undergo a single bowel preparation.
- After obtaining appropriate preoperative medical clearance, a standard bowel preparation with an isoosmotic lavage (polyethylene glycol solution) and oral antibiotics is used for parastomal hernias associated with colostomy. Bowel preparation is not needed for paraileostomy hernias. These patients are instructed to take a liquid diet the day prior to surgery. As with all abdominal surgery, perioperative IV antibiotics should be administered within 1 hour prior to incision and routine venous thromboprophylaxis should be instituted.

Positioning

- The patient is placed in a modified lithotomy position (**FIG 3**) for all cases whether open or laparoscopic because of the possibility of encountering extensive adhesions, which may require surgeon repositioning between the patient's legs. The arm on the working side (opposite the stoma and hernia) should be abducted. Securing the patient to the operative table with use of a bean bag and safety strap or silk tape across the chest is recommended to allow for rotational

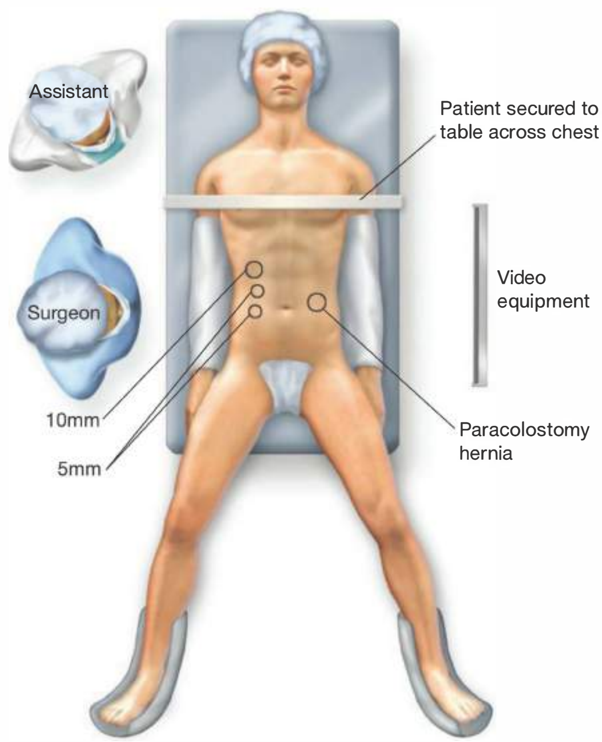

FIG 3 ● Lithotomy position and positioning of surgeon and assistant.

adjustment during the procedure if laparoscopic approach is planned.

- After induction of general anesthesia, a nasogastric and sterile indwelling bladder catheter are placed. A nasogastric tube (NGT) and inpatient hospitalization is advocated for larger hernia repairs to prevent postoperative vomiting that may result in immediate postoperative disruption of the repair.

TECHNIQUES

STOMA RELOCATION

Existing Ostomy

- The new planned stoma site is marked prior to the procedure either during consultation with a stoma nurse or with a pen in the preoperative holding area and an 18-gauge needle after induction of anesthesia.
- A circumferential parastomal incision is made to isolate the stoma from the skin and subcutaneous tissue.
- Dissection is then carried down to the fascia identifying the hernia, reducing its contents, and excising the hernia sac. The bowel is placed into the abdomen using a marking stitch to easily retrieve it when necessary.

Division of Adhesions

- Lysis of adhesions is performed through the stoma site circumferentially and under direct vision. Placement of a wound protector and use of a headlight will facilitate visualization and adhesiolysis.

Relocation of the Ostomy

- Two fingers are now placed into the wound and underneath the abdominal wall to the new stoma site. A disk of skin is removed at the new stoma site. The anterior fascia and rectus muscle is divided vertically, directly over the fingers underneath the abdominal wall. The ostomy site is dilated two fingerbreadths. Using a Babcock clamp, the previously mobilized stoma is passed via the abdominal cavity and brought up through the new fascial opening. Care should be taken to ensure there is no twisting, rotation, or undue tension of the bowel mesentery.
- If extensive adhesions are found or the bowel does not reach the new stoma site, exploratory laparotomy may be necessary.
- A Babcock clamp should be left on the bowel at the new stoma site to prevent it from slipping back into the abdominal cavity until stoma maturation (final step).

Hernia Repair

- The hernia at the old stoma site is repaired by approximating the fascial edges with interrupted nonabsorbable sutures (0 Ethibond). Use of a prosthetic or biologic mesh should be done to ensure adequate closure, especially for fascial defects greater than 4 cm due to the high failure rate with primary repair.[3]

Closure

- If a midline laparotomy was made, it is closed with running 0 polydioxanone (PDS) sutures.
- The skin edges are reapproximated with running 4-0 Monocryl sutures or skin staples.
- The new stoma is matured with interrupted 3-0 chromic sutures and a stoma appliance is placed.

OPEN UNDERLAY TECHNIQUE (MODIFIED SUGARBAKER TECHNIQUE)

Exploratory Laparotomy and Lysis of Adhesions

- The abdomen is prepped, and a sterile 4 × 4 gauze is placed over the existing stoma. Ioban is included in the draping to keep the stoma covered but in the operative field.
- A midline incision is made and lysis of adhesions is performed. Caution should be used when dissecting in the vicinity of the stoma (which is why it is visually kept in the operative field).
- The stoma itself is not typically mobilized for this procedure unless the patient is unsatisfied with the extent of the brooking. In this case, the stoma can be mobilized and rebrooked, and the hernia repair should be performed with a biologic mesh to reduce mesh infection.

Hernia Repair

- Once the proximal bowel of the stoma is freed from surrounding adhesions, the hernia sac is resected and the hernia contents are reduced.
- A dual-sided expanded polytetrafluoroethylene (ePTFE, Gore-Tex DualMesh Biomaterial, WL Grove Associates, Newark, DE, USA) or biologic mesh is selected based on the size of the fascial defect, ensuring there is at least 4 cm additional reach on all sides.
- A precise keyhole incision is made in the mesh, making certain the central opening is small enough to only allow passage of the bowel to the stoma. The mesh is placed around the stoma on the undersurface of the abdominal wall and the ends secured to itself (**FIG 4**). Placement of mesh above the fascia (onlay technique) or into the abdominal wall defect (inlay technique) have been abandoned because of high failure rates.[4]
- The mesh is sutured to the anterior abdominal wall using interrupted 0-Vicryl sutures. Additional sutures made of 2-0 Prolene may be passed through the entire abdominal wall ensuring no migration of the mesh, although this is not necessary because the stoma itself anchors it in place.

Closure

- The midline fascia is closed using running 0-PDS suture.
- The skin edges are reapproximated with running 4-0 Monocryl sutures or skin staples.

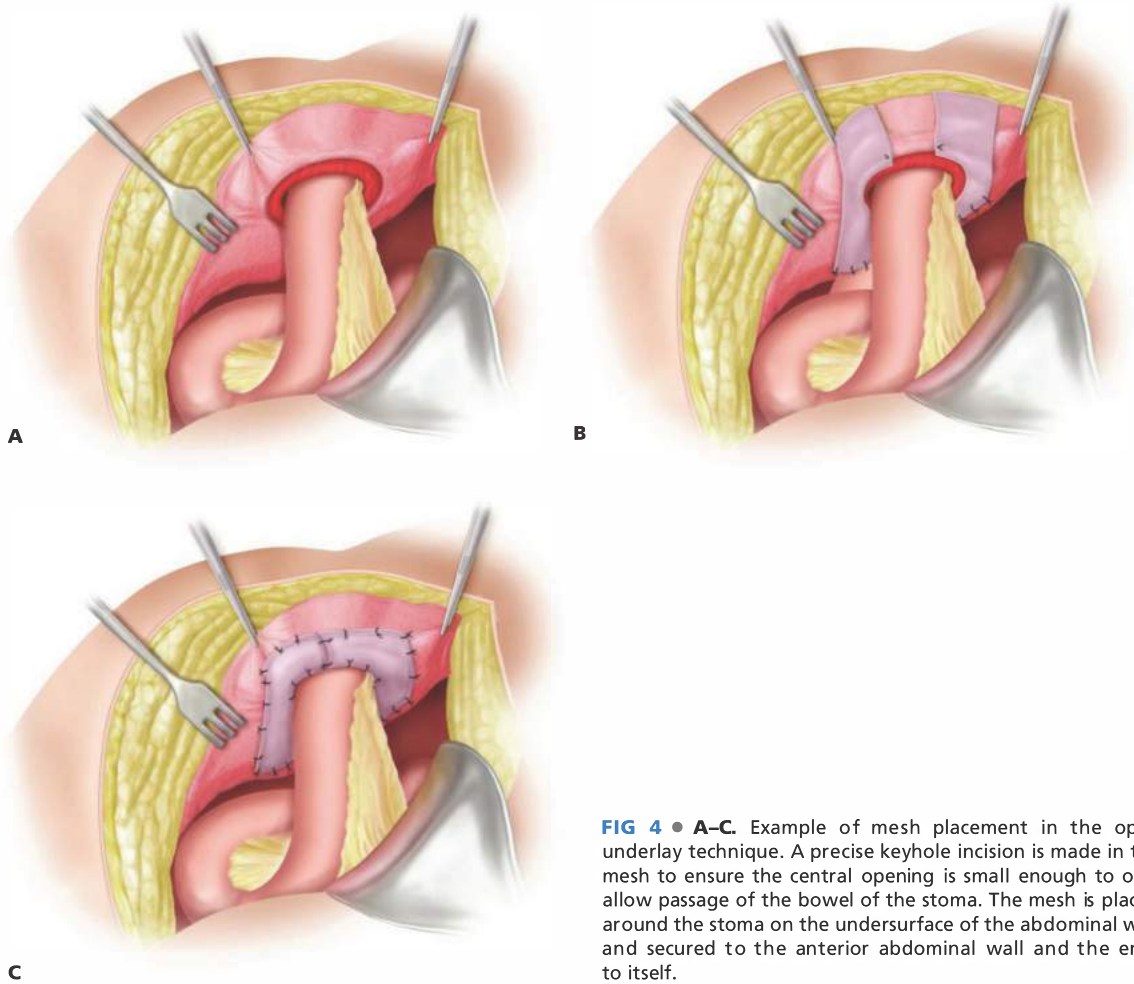

FIG 4 ● **A–C.** Example of mesh placement in the open underlay technique. A precise keyhole incision is made in the mesh to ensure the central opening is small enough to only allow passage of the bowel of the stoma. The mesh is placed around the stoma on the undersurface of the abdominal wall and secured to the anterior abdominal wall and the ends to itself.

LAPAROSCOPIC MESH UNDERLAY TECHNIQUE

Entering the Abdominal Cavity

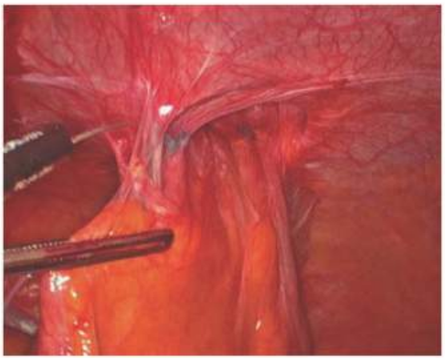
- A 10-mm subcostal incision is made on the side opposite of the stoma. Direct access is gained and a port is placed into the abdominal cavity. Pneumoperitoneum is achieved, and inspection of the abdominal cavity is performed to assess if a laparoscopic approach is both feasible and safe.
- Two additional 5-mm ports are placed under direct visualization laterally according to **FIG 3**.

Lysis of Adhesions

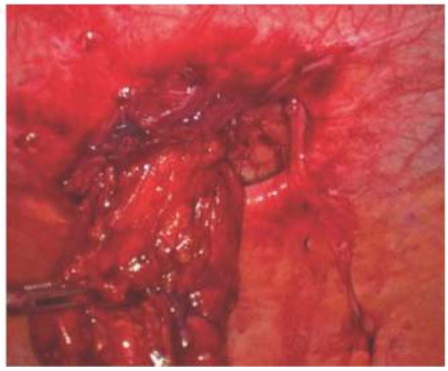
- Laparoscopic lysis of adhesions and reduction of the hernia sac and contents is performed (**FIG 5**). Careful dissection should be performed sharply with gentle countertraction to ensure no injury occurs to the bowel.

Hernia Repair

- The fascial defect is measured using a spinal needle passed intraabdominally and by marking the external abdomen appropriately.
- An ePTFE or synthetic mesh is selected based on the size of the fascial defect, ensuring there is 4-cm additional reach on all sides. Permanent 0-0 sutures are placed on all four sides and the mesh is rolled up and introduced into the abdomen via the 10-mm port. A 5-mm camera should be used in an ipsilateral port to insert the mesh under direct visualization.
- The mesh is unrolled in the abdominal cavity ensuring correct orientation. The previously placed sutures are brought



A



B

FIG 5 ● **A.** Laparoscopic lysis of adhesions to reduce the contents of the parastomal hernia sac and define the size of the fascial defect. **B.** Careful sharp dissection is performed with gentle countertraction to ensure no injury occurs to the bowel wall.

through the abdominal wall using stab incisions and a suture passer.

- A mechanical fixation device, for example, ProTack (Covidien, Mansfield, MA, USA), is used to place tacks around the circumference of the mesh to ensure no bowel can herniate between the mesh and the abdominal wall (**FIG 6**). Additional Prolene sutures are placed 2 cm apart through the abdominal wall around the mesh, except for the side of the mesh through which the bowel to the stoma passes.

Closure

- Once the mesh has been secured in place, the ports are removed under direct visualization and pneumoperitoneum is released. A 0-Vicryl suture is used to close the fascia of the 10-mm port site. 4-0 Monocryl sutures are used to close the skin at all port sites. Adhesive tape or glue can be used on the skin of the small stab incisions created to pass the sutures.

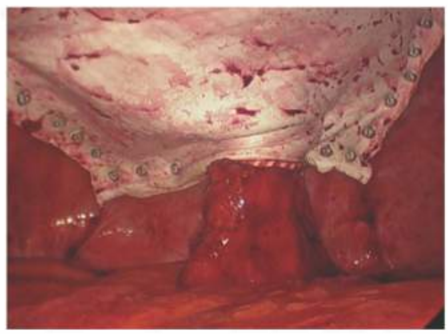


FIG 6 ● Underlay mesh (ePTFE) secured to the anterior abdominal wall with tackers placed using a mechanical fixation device in a laparoscopic approach. The existing ostomy is visible exiting the lateral border of the mesh.

PEARLS AND PITFALLS

Indications	■ Parastomal hernia repair should be undertaken only in patients who are symptomatic and/or with quality of life issues. Relocation is reserved for those who wish more desirable stoma location.
Preoperative planning	■ Preoperative imaging is important to assess the extent of the parastomal hernia as well as address any confounding factors. ■ When considering relocating a stoma, preoperative stoma marking is essential.
Type of hernia repair	■ Open vs. laparoscopic approach without stoma relocation is based on surgeon experience and comfort with laparotomy. Minimally invasive approach offers faster recovery and less pain.
Lysis of adhesions	■ When performing lysis of adhesions, it is important to take extra caution around the stoma.
Hernia repair	■ Primary closure of the hernia site should only be undertaken in hernias <4 cm in size. In patients with larger hernias, use of a mesh for repair will improve success rates. ■ It is important to ensure the keyhole incision made in the mesh is exact to only allow passage of the stoma, therefore preventing future herniation at this site.

POSTOPERATIVE CARE

- Perioperative antibiotics can be administered during the first 24 hours after surgery.
- For small hernia repairs, diet can be resumed and the patient discharged after the recovery room. In most cases, however, the extent of the lysis of adhesions dictates at minimal inpatient observation and possibly an NGT until the ileus resolves.
- Patients should be encouraged to avoid heavy lifting and strenuous activity for 4 weeks following surgery.

OUTCOMES

- Long-term durability of parastomal hernia repair is variable, with recurrence rates reported in up to 50% of patients.[5] Although some studies have suggested that stoma relocation is superior to fascial repair, both approaches carry a high recurrence rate (33% vs. 75%) because neither addresses the underlying pathophysiology driving hernia formation.[3] To address this, use of a mesh to aid in repair has been employed and dramatically reduces hernia recurrence rate to 16%, with no difference between synthetic or biologic mesh.[6,7] Additionally, mesh infection rates are similar, therefore making the less expensive synthetic mesh a more favorable option.[7]
- Mesh repair performed in a laparoscopic approach offers the best results, with a low recurrence rate of 6.6% and an ability to identify additional hernias not evident clinically.[1,6,8]
- Addressing patient risk factors such as obesity, nutritional status, immunosuppression, and comorbid conditions can aid in overall repair success.

COMPLICATIONS

- Postoperative wound infection
- Ileus
- Enterotomy
- Obstruction
- Recurrent hernia

Chapter 7

Umbilical, Epigastric, Spigelian, and Lumbar Hernias

Filip Muysoms

DEFINITION

- A primary ventral hernia is an abnormal protrusion of the contents of the abdominal cavity or of preperitoneal fat through a defect in the abdominal wall that developed spontaneously without trauma to the abdominal wall or prior surgery as the cause of the hernia.[1]
- An umbilical hernia is a primary ventral hernia with its center at the umbilicus.
- An epigastric hernia is a primary ventral hernia in the midline between the umbilicus and the xiphoid.
- A spigelian hernia is a primary ventral hernia in the area of the fascia spigelian aponeurosis.
- A lumbar hernia is a primary ventral hernia in the lumbar area.
- In contrast to umbilical and epigastric hernias, the hernia sac of a spigelian hernia or lumbar hernia is covered with an intact layer of abdominal wall muscle. For spigelian hernias, this is the external oblique muscle (**FIG 1**), and for lumbar hernias, the latissimus dorsi muscle.
- Primary ventral hernias are classified according to the diameter of the hernia defect as shown in Table 1.[2]

DIFFERENTIAL DIAGNOSIS

- Subcutaneous lesions at the site where primary ventral hernias occur, like lipoma, sebaceous cysts, metastatic lesions, and trocar site metastasis.
- Caveat: Epigastric lipoma: In a patient with a clinical subcutaneous lipoma near the midline above the umbilicus, an epigastric hernia should always be suspected.
- Abdominal wall tumors: desmoid tumors (or fibromatosis), soft tissue sarcoma, metastatic lesions.
- Caveat: A "Sister Joseph's nodule" is an umbilical swelling that might be mistaken for an umbilical hernia but is the manifestation of intraperitoneal carcinomatosis.
- Secondary ventral hernias: incisional hernia, trocar site hernia, and recurrent ventral hernias after previous repair.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Symptoms can range from an asymptomatic presentation to acute incarceration with bowel obstruction and/or strangulation.
- Many small umbilical or epigastric hernias are asymptomatic, and often, the patient is not even aware of having a small abdominal wall defect.
- A swelling at the hernia site is often the first sign of a hernia. This swelling is usually present for a long time period and gradually increases in size (**FIG 2**).
- The presence of a reducible swelling, enlarging when straining (Valsalva maneuver), is pathognomonic for an abdominal wall hernia, but not all hernias are reducible and can hinder the clinical diagnosis in those hernias.
- The swelling of an epigastric hernia is often mistaken for a subcutaneous lipoma (**FIG 3**).
- Pain intensity is not always correlated with the size of the hernia defect. Small hernias can cause a sharp pain, whereas umbilical hernias can be quite large without significant pain. The pain is caused by herniation of abdominal contents or of preperitoneal fat through the defect.
- For some hernias that are not palpable, such as spigelian hernias, abdominal wall pain can be the first presenting symptom and diagnosis might only be possible by imaging.
- Acute pain due to incarceration of intestines or omentum is very intense and sharp. Incarceration can be intermittent and resolve by lying down and manual compression of the hernia sac. Reduction of an incarcerated hernia allows the patient to be operated on electively after appropriate preoperative workup. If manual reduction is not possible, an emergency operation to reduce the hernia is indicated.
- Intestinal obstruction and vomiting due to incarcerated small bowel sometimes is the primary presentation in patients who have a subclinical hernia. In obese patients and for spigelian or lumbar hernias, the incarcerated hernia is sometimes not clinically visible or palpable.

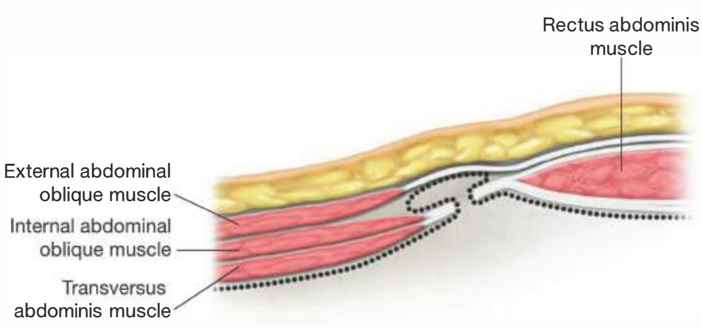

FIG 1 • Spigelian hernias are defects of the insertion of the transversus abdominis muscle and/or internal oblique muscle to the lateral border of the rectus muscle sheath (the spigelian aponeurosis). The external oblique muscle covers the hernia sac superficially.

Table 1: Classification of Primary Ventral Hernias According to the European Hernia Society Classification

EHS Primary Abdominal Wall Hernia Classification		Diameter cm	Small <2cm	Medium ≥2–4cm	Large ≥4cm
Midline	Epigastric				
	Umbilical				
Lateral	Spigelian				
	Lumbar				

Reprinted from Muysoms FE, Miserez M, Berrevoet F, et al. Classification of primary and incisional abdominal wall hernias. Hernia. *2009;13:407–414.*

- Late presentation of an incarcerated hernia includes sepsis from bowel ischemia and intestinal perforation. This can evolve into peritonitis or enterocutaneous fistula.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- For diagnosis of an umbilical or epigastric hernia, clinical examination is sufficient for the majority of patients. Imaging is rarely needed for most patients.
- Imaging with ultrasound or computed tomography (CT) scan can be helpful to measure the hernia defect size in irreducible hernias or obese patients. Sometimes the size of the hernia defect will influence the therapeutic approach, for example, open or laparoscopic technique.
- For spigelian and lumbar hernias, imaging with ultrasound or CT scan is often needed to make the diagnosis: spigelian hernia (**FIG 4**), lumbar hernia (**FIG 5**).
- CT scan imaging of the abdominal wall allows sizing the defect to see the hernia sac contents and to detect signs of intestinal obstruction.

SURGICAL MANAGEMENT

- Small primary umbilical, epigastric, or lumbar hernias do not require an operation, unless they are painful, increase in size, or cosmetic considerations are present. For spigelian hernias, a surgical repair is indicated even for asymptomatic patients because they hold an increased risk of incarceration compared to the other primary ventral hernias.
- There is no consensus whether a suture repair for small primary hernias is sufficient or if every primary ventral hernia should be treated by mesh reinforcement.[3] For inguinal hernias and incisional hernias, the current recommendation is to use mesh in all patients because of the proven decrease in recurrences. Therefore, recurrent umbilical or epigastric hernias should be repaired using a mesh prosthesis, as they are considered to be incisional hernias. Most surgeons agree

FIG 2 ● Typical clinical presentation of an umbilical hernia with an umbilical swelling increasing in standing position and while straining (Valsalva maneuver).

FIG 3 ● This patient not only has an umbilical hernia but also a supraumbilical swelling from a concomitant epigastric hernia.

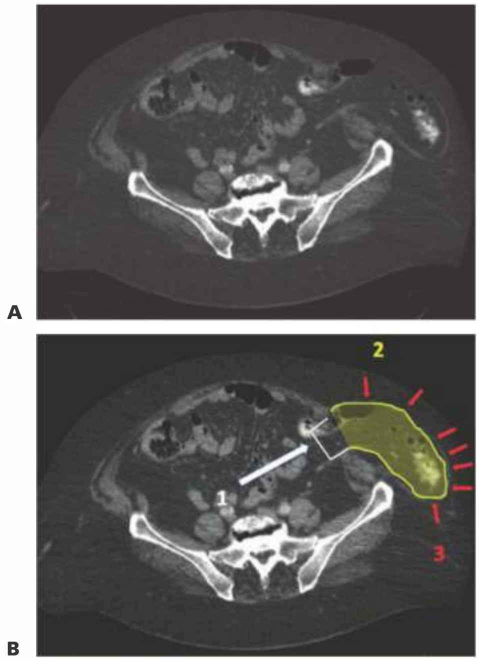

FIG 4 ● **A.** CT of a patient with a left-sided spigelian hernia. The hernia defect is located lateral to the rectus sheath. The hernia sac contains a loop of the sigmoid colon. that only small (<2 cm) primary ventral hernias should be repaired without mesh reinforcement.

- The mesh used to repair abdominal wall hernias can be placed at different positions in relation to the abdominal wall layers. Five positions can be defined: onlay, inlay, retromuscular, preperitoneal, and intraperitoneal (**FIG 6**).[1]
- Laparoscopic repair of ventral hernias is a technique with promising short-term results.[4] The technique is safe but long-term follow-up is needed in order to elucidate whether laparoscopic repair of ventral hernia is efficacious.[4]

Preoperative Planning

- Based on the size and the localization of the hernia, a decision will be made about the preferred approach in the individual patient: mesh or primary repair/open or laparoscopic technique.
- Although some centers perform the repair of small umbilical or epigastric hernias under local anesthesia as a routine, most centers prefer a general anesthesia for the comfort of the patient and the surgeon. Regional anesthesia through a sensory blocking of the anterior abdominal wall, by a transversus abdominis plane block (TAP block), is another less practiced option for postoperative pain control.
- For incarcerated hernias with bowel obstruction, adequate preoperative measures with nasogastric tube suction and rapid "sequence intubation" should be considered to minimize aspiration risk.

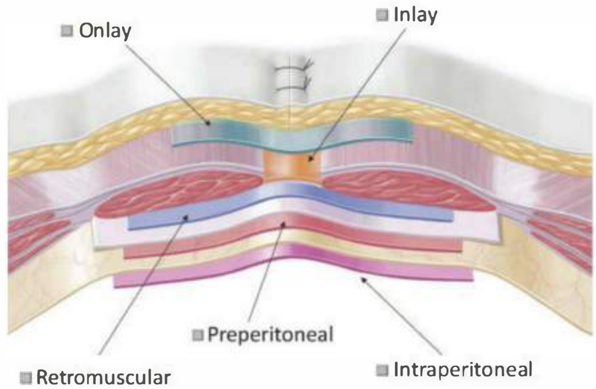

FIG 6 • Different positions of the mesh in relation to the abdominal wall layers to repair a ventral hernia by mesh reinforcement. (From: Winkler MS, Gerharz E, Dietz UA. Narbenhernienchirurgie. Übersicht und aktuelle Trends. *Urologe.* 2008;47:740–747, with permission.)

- Preoperative cleaning and disinfection of the umbilicus is helpful in decreasing the bacterial load during the operation.
- Antibiotic prophylaxis as a routine is not indicated for most hernia repairs because they are clean operations with a low risk of wound infection. In the presence of risk factors for wound infection, antibiotic prophylaxis at induction of anesthesia should be considered.

Positioning

- Patients treated for primary ventral hernias are usually positioned in a dorsal decubitus. Lumbar hernias are positioned in a 90-degree or 45-degree lateral decubitus to expose the lumbar region (**FIG 7**).
- For laparoscopic approach of ventral hernias, the position of the surgeon and the video equipment is determined by the localization of the hernia. It is important to have a wide lateral accessibility of the abdominal wall, because the trocars are placed very laterally to obtain access to hernias on the midline.

FIG 7 • Intraoperative positioning of a patient with a 45-degree lateral decubitus for open approach of a left-sided lumbar hernia.

SUTURE REPAIR

Incision

- For umbilical hernias, the incision of the skin for primary repair can be within the umbilical rim, thus leaving a nearly invisible scar postoperatively. The incision can be placed either cranial or caudal, depending on the site of the hernia sac. It is recommended not to incise the umbilical rim for more than 180 degrees because of the increased risk of devascularization of the umbilical skin after further dissection of the hernia sac, leading to skin necrosis and wound infection.
- For epigastric, spigelian, or lumbar hernias, the incision will be directly above the hernia.
- The skin is retracted with small Volkmann retractors and the subcutaneous layer incised down to the fascia, exposing one side, cranial or caudal of the hernia defect (**FIG 8A**).

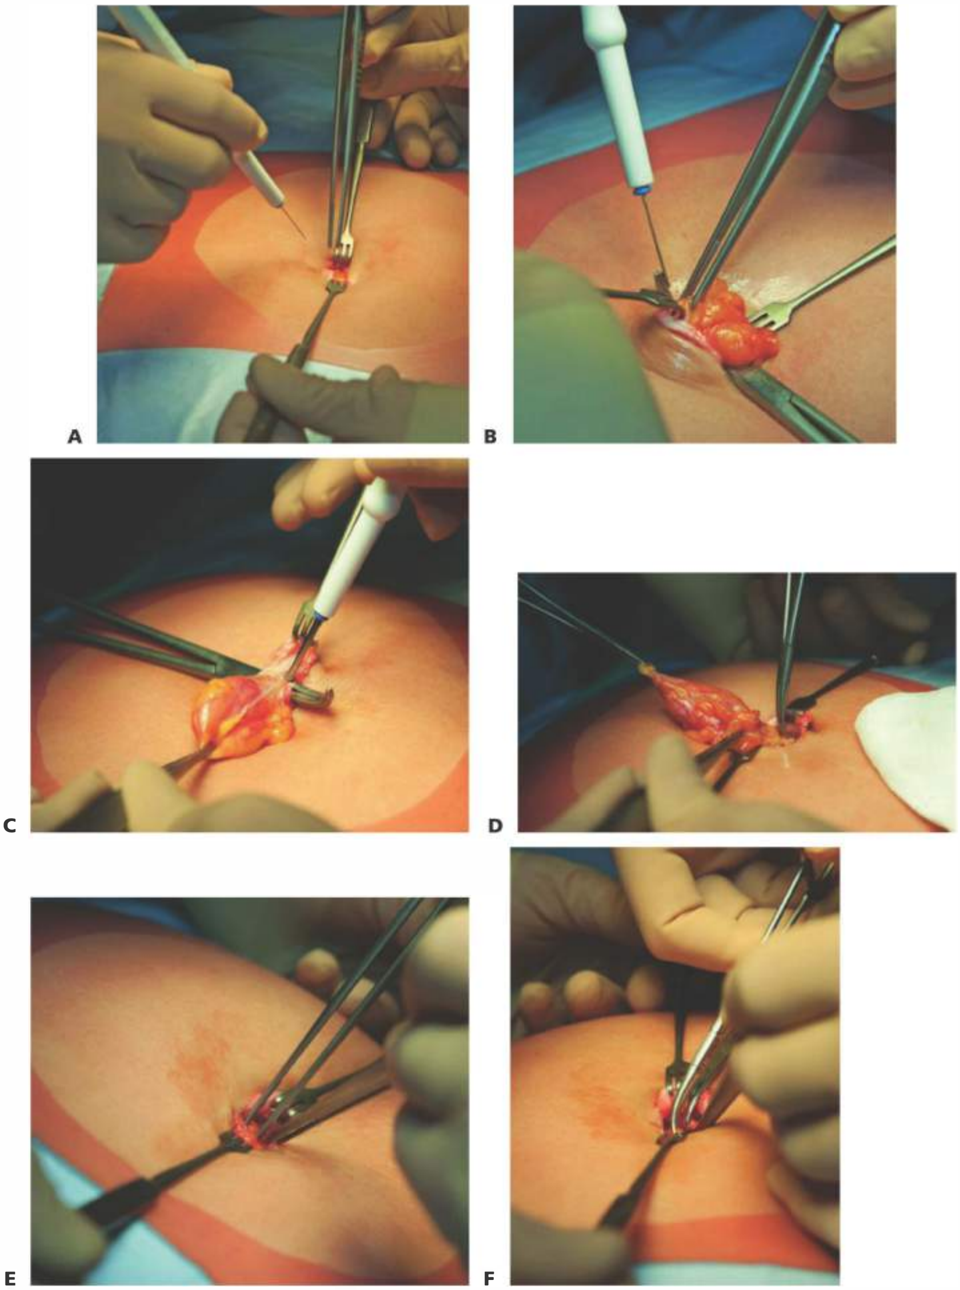

FIG 8 ● **A–F.** Intraoperative pictures of an umbilical hernia repair by open approach.

Dissection of the Hernia Sac

- Starting at the lateral side of the hernia defect, the hernia sac, usually containing preperitoneal fat and/or omentum, is encircled using a curved hemostat clamp. The clamp is pushed through to the other side of the hernia defect (**FIG 8B**).
- The top of the hernia sac is dissected of the umbilical skin, taking care not to injure the skin (**FIG 8C**). This will expose the opposite side of the hernia defect (**FIG 8D**).

Reduction of the Hernia Sac

- The hernia sac and its contents are reduced through the hernia defect behind the abdominal wall muscles (**FIG 8E**). Careful control of hemostasis of the preperitoneal region is performed.
- Sometimes, the contents of the hernia sac are too voluminous to be reduced through the hernia defect. This is often the case in umbilical hernias with herniation of omental fatty tissue and in epigastric hernias with preperitoneal fat. In these patients, we can either resect the herniated fatty tissue or we can enlarge the hernia defect.
- In patients with acute incarcerated hernias, the hernia sac should be opened and the herniated bowel inspected for viability. In case of doubt, a bowel resection should be considered.

Closure of the Hernia Defect by Primary Closure

- The fascial edges of the defect are identified and isolated from the subcutaneous tissue and from the preperitoneal tissue for 5 to 10 mm (**FIG 8F**).
- We close the umbilical and epigastric hernias in a horizontal line. Several options for suturing technique (separate sutures, running suture, or "vest-over-pants" plication sutures) (**FIG 9A–C**) and materials (monofilament vs. braided sutures; nonabsorbable, slowly absorbable, rapid absorbable) are available.
- Similar to the recommendations to close midline laparotomies, we recommend a running suture with small bites (5 mm from the fascial edge and 5 mm between stitches) using a long-term absorbable monofilament suture (**FIG 9B**).

Closure of the Skin

- The skin is sutured either subcutaneously or with separate superficial sutures.

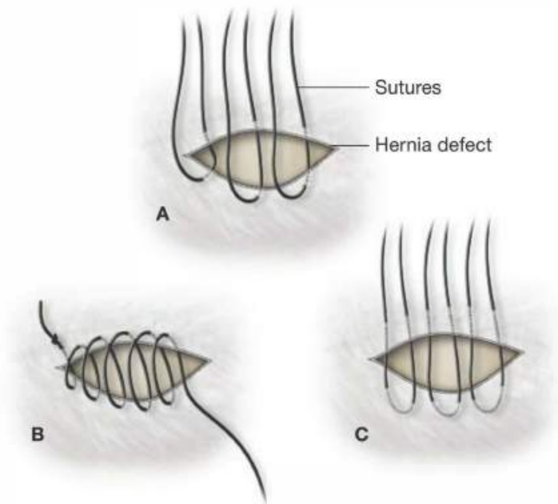

FIG 9 ● Several techniques are available for closure of the hernia defect. **A.** Closure with separate sutures. **B.** Closure with running sutures. **C.** Closure with a vest-over-pants plication, commonly known as the Mayo Clinic technique.

OPEN MESH REPAIR WITH A FLAT MESH

Incision

- This depends on the localization of the hernia. For umbilical hernias, placing a flat mesh will require an incision that is larger than the incision needed for primary closure or for placement of an umbilical ventral patch. Often, a horizontal omega incision (Ω) is chosen. For epigastric, spigelian, or lumbar hernias, the incision is directly over the hernia sac (**FIG 10**).

Dissection of the Hernia Sac and the Hernia Defect

- For umbilical and epigastric hernias, this is similar as for primary hernia repair (**FIG 8B–E**).
- For spigelian and lumbar hernias, an intact muscle layer covers the hernia sac. This is why these hernias can become quite large before they become clinically evident. For a spigelian hernia, the overlying external oblique muscle has to be opened to access the hernia sac. The muscle fascia is split in the direction of its fibers, which is from lateral downward in a ±45-degree angle toward the midline. The hernia sac is thus exposed and contains preperitoneal fat. The sac is reduced underneath the other abdominal wall muscles and the defect is measured.

Closure of the Hernia Defect and Mesh Augmentation

- Usually in open surgery, the mesh is used to augment the primary fascial closure of the hernia defect. There are several options for positioning the mesh in relation to the abdominal wall as shown in **FIG 6**.[1]
- *Onlay position*: The mesh is positioned on top of the fascia underneath the subcutaneous tissue. After closure of the hernia defect, a dissection of the subcutaneous plane is performed for several centimeters around the defect to allow enough overlap of the mesh beyond the margins of the defect.
- *Inlay position*: The mesh is placed inside the hernia defect, which is not closed, and the mesh is sutured to the

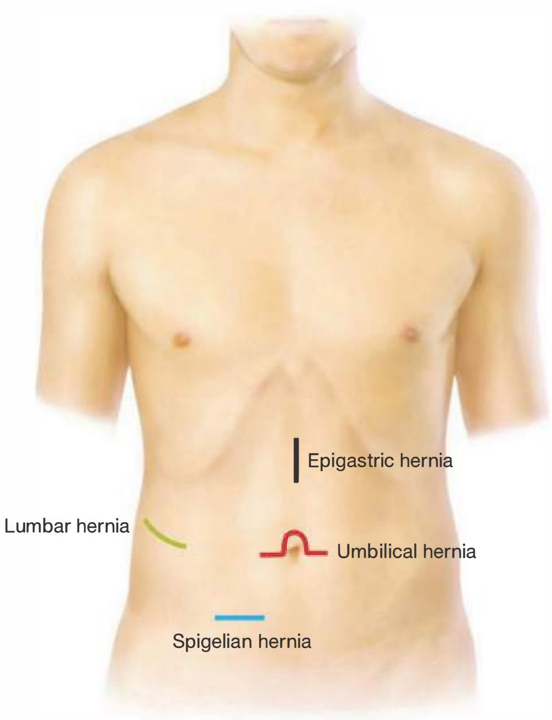

FIG 10 ● Incisions to perform an open primary ventral hernia repair will depend on the localization of the hernia.

margin of the defect. There is a large consensus amongst surgeons that this is not a good way to perform a mesh repair because of the lack of overlap between the mesh and the defect. The amount of overlap is considered to be critical to diminish the risk for recurrence.

- *Retromuscular position for midline hernias*: For umbilical and epigastric hernias, the mesh will be placed behind the rectus abdominis muscle and in front of the posterior rectus fascia. To get enough overlap, a dissection in this plane is needed in all directions for several centimeters. In the cranial and caudal direction, this dissection involves incision of the posterior rectus fascia to allow placement of the mesh behind an intact linea alba. The posterior layer of the rectus fascia is closed. The flat mesh is placed in the dissected retromuscular plane. The anterior rectus fascia is closed in front of the mesh.
- *Retromuscular position for lateral hernias*: For spigelian and lumbar hernias, the mesh is placed behind the intact superficial muscle layer, the external oblique muscle or the latissimus dorsi muscle, respectively. The mesh is placed on top of the closed hernia defect, on the internal oblique muscle or on the quadratum lumborum muscle, respectively.
- *Preperitoneal position*: Another option is to place the mesh behind the posterior rectus fascia, or for lateral hernias, behind the transversus abdominis muscle. The preperitoneal space has to be created by dissecting the peritoneum of the fascia of the deepest abdominal muscle. It is not always easy to develop this plane without creating holes or tears in the peritoneum. These have to be closed if a regular mesh without a protective antiadhesive layer is used.
- *Intraperitoneal position*: There is a consensus that if we want to place a mesh in the intraperitoneal position, thus in contact with the intestines, we have to use a mesh with a protective antiadhesive layer. Unprotected polypropylene or polyester meshes holds an increased risk of causing adhesions and complications such as bowel obstructions, bowel erosions, and fistula.

Fixation of the Mesh

- Several options for fixation of the mesh are available, depending on the mesh positioning.
- For meshes in an intraperitoneal or preperitoneal position, transabdominal sutures can be used. These sutures will fixate the mesh underneath the abdominal wall muscles.
- Suturing the mesh to the posterior fascia or muscular layer can hold the meshes in a retromuscular position. Avoiding transabdominal sutures will avoid the pain related to these sutures.
- For a mesh in the onlay position, sutures can be placed of the mesh to the anterior fascia.
- Fixation with glue applied to the surface of the mesh is a first alternative to the use of sutures.
- Another alternative to the sutures are self-fixating meshes. These meshes have a mechanical fixation either with small gripping hooks or by glue impregnated in the mesh, which becomes active in contact with the moisture of the tissues.
- The size of the mesh and the overlap of the mesh beyond the hernia defect are of critical importance to avoid recurrences.

Closure of the Hernia Defect

- It is recommended that the fascia defect be closed if possible, which is usually the case in primary ventral hernias. A mesh augmentation rather than a bridging of the hernia defect by the mesh is preferred.
- The anterior fascia is closed over the mesh in all repairs except an onlay mesh. In the onlay position, the hernia defect is closed before placing the mesh.

Closure of the Skin

- The skin is sutured either subcutaneously or with separate superficial sutures.

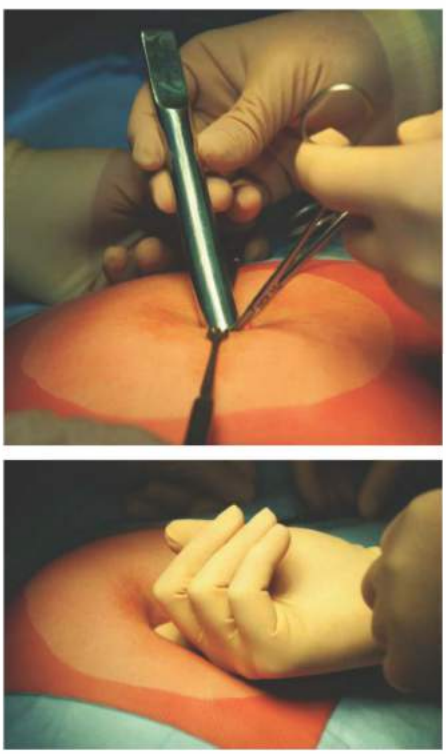
OPEN MESH REPAIR WITH A VENTRAL PATCH

Incision

- The incision needed for repair with a ventral patch is smaller than the incision to place a flat mesh. It is similar to the incision for suture repair. It is recommended not to incise the umbilical rim for more than 180 degrees because of the increased risk of devascularization of the umbilical skin after further dissection of the hernia sac, leading to skin necrosis and wound infection.
- The skin is retracted with small Volkmann retractors and the subcutaneous layer incised down to the fascia, exposing one side, cranial or caudal of the hernia defect (**FIG 8A**).
- The dissection of the hernia sac and reduction of contents is the same as the open primary repair technique.

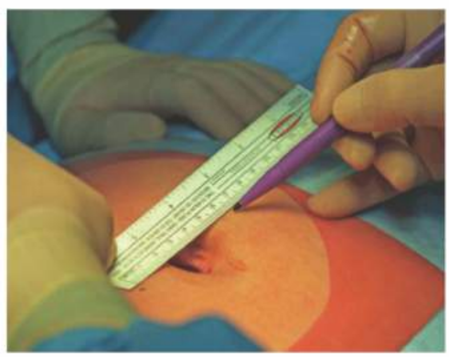
Dissection of the Plane to Position the Mesh Device

- The mesh devices have an antiadhesive layer similar to the meshes used in an intraperitoneal position. Thus, the *intraperitoneal placement* is considered to be safe. If this is done, we consider it of utmost importance that the preperitoneal fat around the hernia is dissected from the abdominal wall around the hernia defect to allow contact between the mesh and the muscular fascia. This is most important cranial to the umbilical hernia, where the round ligament of the liver and its fatty tissue will hinder a correct flat placement of the mesh.
- Alternatively, it is possible in most patients to develop the plane behind the posterior rectus fascia without major damage to the peritoneum. The development of the preperitoneal plane is done through the hernia defect. This allows placement of the mesh device in *a preperitoneal position* and may allow for better contact between mesh and fascia, resulting in better ingrowth while avoiding the possible disadvantages of an intraperitoneal mesh. When using a mesh device, I (*personal opinion of the author*) always try the preperitoneal placement. Only in cases of failure to develop the preperitoneal plane an intraperitoneal position is done.
- The hernia defect can be measured using Hegar dilators to correctly evaluate the size of the defect and classify the hernia accordingly. Because the diameter of the mesh devices does not allow a large overlap beyond the hernia defect, we recommend limiting the repair of ventral hernias with mesh devices to small hernias not larger than 2 cm (**FIG 11A**).
- Isolate the fascia margin from its underlying peritoneum, grasping the fascia edge with the small Volkmann retractors.
- Develop the preperitoneal plane by blunt dissection with the finger if the hernia defect is large enough to allow this (**FIG 11B**). Sometimes, slightly enlarging the hernia defect is needed to allow introducing a digit.



A

B



C

FIG 11 ● **A–K.** An umbilical hernia is repaired using a round mesh device (Proceed Ventral Patch™, Ethicon, Johnson & Johnson) of 6.4-cm diameter. We preferably place the mesh in a preperitoneal position if possible. The mesh is fixed with sutures to the hernia defect, using two central fixation strips, and we usually close the hernia defect on top of the mesh.
*Note: **FIG 11C** and **11D**—In this patient, a mesh of 6.4-cm diameter will be placed. To illustrate the size of dissection needed underneath the posterior rectus fascia, we have measured and drawn a circle of 6.4-cm diameter. (continued)*

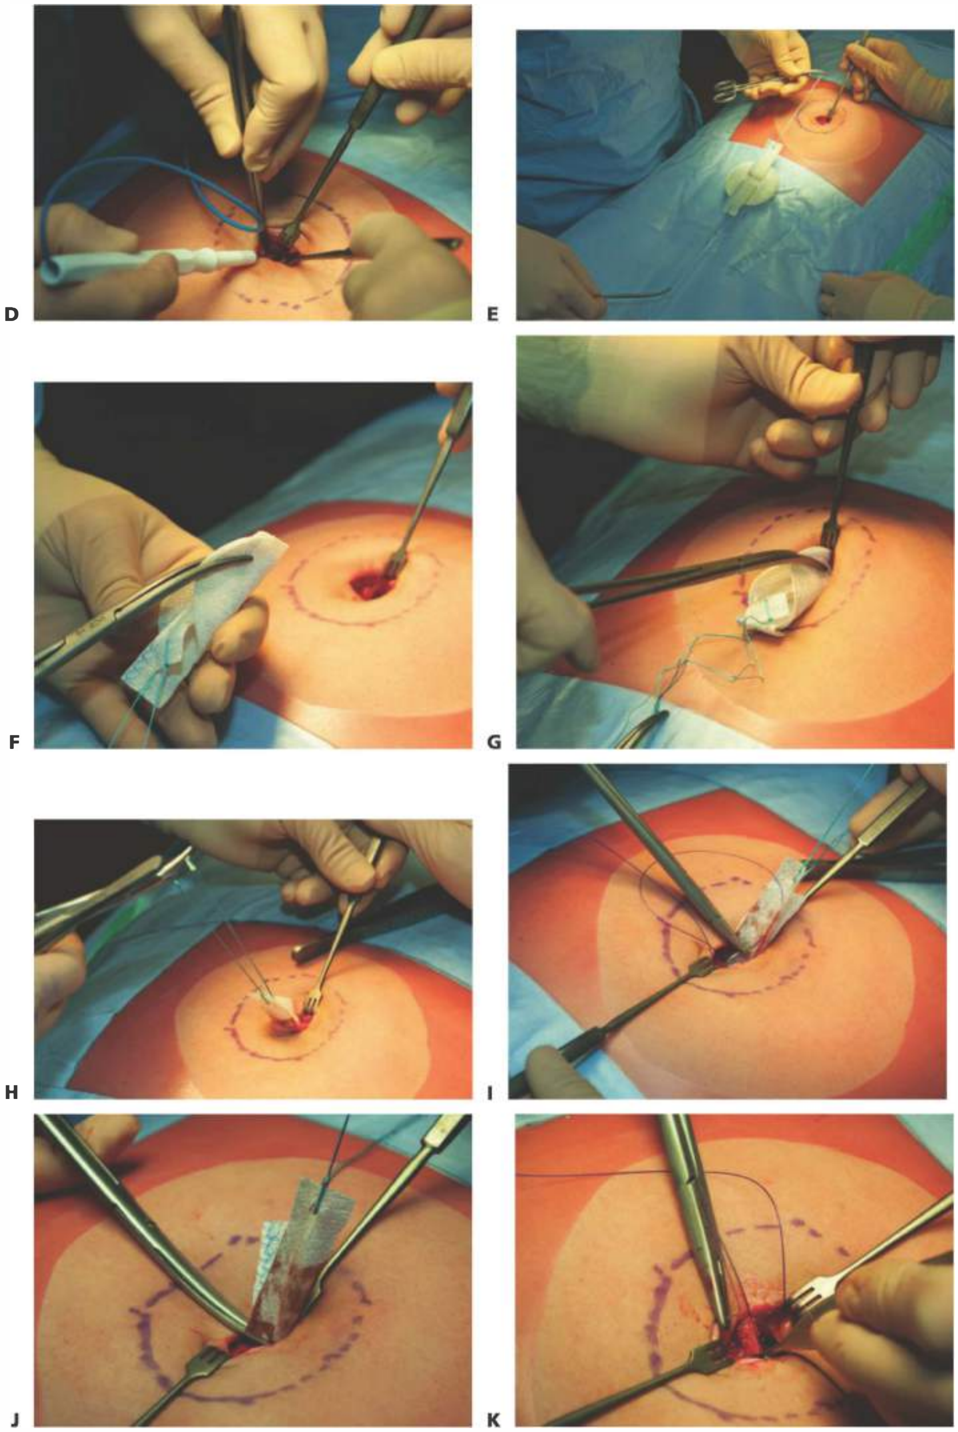


FIG 11 ● *(continued)*

- The dissection of the preperitoneal plane is helped by introducing a gauze in the space created.
- The preperitoneal dissection should be extended far enough to allow easy and flat application of the mesh (**FIG 11C,D**).
- It is important to perform a good hemostatic control of the dissection plane to avoid postoperative hematoma around the mesh.

Introduction of the Mesh Device

- The mesh device is removed from the package after changing surgical gloves.
- The mesh device is 6.4 cm in diameter and has two central strips allowing the mesh to be pulled against the abdominal wall and fixed to the hernia defect (**FIG 11E**).
- The mesh is folded in a manner not to break the internal memory ring at the margin of the mesh and grasped with a clamp (**FIG 11F**).
- While lifting the cranial fascia edge with the retractor, the mesh is pushed in the preperitoneal plane through the hernia defect (**FIG 11G**).
- With two nontraumatic forceps, the mesh is unfolded and checked for a correct flat position.
- The mesh is pulled against the abdominal wall by the central strips, controlling for a correct flat positioning of the mesh (**FIG 11H**).

Fixation of the Mesh Device

- Most round mesh devices for the treatment of small ventral hernias have two central fixation strips to fix the device to the margins of the hernia defect. The caudal strip is fixed to the lower margin of the hernia defect with a U-shaped suture of a slowly absorbable monofilament suture (**FIG 11I**).
- The strip is cut directly above the suture, leaving no mesh material above the fascia (**FIG 11J**).
- The same is done with the cranial strip that is sutured to the upper margin of the hernia defect.

Closure of the Hernia Defect

- Closure of the hernia defect is recommended. It separates the mesh device in the intraperitoneal or preperitoneal position from possible postoperative wound infections.
- As for the primary hernia repair, several options for suturing technique and materials are available: separate sutures, running suture, or vest-over-pants plication sutures (**FIGS 9A–C** and **11K**).

Closure of the Skin

- The skin is sutured either subcutaneously or with separate superficial sutures. A sterile bandage is placed.

LAPAROSCOPIC MESH REPAIR

Creation of the Pneumoperitoneum and Trocar Placement

- The surgical field should be prepped and draped widely, with good exposure of the lateral parts of the abdomen. The trocars are placed very laterally to allow for a good view of the anterior abdominal wall and optimal angles when placing the tacks to fixate the mesh (**FIG 12**). For a midline hernia or for a right spigelian hernia, the trocars will be placed on the left side. For a left-sided spigelian hernia, the trocars are placed on the right side.
- The pneumoperitoneum is created with the use of a Veress needle placed subcostally. Alternatively, an open access can be performed with placement of a blunt trocar.
- Three trocars are placed in the flank on the anterior axillary line (**FIG 12**). When a large mesh is used, fixation on the surgeon's side will need an extra contralateral trocar to allow the tacks to be applied. For most primary ventral hernias, three trocars on one side are sufficient.

Adhesiolysis, Hernia Reduction, and Preconditioning of the Abdominal Wall

- Adhesiolysis, which is sometimes very difficult and time-consuming in laparoscopic incisional hernia repair, is usually not a major issue in primary ventral hernias. If any adhesions are present, they are most often between the omentum and the hernia sac. Adhesiolysis has to be performed carefully, avoiding the use of cautery or other energy sources to minimize the risk of an inadvertent bowel injury.
- The peritoneum of the hernia sac is reduced. Care is taken not to injure the overlying skin while dissecting the sac. The skin above an umbilical hernia may be very thin.
- It is important to precondition or prepare the area of the anterior abdominal wall that will be in contact with the intraperitoneal mesh. This is a part of the operation called "preparing the landing zone" and involves the removal of the fatty tissue and peritoneum around the hernia defect.[5] Above the umbilicus, the falciform ligament of the liver will be removed from the abdominal wall. Below the umbilicus, the fat between the plica umbilicalis mediana of both sides will be dissected down from the abdominal wall, thus exposing the posterior part of the rectus muscles.
- The defect of the hernia can be left open (i.e., bridging technique: the defect is covered and "bridged" by the intraperitoneal mesh) or can be closed (i.e., mesh augmentation: the intraperitoneal mesh is covering the closed hernia defect). *(See video 1: closure and video 2: defect left open in the accompanying eBook.)* There is no consensus whether closure of the hernia defect has advantages to the bridging of the defect.

Mesh Placement and Fixation of the Mesh

- The mesh used during laparoscopic ventral hernia repair needs an antiadhesive side that will be in contact with the viscera. Many different meshes are available for this purpose.[5]
- It is mandatory to have a good overlap of the mesh beyond the hernia defect. An overlap of at least 5 cm in all directions is considered a minimum (**FIG 13**). This is

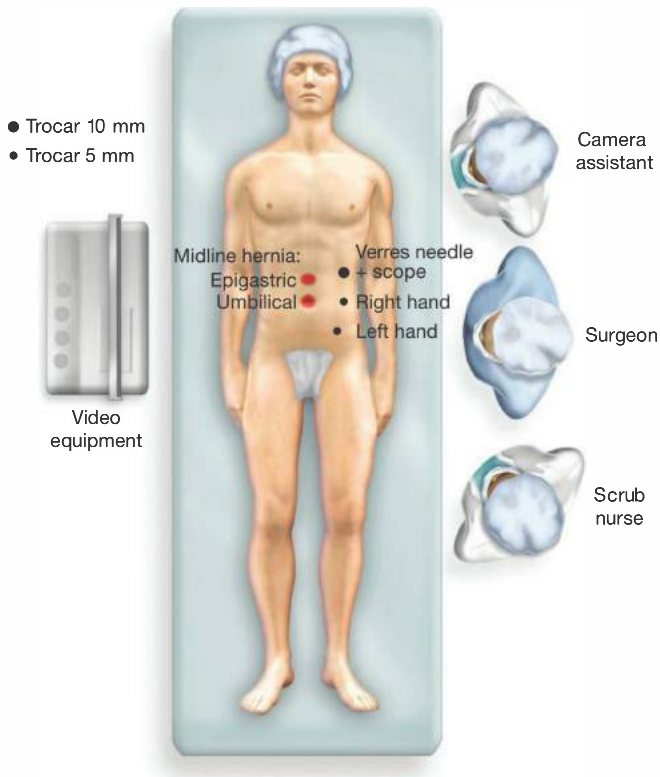

FIG 12 ● Drawing of the intraoperative setting and trocar positions for a laparoscopic ventral hernia repair.

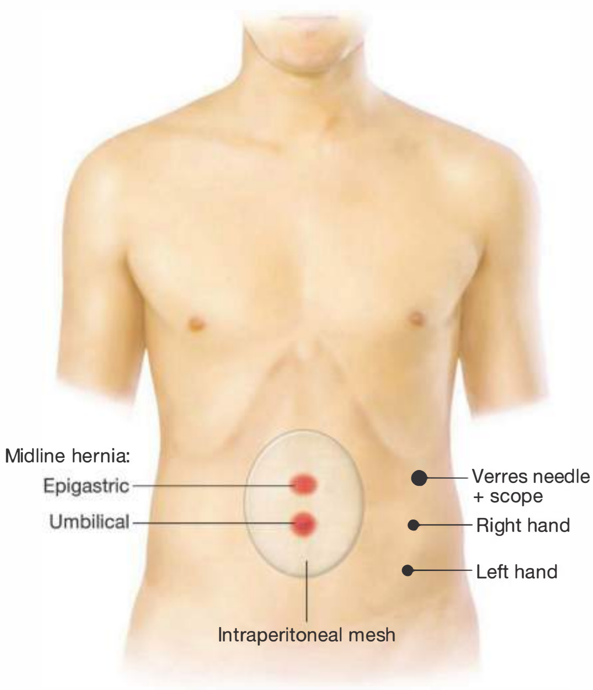

FIG 13 ● A good symmetrical positioning of the mesh with ample overlap beyond the hernia defect is needed.

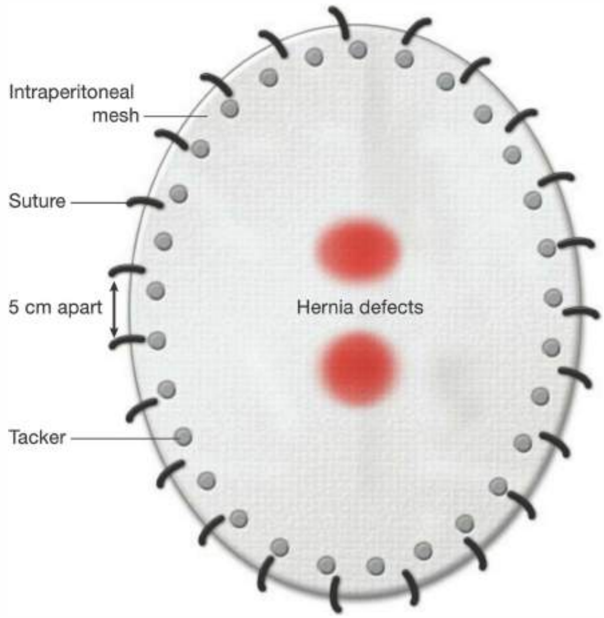

FIG 14 ● Fixation with sutures and tackers during laparoscopic ventral hernia repair.

necessary because all meshes shrink over time. Moreover, it is important to position the mesh symmetrically around the hernia defect. Because of the sharp angle between the abdominal wall and the tacker device, there is a tendency to push the mesh away from the surgeon's side, resulting in an asymmetric mesh placement.

- Several devices are available for the fixation of the mesh.[5] Some of the tackers are absorbable. There is no consensus if the mesh can be adequately fixed with tackers alone or if the addition of transabdominal sutures is needed. Most reported techniques involve a combination of sutures and tackers ("suture and tackers technique") (**FIG 14**) or the use of a double row of tackers ("double crown technique") (**FIG 15**). During the initial experience, the use of four cardinal sutures to orient and position the mesh is very helpful (**FIG 16**).

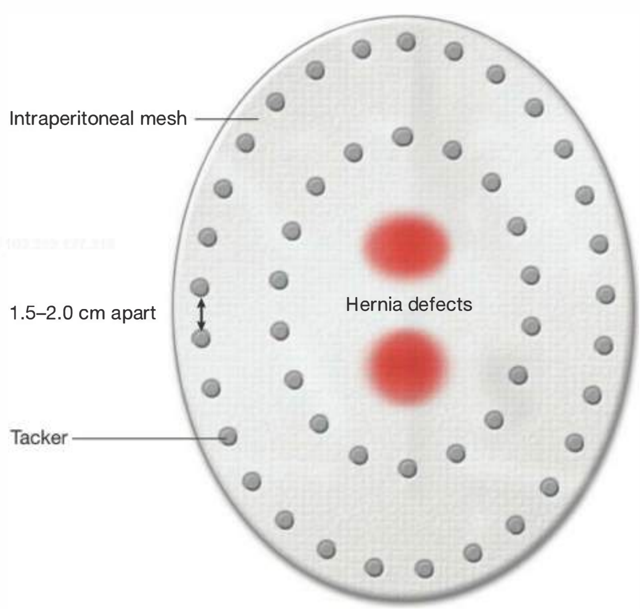

FIG 15 ● "Double crown" fixation during laparoscopic ventral hernia repair.

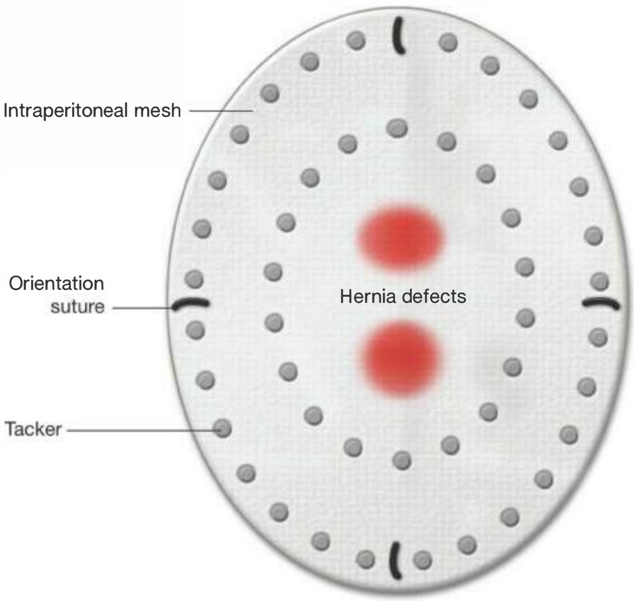

FIG 16 ● Double crown fixation with four cardinal sutures orientation for laparoscopic ventral hernia repair.

PEARLS AND PITFALLS

Indications	■ Small asymptomatic umbilical, epigastric, or lumbar hernias do not need repair and a "watchful waiting" policy can be proposed. ■ Spigelian hernias need surgical treatment because they hold an increased risk of incarceration. ■ Incarcerated hernias should be operated in emergency.
Medical imaging	■ For most umbilical and epigastric hernias, medical imaging is not necessary for diagnosis and treatment planning. ■ Spigelian and lumbar hernias can often only be diagnosed with medical imaging, if they are clinically not palpable.
Mesh repair	■ Suture repair is only applicable in small ventral hernias. ■ A mesh repair will decrease the risk for recurrent ventral hernia. ■ Several mesh positions and surgical approaches are possible. ■ A good overlap of the mesh beyond the hernia defect margin is important to compensate for mesh shrinkage.
Laparoscopic repair	■ A mesh with antiadhesive properties has to be used for intraperitoneal placement. ■ Flat and symmetric positioning of the mesh around the hernia defect is the goal. ■ The abdominal wall around the hernia in contact with the mesh should be adequately prepared and fatty tissue removed. ■ Several mesh fixation alternatives exist, without a clear consensus on the optimal approach. ■ Closure of the hernia defect is optional during laparoscopic ventral hernia repair.

POSTOPERATIVE CARE

- Repair of primary ventral hernias can most often be performed in an ambulatory setting. Restriction of lifting heavy weight and intense sporting activities for 2 weeks is advocated. An abdominal binder to support the hernia repair can have a positive impact on early ambulation and pain control.

OUTCOMES

- Nationwide Danish follow-up data 41 months after surgery show a reoperation rate for recurrence of 4% and a total clinical recurrence rate of 15%.[6]
- From the same Danish database, we know that umbilical and epigastric hernia repair has a low morbidity and mortality but a high readmission rate mostly because of wound

problems, seroma formation, or pain.[7] Moreover, many patients complained about pain and discomfort 3 years after elective repair of a small umbilical or epigastric hernia.[8]

COMPLICATIONS

- Seroma
- Hematoma
- Surgical site infection
- Mesh infection
- Recurrence
- Chronic pain

Chapter 8 Vagotomy: Truncal and Highly Selective

Mary T. Hawn George A. Sarosi Jr. Ashley Augspurger Davis

DEFINITION

- Truncal vagotomy is defined as the division of the anterior and posterior vagus nerves, which innervate the stomach and remainder of the gastrointestinal (GI) tract, at the level of the distal esophagus. Vagotomy eliminates cholinergic stimulation to gastric parietal cells and decreases parietal cell response to gastrin and histamine, thereby reducing gastric acid secretion. By transecting at the entrance point into the abdomen, all innervation to the liver, gallbladder, pancreas, and small intestine is also divided. Truncal vagotomy requires a drainage procedure due to the disruption of antral and pyloric muscular innervation.
  - For many years, vagotomy was one of the cornerstones of surgical treatment of ulcers. However, with further understanding of the role of *Helicobacter pylori* in ulcer pathogenesis and advancement in pharmacologic management including proton pump inhibitors (PPIs) and histamine blockers, the role of surgery has changed. Of the classic indications for ulcer, surgery, bleeding, perforation, obstruction, and intractability, vagotomy is only commonly used in those patients who require surgical control of ulcer bleeding.
  - Level one evidence suggests that it is not necessary in the treatment of duodenal perforation in patients who are *H. pylori* positive,[1] and the number of patients requiring operation for gastric outlet obstruction and intractability has declined dramatically with the advent of improved pharmacologic and endoscopic therapy of peptic ulcer disease (PUD). The incidence of definitive acid reduction surgery decreased by more than 50% from 1993 to 2006.[2]
- Highly selective vagotomy (HSV) is defined as the division of the gastric branches of the nerves of Latarjet. The nerves of Latarjet, celiac division of posterior vagus, and hepatic division of anterior vagus are preserved. Therefore, cholinergic stimulation is selectively eliminated to reduce acid secretion by parietal cells in the body and fundus, and the innervation of the antrum and pylorus, biliary tract, and small and large intestines are untouched. A drainage procedure is not required with HSV. This is also known as "parietal cell vagotomy" or "proximal gastric vagotomy."
  - The operation was developed to avoid the need for a gastric drainage procedure, which is required with truncal vagotomy, as up to one-third of patients will develop delayed gastric emptying following this procedure. Despite the elegance of parietal cell vagotomy, it is a technically demanding operation with a higher ulcer recurrence rate and much longer learning curve than truncal vagotomy. In an era when few vagotomies are performed, it has largely fallen out of favor.[3]
- Of historical note, a selective vagotomy sections the anterior vagus just distal to the point where the branch to the gallbladder and liver and the posterior vagus just distal to the branch to the pancreas and small intestines. Although in theory this might reduce the side effects of vagotomy, it is unclear in practice that this had any effect on outcomes.

DIFFERENTIAL DIAGNOSIS

- In a patient with acute severe upper GI bleeding, the differential diagnosis includes a bleeding peptic ulcer, bleeding esophageal or gastric varices secondary to portal hypertension, esophageal mucosal diseases such as severe esophagitis and Mallory-Weiss tears, gastric arteriovenous malformations and Dieulafoy's lesion, and rarely, ulcerated tumors or hemobilia.
- In a patient with acute abdominal pain and free air, the differential diagnosis should include a perforated peptic ulcer, perforated diverticulitis, perforated appendicitis, and small bowel perforation.
- In the patient with gastric outlet obstruction, the differential diagnosis includes PUD, gastric cancer, duodenal web, functional delay in gastric emptying, and chronic ulcer disease related to nonsteroidal antiinflammatory drug (NSAID) or aspirin use.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The majority of operations for PUD performed now are urgent or emergent operations for complicated ulcer disease.
- A thorough history and physical should be obtained with key focus on the duration of symptoms, previous ulcer therapy, NSAID or aspirin use, and smoking history. Consider investigation into hypersecretory and malignant etiologies in patients with refractory ulcer disease.
- Patients should be specifically questioned regarding *H. pylori* status and prior *H. pylori* treatment including a history of eradication. In patients unable to stop antiinflammatory drug use or those with *H. pylori*–negative ulcer disease, it may be reasonable to consider performing an acid-reducing procedure at the time of ulcer repair.
- Bleeding can occur in 15% to 20% of patients with PUD and is the most common ulcer-related complication.[4] The majority will resolve with conservative or endoscopic treatment. In patients undergoing operation for a bleeding duodenal ulcer, the best available evidence suggests that vagotomy should be combined with oversewing of a duodenal ulcer.[5] As such, the patient's *H. pylori* status, history of prior NSAID use, or prior ulcer disease will not affect the use of vagotomy in the management of their bleeding duodenal ulcer
- Perforations occur in up to 10% of ulcer complications.[4] Patients that will most likely to benefit from acid-reducing surgical intervention during repair of a perforation include those that have contraindications to PPI, perforation on PPI, or prior eradication of *H. pylori*.
- Obstruction is the least common complication of ulcer disease at 5% to 8% and occurs as a result of scarring of the pylorus.[4] Endoscopy often delineates location and degree of the obstruction and also allows for therapeutic balloon dilation of the pylorus. Surgery is reserved for failure of less invasive treatments.

- Intractable disease encompasses failure of medical management to heal the ulcer, relapse of disease while on current therapy, or multiple courses of medical therapy. Medical management includes acid suppression, *H. pylori* eradication, and NSAID cessation. Symptoms should be substantiated with endoscopic visualization of a persistent or recurring ulcer.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- In a patient with sudden onset acute abdominal pain and physical exam findings of peritonitis, an upright chest radiograph confirming the finding of free intraperitoneal air is a sufficient workup prior to proceeding to the operating room (OR) for a presumed perforated ulcer.
- In patients with a history and physical consistent with a perforated ulcer, but without free air on radiograph, a computed tomography (CT) scan or upper GI contrast study using water-soluble contrast can help to make the diagnosis.
- Testing for *H. pylori* is used to confirm presence of or gauge the eradication of disease. Antibody testing assesses overall exposure but is not specific for active disease. Urease breath test and stool antigen test can be used to confirm eradication. Full treatment of *H. pylori* should be attempted before definitive acid reduction surgery is considered.
  - Stool antigen testing for *H. pylori* should be performed prior to operation for PUD, as knowledge of *H. pylori* status may help determine the need for vagotomy. As mentioned earlier, it may not be necessary to perform vagotomy for *H. pylori* positive disease, but may be considered in treatment of *H. pylori*-negative ulcer disease.
- Serum gastrin levels should be tested to rule out hypergastrinemic syndromes.
- Endoscopy is part of standard investigation of ulcer disease when symptoms persist despite medical therapy. Endoscopy is also used to assess ulcer healing and perform biopsies to evaluate malignancy, gastritis, and *H. pylori* infection.
- In patients with a bleeding peptic ulcer, the surgeon should be present at the time of upper endoscopy to gain an accurate anatomic understanding of the location of the ulcer. Patients with gastric ulcers not caused by acid, such as ulcers along the lesser curvature proximal to the incisura or near the gastroesophageal (GE) junction, will not require a vagotomy. Patients with duodenal or prepyloric ulcer should undergo vagotomy at the time of their operation for bleeding control.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients undergoing emergency surgery for peptic ulcer bleeding will have a stomach full of blood and are at significant risk of aspiration. A nasogastric tube should be placed prior to induction for all vagotomy procedures, and rapid sequence induction should be used if possible.
- When performing an emergency operation for bleeding, the surgeon should ensure that blood is cross-matched and available.
- For laparoscopic procedures, having the ability to perform intraoperative esophagogastroduodenoscopy (EGD) can facilitate the identification of the ulcer in difficult cases.
- With truncal vagotomy, the gastric antrum and pylorus are denervated and concomitant drainage procedure must be performed.
  - Options include pyloroplasty, gastrojejunostomy, or gastric resection with reconstruction (see Part 2, Chapter 9).
- HSV preserves antral muscular function and the pylorus mechanism. It is not necessary to perform a drainage procedure.
- Transthoracic vagotomy requires double lumen intubation tube and separate lung ventilation; for sufficient exposure to distal esophagus, the left lung must be collapsed.
- Perioperative antibiotics should be administered; cefazolin is standard, clindamycin plus a fluoroquinolone or aminoglycoside for penicillin allergy.

Positioning—Open

- Open approach: Patient is supine with the arms tucked or extended.
  - Space is left on the patient's left side to attach a Bookwalter or Omni retractor to the bed rail.
- Reverse Trendelenburg position of the table will help with exposure of the hiatus.

Positioning—Laparoscopic

- Laparoscopic approach: Patient is supine with right arm tucked. Surgeon stands on patient's right and assistant stands on patient's left.
- Reverse Trendelenburg position of the table will help with exposure of the hiatus.

Positioning—Transthoracic

- Patient is placed in right lateral decubitus position.

TECHNIQUES

TRUNCAL VAGOTOMY—OPEN

Skin Incision and Retractor Positioning

- Use a standard upper midline incision, from just below xiphoid process to level of the umbilicus.
- A body wall retractor blade is placed on either side of the upper half of the incision to facilitate exposure.
- Depending on the size of the left lateral segment of the liver, it may be necessary to divide the avascular portion of the left triangular ligament to allow the left lateral segment to be retracted in order to facilitate visualization of the abdominal esophagus (**FIG 1**).

Exposure of the Esophagus

- The pars flaccida and the phrenoesophageal ligament are divided to expose the right crus and anterior esophageal wall. Take caution to recognize and preserve an accessory left hepatic artery when dividing the pars flaccida. The position of the esophagus can be verified by palpation of the nasogastric tube within the lumen of the esophagus.
- Identify the right crus of the diaphragm; gently dissect to expose the anterior surface of the esophagus. This peritoneal incision should be carried across the

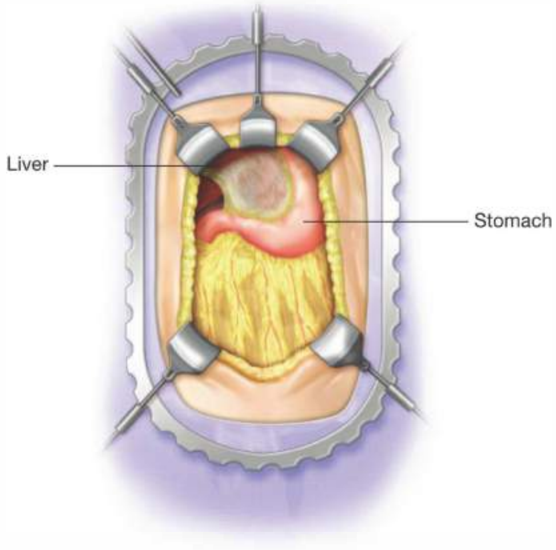

FIG 1 ● A Bookwalter-style self-retaining retractor provides excellent exposure of the stomach and duodenum for drainage procedures. Placement of four abdominal wall blades, two on either side of the upper and lower aspect of the wound will provide the optimum exposure. A Harrington or malleable retractor on the left lobe of the liver can facilitate exposure.

anterior surface of the esophagus and onto the left crus of the diaphragm to expose the anterior surface of the esophagus (**FIG 2A**). By applying downward and rightward traction on the stomach, the surgeon can place the esophagus on tension to enhance exposure (**FIG 2B**).

- Continue to develop a plane between right crus and the esophagus; extend posteriorly to create a retroesophageal window.
- The esophagus is then dissected circumferentially and this, again, can be facilitated by palpating the nasogastric tube in the lumen of the esophagus.
- A Penrose drain is placed around the GE junction to assist with downward traction on the GE junction.

Identification and Division of the Anterior (Left) Vagus Nerve

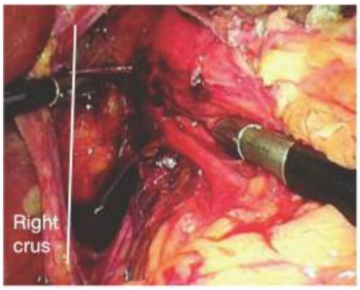
- The vagus nerves rotate counterclockwise at the level of the esophageal hiatus with the right vagus nerve coursing more posterior and the left vagus nerve anterior with respect to the esophagus.
- The left (anterior) vagus nerve is typically anterior and just right of midline at the 1 o'clock to 2 o'clock position. It is often almost within the longitudinal muscle layer (**FIG 3**).
  - Downward traction of the GE junction via the Penrose drain can help tense the nerve like a guitar string to help with palpation.
  - Dissect the nerve off the anterior surface of esophagus using a right angle with sharp dissection, minimal cautery.
  - Any additional anterior vagus nerve should be dissected free of esophagus if present. In about 10% of cases, two or rarely more anterior vagal branches may be found.[6]
- A medium clip is then placed on the nerve(s) at the level of the diaphragm and a second clip is placed on the nerve 3 to 4 cm distal to the first. The segment of nerve(s) between the clips is excised and sent for pathology to verify nervous tissue was excised (**FIG 4**).

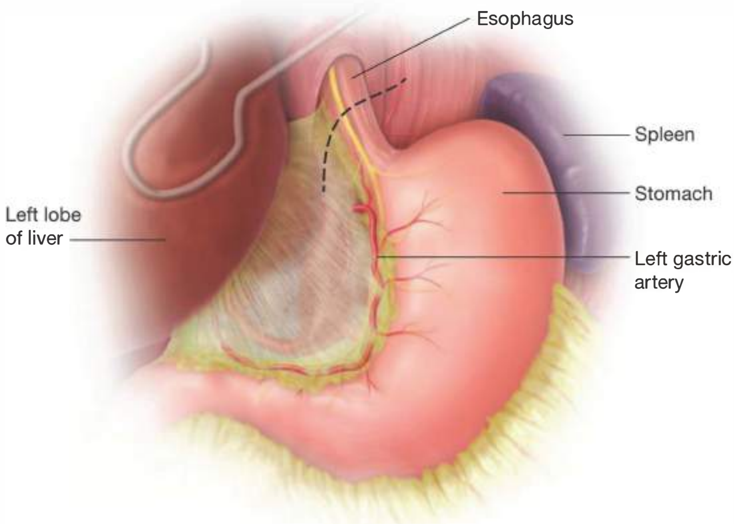
Identification and Division of the Posterior (Right) Vagus Nerve

- The right (posterior) vagus is found at the 7 o'clock position and is often up to a centimeter away from the esophageal wall between the esophagus and the right crus (**FIG 5**).
  - In about 15% of cases, it may be located to the left of midline.[6]
- To identify the posterior vagus trunk(s), the surgeon should again apply downward traction on the Penrose while sweeping the index finger of the right hand posterior to the esophagus from the left crus to the right.
  - The surgeon's finger should be right on the esophageal wall and any tense bands identified should be hooked with a right angle and dissected free from the esophageal wall (**FIG 6**).
- A clip should be placed at the level of the diaphragm and a second clip is placed on the nerve 3 to 4 cm distal. The segment of nerve(s) between the clips is excised and sent for pathology to verify nervous tissue.
- Continue with gastric drainage procedure as indicated: pyloroplasty, gastrojejunostomy, or gastric resection with reconstruction (see Part 2, Chapter 9).

Assessment of Hemostasis and Closure

- After verifying that no additional vagal trunks can be identified, the surgeon should inspect the diaphragmatic hiatus. During blunt mobilization of the GE junction, a hiatal hernia is sometimes created.
  - If the surgeon can insert more than the one finger adjacent to the esophagus through the hiatus, the right and left crura should be reapproximated with one or two 0 braided polyester or silk sutures to prevent the development of a postoperative hiatal hernia.
  - At the completion of the repair, a single finger should be able to be inserted alongside the esophagus to avoid postoperative dysphagia.
- After hemostasis is verified, the midline is closed in usual standard fashion.





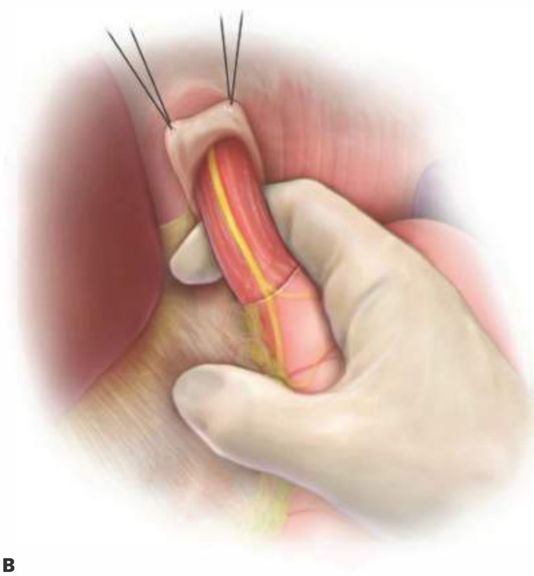


FIG 2 ● **A.** Photo **(left)** and illustrations of the peritoneum of the pars flaccida is incised to expose the right crus of the diaphragm and the esophagus. This peritoneal incision should be carried across the anterior surface of the esophagus and onto the left crus of the diaphragm to expose the anterior surface of the esophagus. **B.** Beginning on the left of the esophagus, blunt dissection with a finger or a Kittner dissector will allow the surgeon to separate the esophagus from the left crus. With gentle blunt dissection, it is possible to encircle the esophagus with the right index finger.

FIG 3 ● As seen in this intraoperative photo, the anterior vagus trunk is a large band intimately associated with the muscular wall of the esophagus and often located on the right anterior surface of the esophagus.

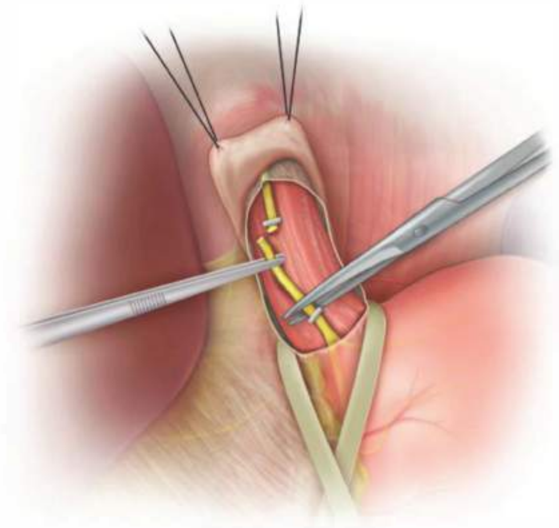

FIG 4 ● The anterior vagus trunk is carefully dissected from the anterior surface of the esophagus, and a medium clip is then placed on the nerve(s) at the level of the diaphragm and a second clip is placed on the nerve 3 to 4 cm distal to the first. The segment of nerve(s) between the clips is excised and sent for pathology to verify nervous tissue was excised.

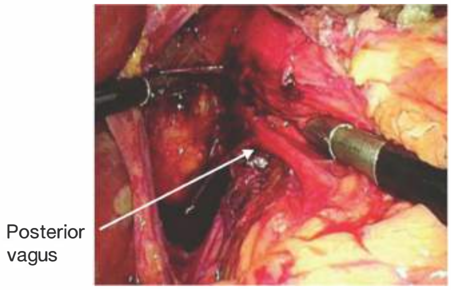

FIG 5 ● As shown in this intraoperative photo, the posterior vagal trunk is less intimately associated with the esophageal musculature.

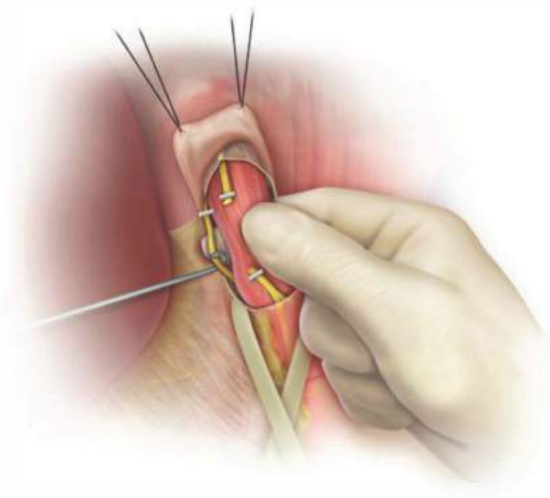

FIG 6 ● To identify the posterior vagus trunk(s), the surgeon should again apply downward traction on the Penrose while sweeping the index finger posterior to the esophagus from the left crus to the right. The surgeon's finger should be right on the esophageal wall and any tense bands identified should be hooked, dissected free from the esophageal wall, and divided between clips.

TECHNIQUES

LAPAROSCOPIC TRUNCAL VAGOTOMY

Port Placement and Liver Retraction

- Port placement (FIG 7)
    - 5-mm periumbilical camera port 2 cm to the left of midline
    - 5-mm subxyphoid trocar for liver retraction
    - 5-mm right midclavicular line, two fingerbreadths below costal margin: left hand working port
    - 5-mm trocar between the right midclavicular line and camera trocar
    - 5-mm left anterior axillary line, below costal margin: stomach retraction
- A Nathanson liver retractor is placed to elevate the left lobe of the liver.
    - The patient is positioned supine with the right arm tucked.
    - The surgeons stands to the patient's right and the assistant to the patient's left.

Exposure of the Esophagus

- The peritoneum of the pars flaccida and the phrenoesophageal ligament is incised with a Harmonic scalpel or bipolar cautery device to expose the right crus of the diaphragm onto the anterior surface of the esophagus and across to the left crus to expose the entire surface of the esophagus.
- The position of the esophagus can be verified by palpation of the nasogastric tube within the lumen of the esophagus or by performing an intraoperative EGD.
- The peritoneum overlying the medial edge of the right crus of the diaphragm is identified and incised, and then, blunt dissection is used to elevate the esophagus off of the right and left crus to make a retroesophageal window.

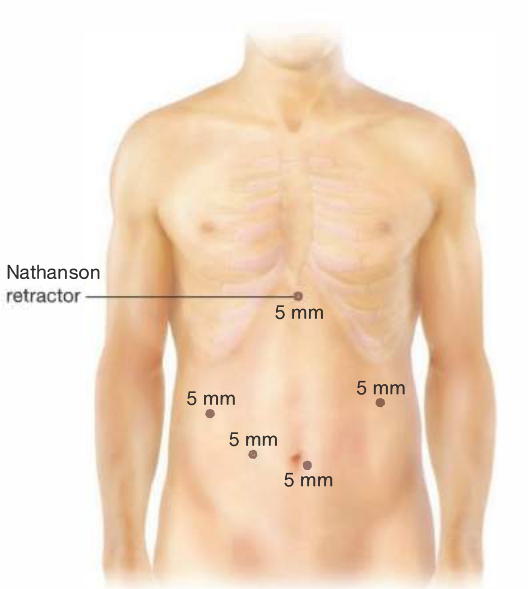

FIG 7 ● Shows the standard port placement used for a laparoscopic vagotomy.

- A grasper is then passed though the window and a Penrose drain is used to encircle the esophagus.

Identification and Division of the Anterior (Left) Vagus Nerve

- With the magnification inherent in laparoscopy, the anterior vagus can often be visualized directly on the anterior surface of the esophagus (FIG 3).
    - If the nerve cannot be easily visualized, downward traction on the GE junction obtained by having the assistant pull down on the Penrose will make the nerve tense like a guitar string and will allow for either visual or tactile identification of the anterior vagus.
- Using a Maryland dissector, the surgeon should carefully dissect the anterior vagus away from the esophageal muscle and elevate the nerve.
- Using sharp dissection with the Harmonic scalpel or bipolar cautery device, the surgeon should free up the vagus to the diaphragmatic hiatus.
- An endoclip should be placed across the nerve at the hiatus and a second clip placed 3 to 4 cm inferior to the first. The portion of the nerve between the clips is then excised and sent to pathology.
- A search for additional anterior trunks should be conducted as discussed previously.

Identification and Division of the Posterior (Right) Vagus Nerve

- The posterior vagus is less closely associated with the esophageal wall.
- To identify the posterior vagus trunk(s), the assistant should apply caudal and leftward traction on the Penrose drain with a grasper inserted through the left upper quadrant port.
    - The posterior vagus should become visible at this point as a tight band traversing between the posterior wall of the esophagus and the right crus of the diaphragm (FIG 5).
    - Many times, the posterior vagal trunk will be encircled within the Penrose drain, and the Penrose will need to be repositioned to allow the dissection of the nerve trunk away from the esophagus.
- Using sharp dissection with the Harmonic scalpel or bipolar cautery device, the surgeon should free up the vagus to the level of the diaphragmatic hiatus
- An endoclip should be placed at the level of the diaphragm and a second clip is placed on the nerve 3 to 4 cm distal. The segment of nerve(s) between the clips is excised and sent for pathology to verify nervous tissue was excised.

Assessment of Hemostasis and Closure

- Again, verify no additional vagal trunks
- Inspect the diaphragmatic hiatus as described earlier and reapproximate if necessary.
- Remove laparoscopic ports under direct vision to ensure hemostasis.
- Close skin in the usual standard fashion, with fascial closure for port sites greater than 5 mm.

TRANSTHORACIC VAGOTOMY

Port Placement

- 10-mm camera port in 7th or 8th intercostal space, posterior axillary line
- 10-mm instrument trocar along anterior axillary line at 6th and 10th intercostal space, forming a semicircle with the camera port
- 5 mm can be placed in 10th or 11th intercostal space along posterior axillary line if needed (**FIG 8**).

Exposure of the Esophagus

- The left lung will need to be collapsed to visualize the distal esophagus.
- Transect the pulmonary ligament with scissors or electrocautery and retract the collapsed lung superiorly (**FIG 9**).
- Incise the mediastinal pleura to expose the esophagus.

Identification and Division of the Anterior (Left) Vagus Nerve

- With the magnification in laparoscopy, the anterior vagus can often be visualized directly on the anterior surface of the esophagus.
- Using a Maryland dissector, the surgeon should carefully dissect the anterior vagus away from the esophageal muscle and elevate the nerve, placing tension by pulling toward the surgeon.

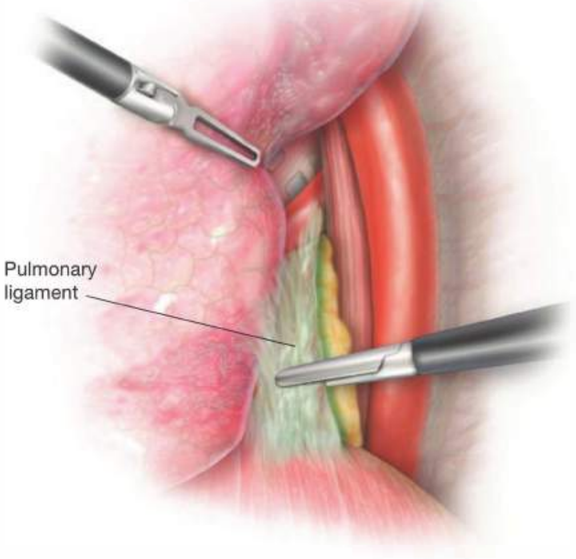

FIG 9 ● To expose the distal esophagus, transect the pulmonary ligament and retract the collapsed left lung superiorly.

- Using sharp dissection with the Harmonic scalpel or bipolar cautery device, the surgeon should free up 3 to 4 cm of the vagus nerve (**FIG 10**).
- An endoclip should be placed across the nerve at the hiatus and a second clip placed 3 to 4 cm inferior to the first. The portion of the nerve between the clips is then excised and sent to pathology.

Identification and Division of the Posterior (Right) Vagus Nerve

- The posterior vagus is less closely associated with the esophageal wall.

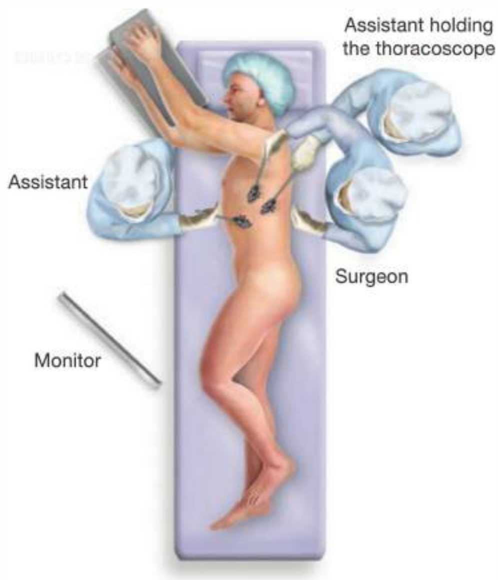

FIG 8 ● Positioning and port placement for the transthoracic vagotomy. Patient is in the right lateral decubitus. Note hand ports are as far away as possible from each other but forming semicircle with video port.

FIG 10 ● Anterior vagus is identified on top of the esophagus. It is carefully dissected by spreading parallel to esophagus and then placed on tension by pulling toward the surgeon. A segment is then clipped for removal and sent to pathology.

- Place gentle upward traction on the esophagus. Using a Maryland dissector, continue to spread parallel to the nerve and esophagus in the retroesophageal plane.
    - Pull vagus again toward the surgeon to tense nerve like a guitar string in order to transect the nerve.
- Using sharp dissection with the Harmonic scalpel or bipolar cautery device, the surgeon should free up 3 to 4 cm of the vagus nerve (**FIG 11**).
- An endoclip should be placed across the nerve at the hiatus and a second clip placed 3 to 4 cm inferior to the first. The portion of the nerve between the clips is then excised and sent to pathology.

Assessment of Hemostasis and Closure

- After hemostasis is ensured, a red rubber should then be inserted through on the camera ports and fed proximally over the lung tissue to act as a chest tube.
- The camera port is then withdrawn and lung reinflated under direct visualization.
- Closure of laparoscopic port sites in usual standard fashion.

FIG 11 ● Gentle traction placed on esophagus to pull anterior in the chest. The posterior vagus nerve is dissected from the tissue below the esophagus. This is again pulled toward surgeon to aid in excision.

HIGHLY SELECTIVE VAGOTOMY

Exposure of Esophagus

- The phrenoesophageal ligament overlying the esophagus is incised and the esophagus is encircled with a Penrose drain.

Exposure of Vagus Nerves, Nerve of Latarjet

- The anterior and posterior vagus nerves are identified and each encircled with a vessel loop. Dissection is carried far enough into the posterior mediastinum to identify main vagal trunks.
- Examine the lesser curvature of the stomach to identify the nerve of Latarjet (**FIG 12**).
- Dissect 6 to 7 cm proximal to the pylorus along the lesser curvature of the stomach at the incisura angularis. It is key to leave the terminal branches of the nerve, referred to as "crow's foot," to maintain innervation to the antrum and pylorus (**FIG 13**).
- Divide the lesser omentum from the lesser curve from the incisura angularis and continue to divide the vagal branches to 6 cm proximal to the GE junction. Stay inside the main vagal braches.
    - Clamp and divide neurovascular branches along the lesser curve as close to the stomach as possible to avoid injury to the nerve of Latarjet (**FIG 14**).
    - There is an anterior and posterior bundle and they should be divided separately.
- Invert the lesser curvature of the stomach with interrupted Lembert sutures.

Hemostasis and Closure

- Midline is closed in usual standard fashion.
- Laparoscopic ports close in usual standard fashion, with fascial closure for port sites greater than 5 mm.

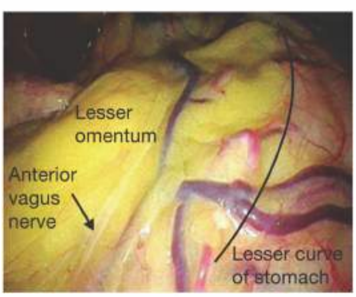

FIG 12 ● Identify the lesser curve of the stomach; see the anterior vagus nerve coursing in on the lesser omentum.

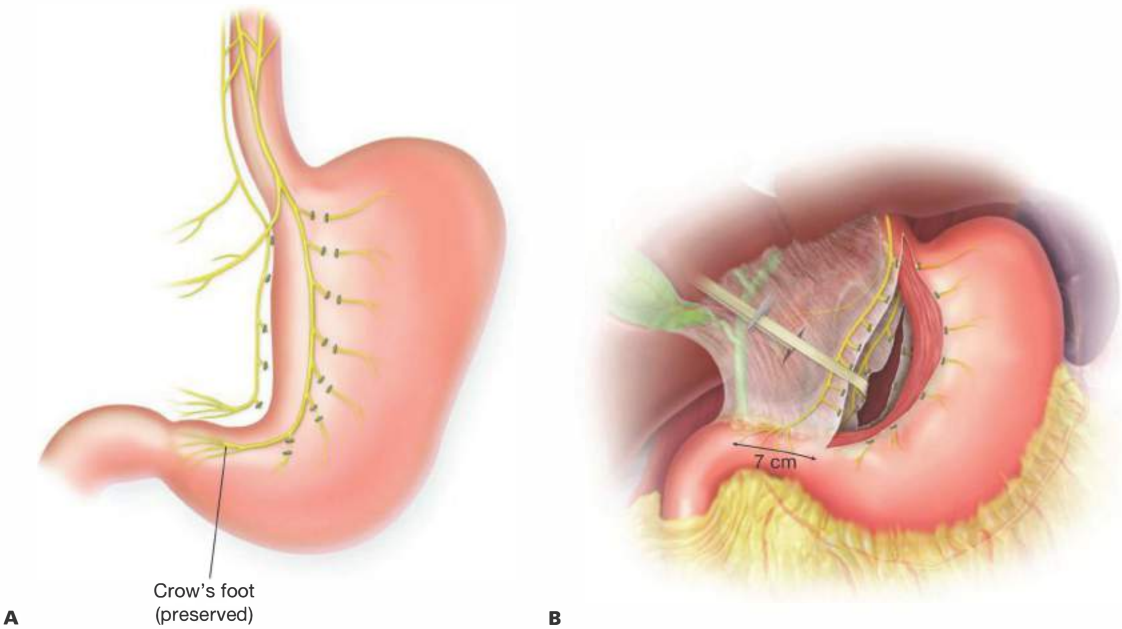

FIG 13 ● **A,B.** Dissection occurs along the lesser curvature of the stomach from proximal to the GE junction to the incisura angularis, 6 to 7 cm proximal to the pylorus. Leave the terminal branches of the nerve, referred to as "crow's foot," to maintain innervation to the antrum and pylorus.

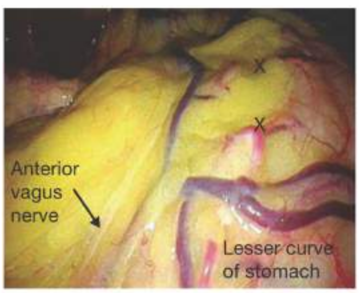

FIG 14 ● Clamp and divide neurovascular branches along the lesser curve as close to the stomach as possible to avoid injury to the nerve of Latarjet. Marked by the *X*. There is an anterior and posterior bundle and they should be divided separately.

PEARLS AND PITFALLS

Indications	■ In patients with evidence of active *H. pylori* infection, treatment of the ulcer complication and antihelicobacter therapy may be sufficient. ■ When the operative indication is GI bleeding, the surgeon should verify if the bleeding source is in a location associated with a high acid state such as the duodenum or prepyloric stomach.
Exposure	■ Take caution when encircling the esophagus and dissecting the vagus off of the esophagus to prevent injury. ■ Avoid the use of cautery when dissecting the vagal fibers away from the esophageal surface.
Vagotomy	■ Ten percent of patients will have more than one anterior or posterior vagal trunks; care must be taken to look for additional fibers after division of the first trunk. ■ Always send a section of the excised vagal trunk to pathology to verify that nervous tissue was excised. ■ Most ulcer reoccurrences result from incomplete vagotomy. ■ Care to resect above the criminal nerve of Grassi (**FIG 15**) ■ Injury to thoracic duct in transthoracic approach

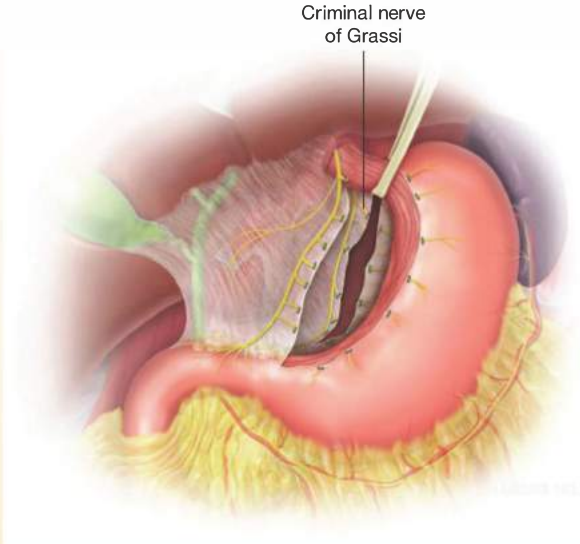

FIG 15 ● Criminal nerve of Grassi—Vagus nerve must be dissected proximal to criminal nerve of Grassi which, if undivided, can keep high acid levels postvagotomy.

Drainage procedure	■ A drainage procedure, a pyloroplasty, gastrojejunostomy, or antrectomy should always be combined with a truncal vagotomy as up to one-third of patients will develop gastric stasis after vagotomy alone.
Paraesophageal herniation	■ Inspect the esophageal hiatus at the conclusion of the procedure to verify that an iatrogenic paraesophageal hernia has not been created.

POSTOPERATIVE CARE

- Nasogastric suction may be used in the early postoperative period. In patient who has undergone gastric drainage procedure or perforation repair, postoperative ileus may last as long as 7 to 10 days.
- Consistent with other foregut surgery, diet advancement is as tolerated.
- Intolerance to diet should prompt investigation for delayed gastric emptying.
- In patients operated on for perforated ulcers, broad-spectrum antibiotic therapy including antifungal agents should be administered postoperatively.
- Patients who are found to be *H. pylori* positive should receive 10 to 14 days of antibiotic therapy directed at *H. pylori* eradication. Eradication should be confirmed by repeat testing.
- Patients operated on for bleeding should be carefully monitored for rebleeding for up to 96 hours.
- Patients chronically using NSAIDS or aspirin products should be counseled to avoid further use of these medications. Patients who are medically unable to discontinue these drugs should be started on a PPI.
- Transthoracic patients should be monitored with daily chest radiographs until the chest tube is removed appropriately.

OUTCOMES

- **Vagotomy**
  - Truncal vagotomy has demonstrated 80% reduction in basal acid secretion.[7]
  - Truncal vagotomy has the lowest reoccurrence rates (1% to 10%) but have the highest morbidity (20% to 25%) and mortality (0.5% to 2%).[8,9] Ulcer recurrence rates also vary based on drainage procedure, with best results from total vagotomy with antrectomy.
  - Common postoperative morbidity includes diarrhea (10% to 25%), dumping syndrome (10% to 20%), and bile reflux gastritis (2%).[8,9]
  - Vagal-mediated receptive relaxation of the stomach is abolished; there may be more rapid emptying of liquids and solids.
- **HSV**
  - Lower mortality and morbidity including diarrhea and dumping syndrome (1% to 5%).[3]
  - Higher ulcer recurrence rates, greater than 10% at 5 years.[3]
  - Vagal-mediated receptive relaxation of the stomach is abolished, and therefore, there is more rapid emptying of liquids. However, with preservation of antrum innervation, emptying of solids is unaffected.

COMPLICATIONS

- Esophageal perforation
- Bleeding
- Incomplete vagotomy—failure to identify accessory vagus nerves. Vagus must be taken proximal to the criminal nerve of Grassi, the first gastric branch of the posterior vagus.
- Delayed gastric emptying
- Dumping syndrome
- Pleural effusion

Chapter 9

Drainage Procedures: Pyloromyotomy, Pyloroplasty, Gastrojejunostomy

George A. Sarosi, Jr.

DEFINITION

- Drainage procedures, or more properly gastric drainage procedures, are a variety of surgical approaches used to either render incompetent or bypass the pylorus. Drainage procedures are often performed in conjunction with procedures that interrupt vagal innervation of the pylorus, and the purpose is to facilitate gastric drainage. Originally performed in conjunction with a truncal vagotomy for the treatment of peptic ulcer disease, drainage procedures are also performed to facilitate gastric emptying when the stomach is used as an esophageal replacement and occasionally to address poor gastric emptying in patients who have undergone fundoplication or paraesophageal hernia repair. Gastrojejunostomy is also frequently used to treat duodenal or gastric outlet obstruction.

DIFFERENTIAL DIAGNOSIS

- In patients who have undergone prior gastroesophageal (GE) junction surgery, the differential diagnosis for abdominal bloating includes visceral hypersensitivity (irritable bowel syndrome [IBS]), gastroparesis, postsurgical delayed gastric emptying secondary to vagal injury, paraesophageal herniation of the fundoplication or portions of the stomach, and overeating or excess consumption of inappropriate foods such as carbonated beverages.
- In patients who have undergone esophageal replacement with a gastric conduit, the differential diagnosis of dysphagia, early satiety, or regurgitation of undigested foods includes anastomotic structure, an inadequate-sized hiatal opening, torsion of the conduit, paraesophageal hernia, and competent pylorus.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Depending on the indication for a drainage procedure, certain historical elements and physical findings should be sought.
  - For patients with peptic ulcer disease, the duration of symptoms and any prior treatment of peptic ulcer disease should be sought. In addition, knowledge of the patients' *Helicobacter pylori* status and prior *H. pylori* treatment is important. Finally, a history of use of nonsteroidal antiinflammatory drugs (NSAIDs) or aspirin products should be sought.
    - In patients with a prior history of peptic ulcer disease who are undergoing surgical treatment of a bleeding ulcer, a history of prior ulcer disease should alert the surgeon to the possibility of encountering a scarred and possibly fibrotic duodenum.
    - Patients known to be *H. pylori* positive who have not had treatment for their *H. pylori* may not require an acid-reducing procedure at the time of surgical bleeding control. Simple ligation of the bleeding site may be sufficient.
    - Patients with a significant history of NSAID or aspirin product use are at a significant risk of recurrent ulcers and must be counseled to avoid all these products in the future.
  - For patients undergoing drainage procedures after esophageal replacement with a gastric conduit, patients should be questioned carefully about their symptoms. Patients with poor gastric drainage will describe early satiety, bloating, regurgitation, or emesis of undigested food. Patients with anastomotic strictures typically will describe dysphagia.
  - For patients undergoing or who have undergone a fundoplication, a history of postprandial abdominal pain, bloating, or early satiety should be sought, as this can be a symptom of poor gastric emptying, which can be confirmed with a gastric emptying study.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- In patients undergoing emergency operations for upper gastrointestinal hemorrhage, all patients should undergo esophagogastroduodenoscopy (EGD) prior to operation with an attempt at endoscopic hemostasis. The operating surgeon should make every effort to be present during the endoscopy, as accurate anatomic information regarding the location of the ulcer will facilitate the operation.
- In patients suspected of having poor emptying of their gastric conduit after esophageal replacement, gastric emptying studies are of limited use due to the altered anatomy and the lack of reference values for emptying. The author has used EGD and botulinum toxin injection as a diagnostic test for patients with poor emptying of the conduit.[1] Those who have an improvement in symptoms have been offered surgical drainage procedures.
- In patients with prior fundoplication or paraesophageal hernia repair suspected of having delayed gastric emptying, nuclear medicine gastric emptying studies are helpful in identifying patients who could benefit from a drainage procedure. Hamrick et al.,[2] in a large series of revisional paraesophageal hernia patients, used a T1/2 emptying time of 90 minutes as an indication for the addition of a gastric drainage procedure with good results. Alternatively, EGD and botulinum toxin injection of the pylorus can also be used as a diagnostic study.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients undergoing drainage procedures will have poor gastric emptying and will be at risk for aspiration during induction of anesthesia. For elective procedures, patients should be placed on a clear liquid diet 24 hours prior to surgery and made NPO the night before the procedure. Patients undergoing emergency surgery for peptic ulcer bleeding will have a stomach full of blood and are at significant risk of aspiration. Whenever feasible, rapid sequence induction should be used. Antibiotic prophylaxis with 1 to 2 g of cefazolin is the standard approach; clindamycin plus a fluoroquinolone or aminoglycoside is the appropriate choice for those patients with allergies to cefazolin. When performing an emergency operation for bleeding, the surgeon should ensure that blood is crossmatched and available. For laparoscopic procedures, having the ability to perform intraoperative EGD can facilitate the identification of the pylorus and bleeding source in difficult cases.

Positioning

- For open drainage procedures, the patient is positioned in the supine position with both arms extended. Space is left on the patient's left side to attach a Buchwalter or Omni retractor to the bed rail. During the surgical procedure, the patient will often be placed in reverse Trendelenburg to facilitate exposure of the upper abdominal organs. In a laparoscopic approach, the same position is used, but a footboard and safety strap should also be added to prevent the patient from sliding when steep reverse Trendelenburg position is used.

OPEN PYLOROPLASTY

Skin Incision and Retractor Positioning

- An upper midline incision is used for all open drainage procedures. This should begin at the level of the umbilicus and extend to just below the xiphoid process. Body wall retractor blades are placed on either side of the upper half of the incision to facilitate exposure. If necessary, a malleable or Harrington retractor blade can be placed on the left lobe of the liver to expose the pylorus (FIG 1).

Kocher Maneuver

- A Kocher maneuver is performed to facilitate exposure of the duodenum and pylorus and to eliminate tension on the suture line. A forceps is used to grasp the peritoneum lateral to the duodenum, which is then incised with scissors or the electrosurgical device. The surgeon then can insert an index finger behind the duodenum and head of the pancreas and sweep the finger to the right, elevating the lateral duodenal ligament and avascular retroperitoneal tissues, which can then be divided with the electrosurgical device (FIG 2). The plane of dissection should remain close to the duodenal wall to avoid injury to the gonadal vein on the anterior surface of the inferior vena cava. The duodenum and head of the pancreas should be mobilized from the junction of the duodenal bulb and second portion of the duodenum to just before the lateral aspect of the superior mesenteric vein. If the procedure is being performed for a bleeding duodenal ulcer, the Kocher maneuver step can be deferred until after control of the bleeding vessel has been achieved.

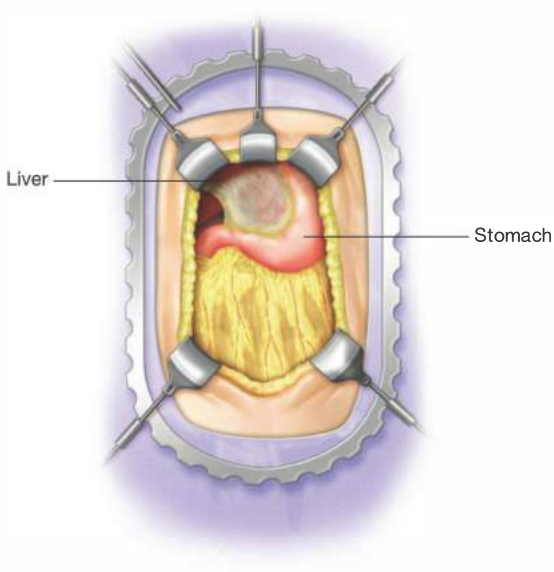

FIG 1 ● A Bookwalter style self-retaining retractor provides excellent exposure of the stomach and duodenum for drainage procedures. Placement of four abdominal wall blades, two on either side of the upper and lower aspect of the wound, will provide the optimum exposure. A Harrington or malleable retractor on the left lobe of the liver can facilitate exposure.

Pyloric Incision

- The pylorus is identified either visually or by palpation of the muscular ring with a finger inserted from the gastric side. Beginning roughly 2 cm proximal to the pylorus on the gastric antrum, incise the gastric wall, enter the lumen, and extend the incision distally parallel to the long axis of the bowel across the pylorus onto the duodenum to distance of roughly 5 cm using the electrosurgical device (FIG 3). This incision will provide reasonable exposure of the duodenal bulb. If the operation is being performed for ulcer bleeding, the incision can be extended further along the duodenum to expose the bleeding site. The pyloroplasty incision can be facilitated by placing a seromuscular stay stitch on the superior and inferior edge of the pylorus.

Bleeding Control

- If the operation is being performed for a bleeding duodenal ulcer, the ulcer is identified on the posterior aspect of the duodenal bulb. Temporary hemostasis is achieved by digital pressure, and then definitive hemostasis is achieved by placing three 2-0 silk suture ligatures. The first suture is placed at the cranial margin of the ulcer, encircling the proximal gastroduodenal artery (GDA). The second suture is placed at the caudal edge of the duodenal ulcer encircling the distal GDA. The final suture is a U suture placed underneath the ulcer crater to control the posterior entry of the transverse pancreatic artery into the back wall of the GDA (FIG 4).

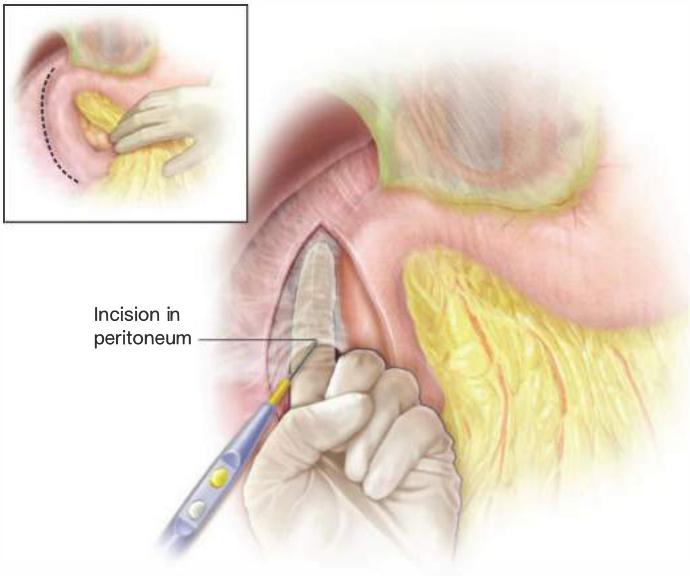

FIG 2 ● Application of leftward traction on the stomach and duodenum will allow the surgeon to score the peritoneum lateral to the duodenum with the electrosurgical device as shown in the *inset*. The surgeon's index finger can then bluntly elevate the avascular tissues between the duodenum, pancreas, and vena cava, making division of these tissues with the electrosurgical device easy.

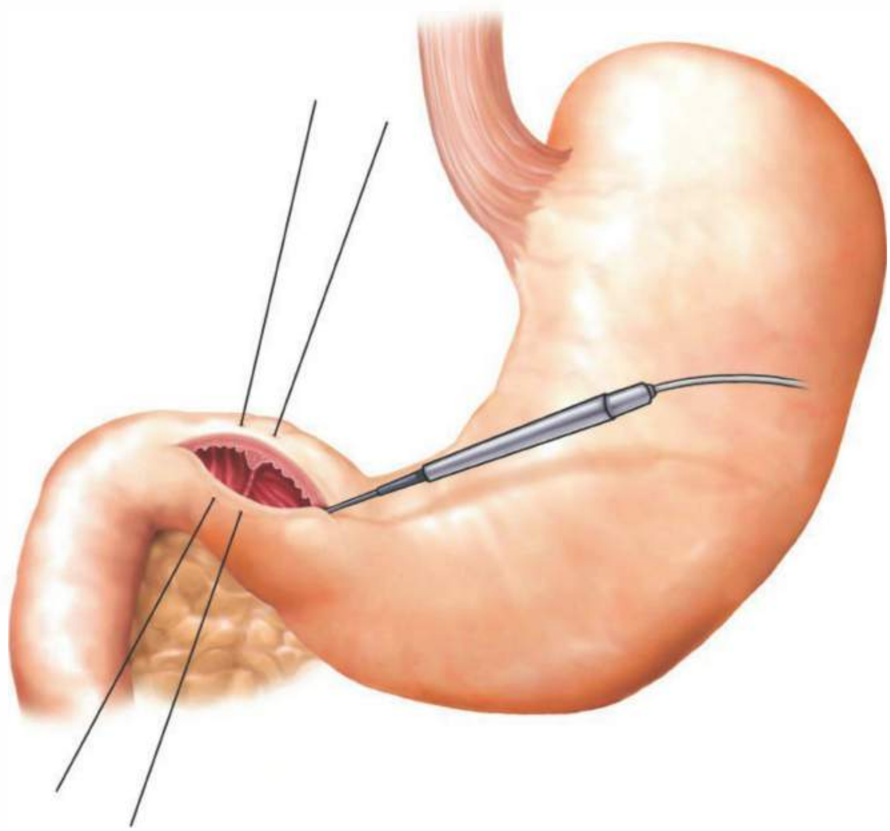

FIG 3 ● Placing silk stay sutures superior and inferior to the proposed pyloroplasty incision will make the entry into the duodenum easier. (From Nussbaum MS. *Master Techniques in Surgery: Gastric Surgery.* Philadelphia, PA: Lippincott Williams & Wilkins; 2013.)

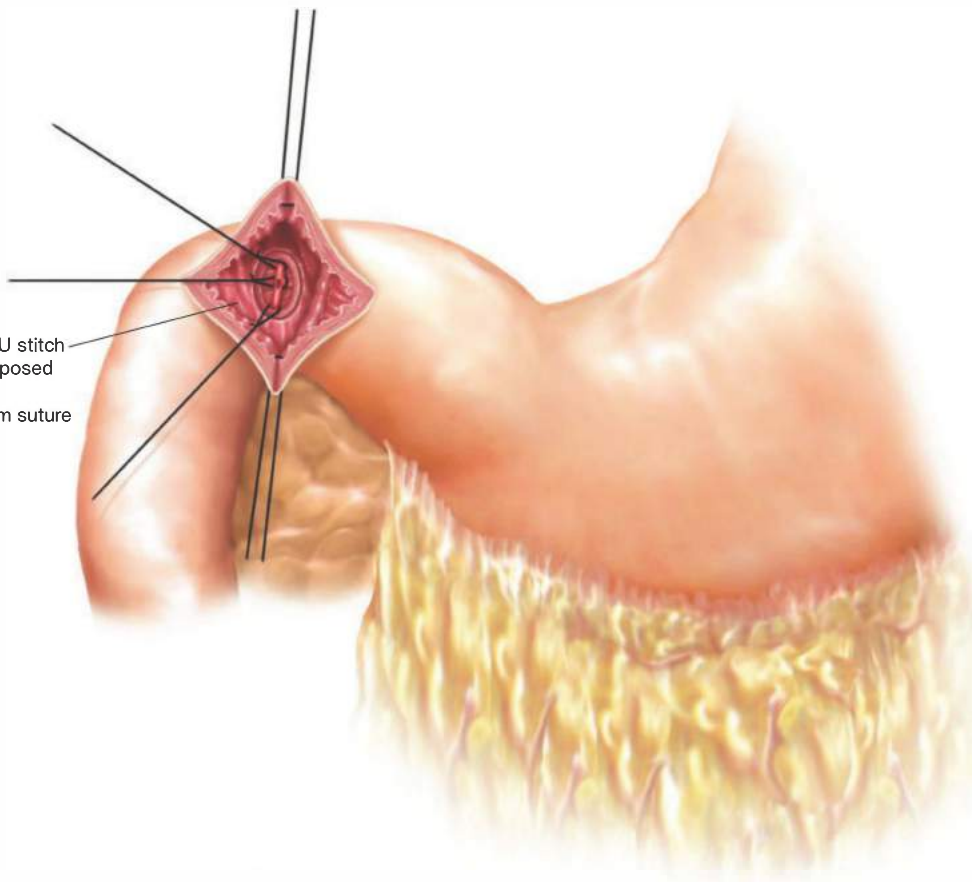

FIG 4 ● When operating to ulcer bleeding, placing the pyloroplasty incision directly over the ulcer crater will optimize exposure. Control of bleeding from the GDA is achieved with three sutures. A simple or figure-of-eight suture is placed at the cranial and caudal edge of the ulcer to ligate the trunk of the GDA. A third horizontal U stitch is placed under the ulcer crater to control the transverse pancreatic branches. GDA, gastroduodenal artery. (From Nussbaum MS. *Master Techniques in Surgery: Gastric Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2013.)

Closure of Pyloroplasty—Heineke-Mikulicz

- The most common closure of the pyloroplasty is the Heineke-Mikulicz approach, closing the longitudinal pyloroplasty with a single layer of sutures in a transverse fashion. This closure is appropriate when the duodenum is not distorted or scarred and the pyloroplasty incision is shorter than 6 to 7 cm. The closure is performed by applying superior and inferior traction on the stay sutures, converting the longitudinal gastroduodenal incision into a transverse incision. The incision is then closed with interrupted 3-0 silk sutures or 3-0 polyglycolic acid sutures with either a full-thickness simple stitch or a Gambee stitch. The closure is best performed by starting at the top corner of the incision and alternating from the top to the bottom proceeding toward the middle. The sutures may be tied as they are placed until the last three sutures, which should be left untied until all of the sutures are placed to ensure that the mucosal layer is included in all of the bites (**FIG 5**). A vascularized pedicle of omentum is then placed over the closure and the stay sutures tied over the omental pedicle to hold it in place in the fashion of a Graham patch.

Closure of Pyloroplasty—Finney

- If the duodenum is significantly inflamed or scarred from chronic peptic ulceration or if a longer duodenotomy is required to obtain hemostasis on a bleeding source beyond the duodenal bulb, a Finney closure of the pylorus is appropriate to prevent tension on the closure and gastric outlet obstruction. The Finney closure is in essence a side-to-side gastroduodenostomy with the pylorus at the cranial apex of the anastomosis. The duodenum will need to be completely mobilized to allow

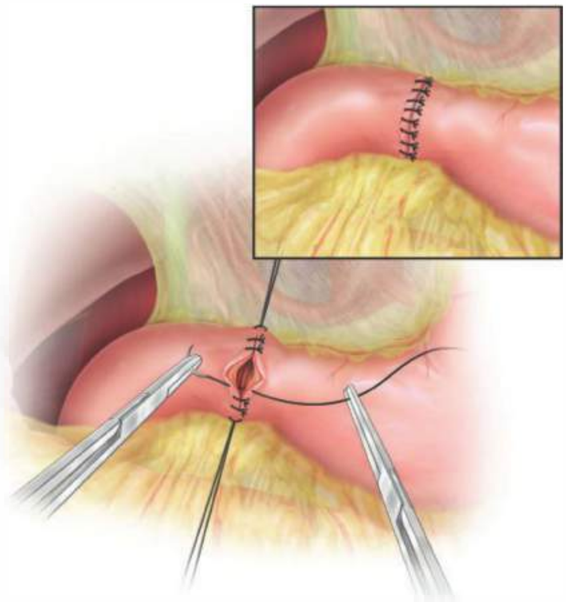

FIG 5 ● With traction applied to the stay sutures, the longitudinal pyloroplasty is closed transversely using interrupted sutures alternating from either end of the closure. The *inset* shows the completed closure.

this closure to be tension free. Remove the inferior stay suture and apply cranial tension on the superior stay suture to convert the longitudinal incision into an inverted U shape. The Finney closure is a standard two-layered anastomosis. A back row of interrupted 3-0 silk seromuscular (Lembert) sutures is placed between the inferior edge of the duodenum and the gastric wall (**FIG 6A**). These sutures should be placed 5 to 10 mm from the cut edge of the mucosa. It is often necessary to extend the incision on the gastric side of the pylorus to ensure that the lengths of the two arms of the incision are equal. When extending the pyloroplasty in this fashion, it is advisable to cheat toward the greater curvature of the stomach. Next, begin the inner layer of the closure using a 3-0 polyglycolic acid running suture beginning at the divided pylorus muscle, suturing the inferior edge of the duodenum to the inferior edge of the stomach (**FIG 6B**). Run this suture around the inferior edge of the closure onto the anterior edge of the gastroduodenal anastomosis. Next, begin a second running 3-0 polyglycolic acid at the superior edge of the cut pylorus, suturing the superior edge of the duodenum to the stomach and running toward the other suture (**FIG 7A**). Many surgeons prefer to use a Connell suture on the anterior wall to achieve better mucosal inversion. Tie the two sutures and then complete the pyloroplasty closure with an anterior layer of interrupted 3-0 silk seromuscular sutures (**FIG 7B**).

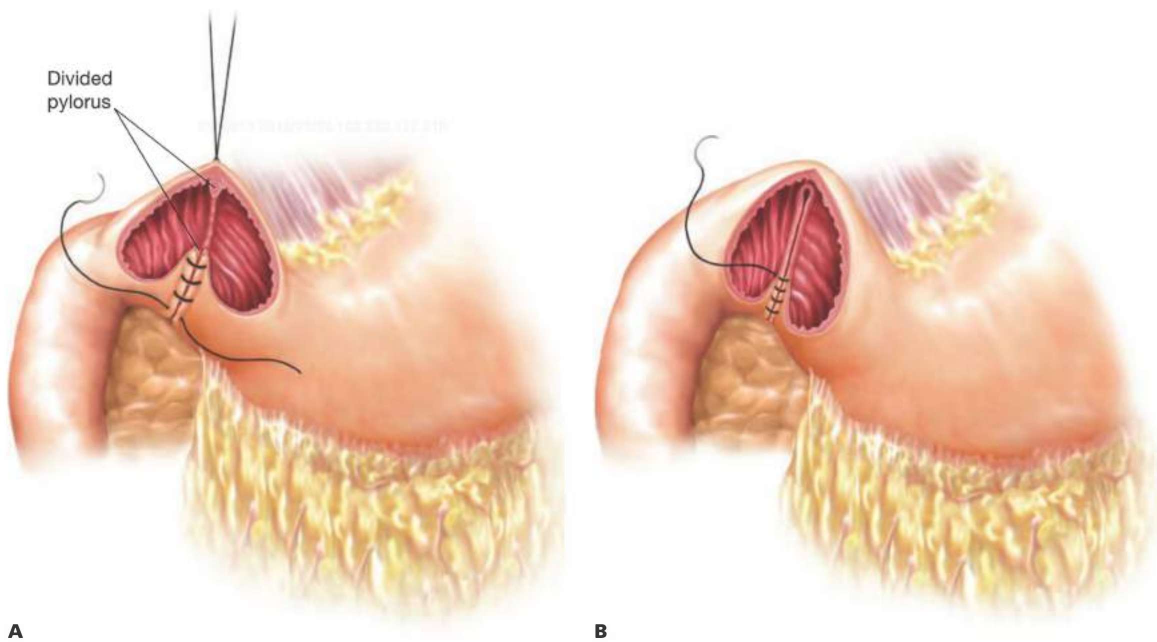

FIG 6 ● **A.** With superior traction on the superior stay suture, the back row of the Finney pyloroplasty is created by approximating the duodenum to the greater curvature of the stomach with seromuscular sutures. **B.** The back portion of the inner row is begun using a running suture approximating the duodenal mucosa to the gastric mucosa beginning at the inferior edge of the transected pylorus. This suture is then run up to the anterior surface of the pyloroplasty.

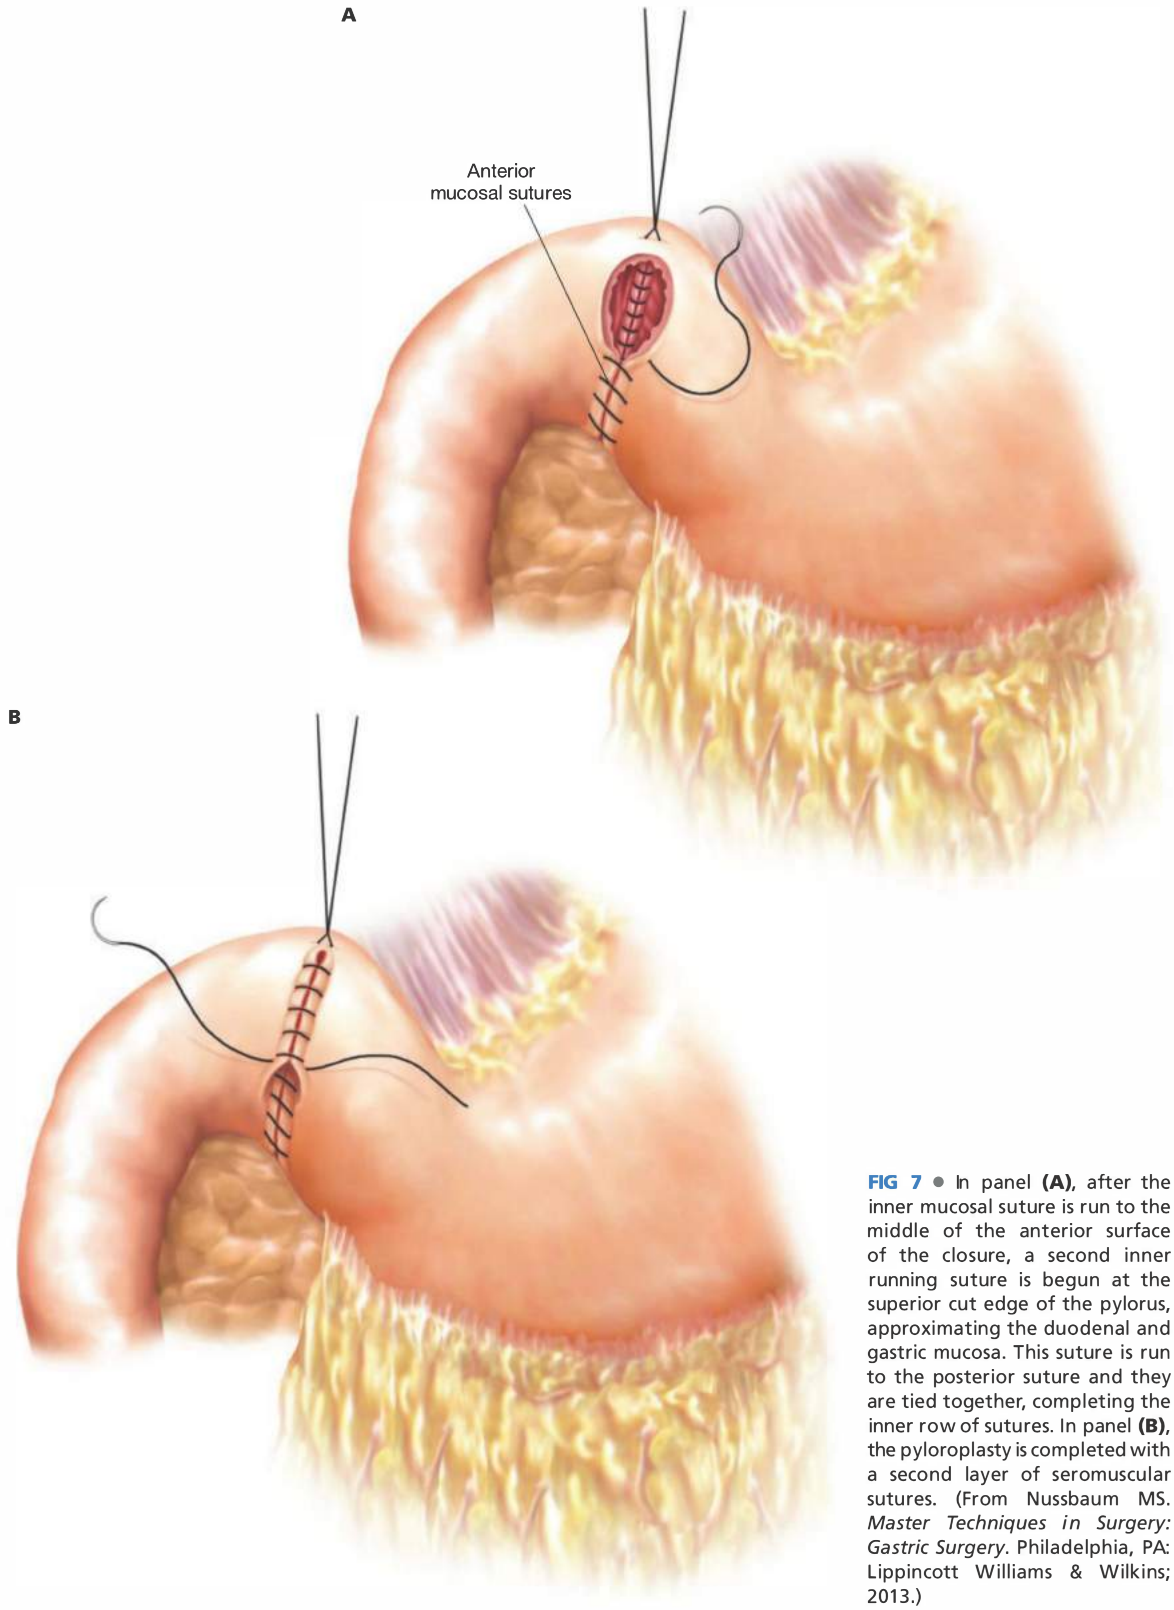

FIG 7 ● In panel **(A)**, after the inner mucosal suture is run to the middle of the anterior surface of the closure, a second inner running suture is begun at the superior cut edge of the pylorus, approximating the duodenal and gastric mucosa. This suture is run to the posterior suture and they are tied together, completing the inner row of sutures. In panel **(B)**, the pyloroplasty is completed with a second layer of seromuscular sutures. (From Nussbaum MS. *Master Techniques in Surgery: Gastric Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2013.)

OPEN PYLOROMYOTOMY

Incision and Identification of the Pylorus

- An upper midline incision and fixed retractor is used as described previously for pyloroplasty (**FIG 1**). The pylorus is identified either visually or by palpation of the muscular ring with a finger inserted from the gastric side.

Serosal Incision and Division of Muscular Fibers

- A 3-cm long longitudinal serosal incision is made across the pylorus, beginning 1 to 2 cm proximal to the pylorus on the gastric side and extending 1 cm distal to the pylorus. This serosal incision can be performed either with a knife or an electrosurgical device (**FIG 8A**). If the electrosurgical device is used, care should be exercised to avoid deep penetration into the muscularis and thermal injury to the mucosa. Beginning on the gastric side of the incision, use a fine tipped hemostat to dissect the muscular fibers off of the submucosa and divide the circular muscular fibers with a knife (**FIG 8B**). Muscular bleeders can usually be controlled with pressure, and there is a very limited role for cautery at this point of the operation. Great care should be taken to avoid mucosal injury especially on the duodenal side, as the submucosa is thinner and more fragile. When properly performed, the mucosa and submucosa will bulge out of the incision (**FIG 8C**).

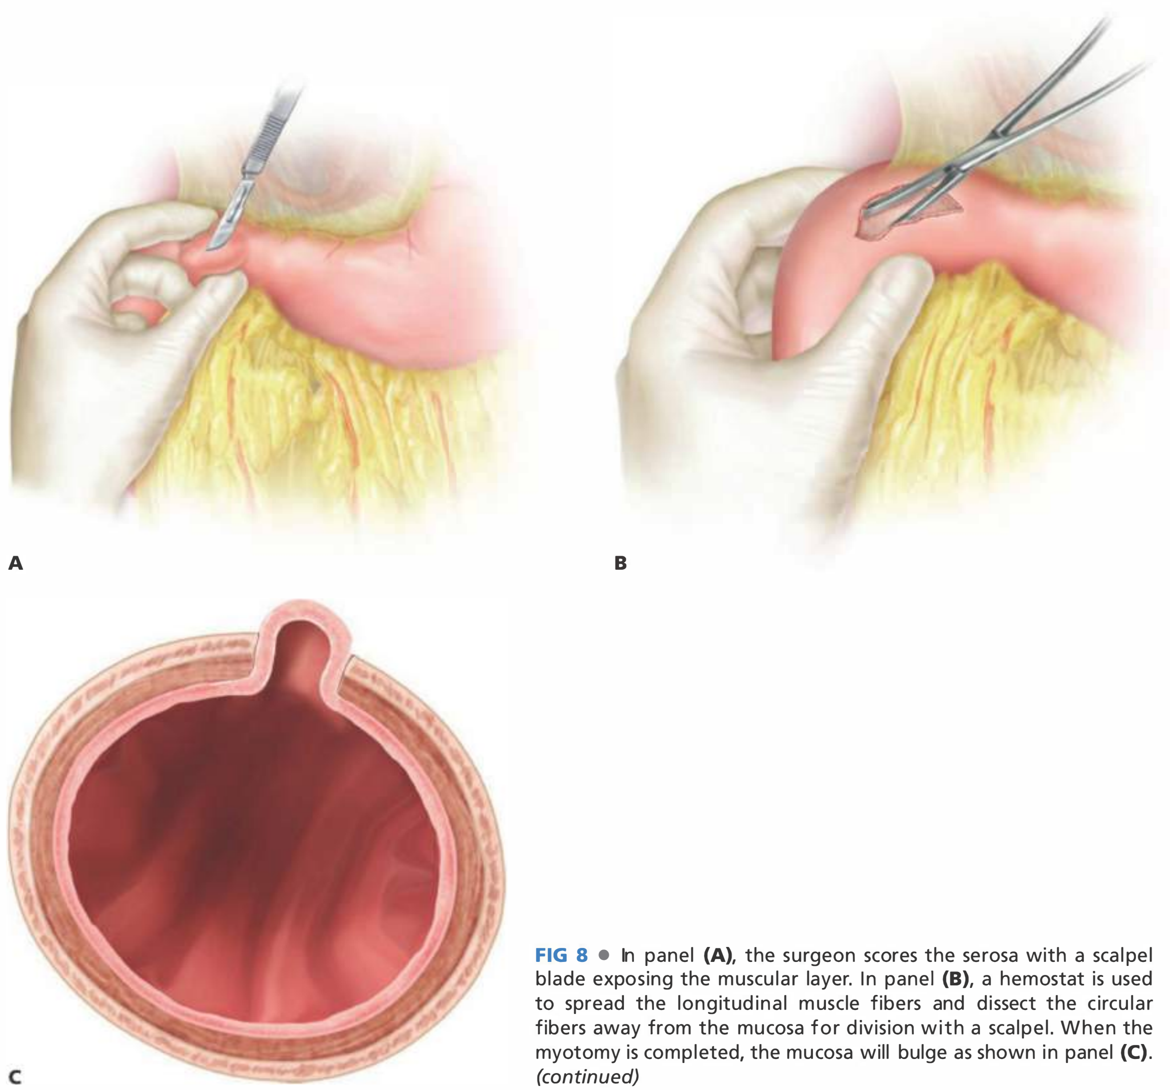

FIG 8 ● In panel **(A)**, the surgeon scores the serosa with a scalpel blade exposing the muscular layer. In panel **(B)**, a hemostat is used to spread the longitudinal muscle fibers and dissect the circular fibers away from the mucosa for division with a scalpel. When the myotomy is completed, the mucosa will bulge as shown in panel **(C)**. *(continued)*

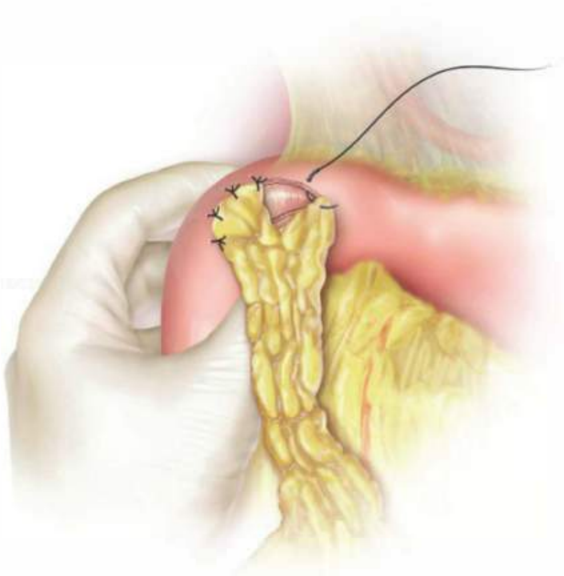

D

FIG 8 ● *(continued)* An omental patch is then sewn to the serosal edges of the myotomy to cover the mucosa in as shown in panel **(D).**

Omental Patch

- A vascularized pedicle of omentum is placed over the pyloromyotomy and sutured with three 3-0 silk sutures. The first is placed through the superior edge of the divided pyloric ring and the superior edge of the omental pedicle to prevent the two cut edges of the pylorus from coming into contact. The next two are placed between each lateral edge of the serosal incision and the lateral edges of the omental patch to ensure that the patch covers the entire pyloromyotomy (**FIG 8D**).

OPEN GASTROJEJUNOSTOMY

Skin Incision and Retractor Positioning

- An upper midline incision is used for all open drainage procedures. This should begin at the level of the umbilicus and extend to just below the xiphoid process. Body wall retractor blades are placed on either side of the upper half of the incision to facilitate exposure (**FIG 1**). If necessary, a malleable or Harrington retractor blade can be placed on the left lobe of the liver to expose the stomach and pyloric region.

Preparation of the Stomach and Identification of Proximal Jejunum

- There is insufficient evidence to recommend a posterior gastrojejunostomy over an anterior gastrojejunostomy, and an antecolic, anterior gastric wall gastrojejunostomy is the easiest to create. Identify the pylorus, and then identify a point, 5 cm proximal to the pylorus, as the gastric site of the anastomosis. Next, identify the ligament of Treitz, and select a section of the jejunum 15 to 30 cm distal to the ligament of Treitz, which will easily reach the distal stomach without tension.

Construction of the Anastomosis

- A standard double-layered side-to-side anastomosis is constructed by aligning the small bowel with the stomach in an isoperistaltic fashion, with the distal portion of the small bowel located closest to the pylorus. The back row of the anastomosis is first created by suturing the jejunum to the greater curvature of the stomach using seromuscular 3-0 silk interrupted sutures. The tails of the sutures at either corner are left long to allow them to be used as stay sutures (**FIG 9A**). Using the electrosurgical device, a full-thickness jejunotomy is made in the small bowel, and a gastrotomy is made in the stomach roughly 5 mm from the outer layer of the anastomosis (**FIG 9B**). Beginning in the middle of the posterior portion of the anastomosis, the inner layer of the anastomosis is constructed by running two 3-0 polyglycolic acid sutures from the middle of the back row in opposite directions (**FIG 10A**). Many surgeons prefer to use Connell sutures on the anterior row to achieve better eversion, but this step is not necessary (**FIG 10B**). The anastomosis is completed with an outer anterior layer of seromuscular 3-0 silk interrupted sutures.

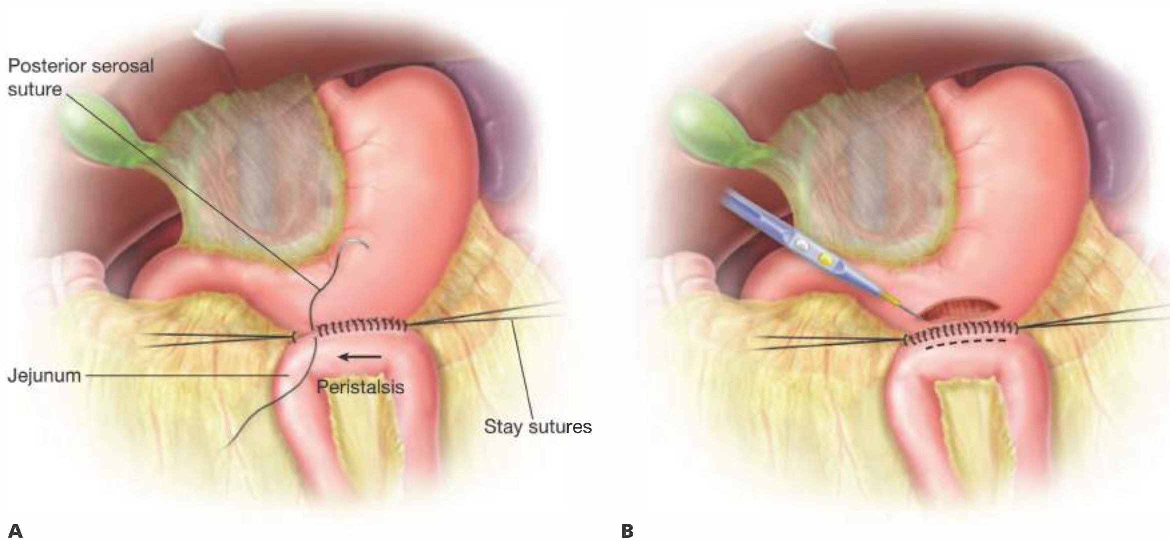

FIG 9 ● An antecolic, isoperistaltic gastrojejunostomy is begun by placing a back row of seromuscular sutures between the greater curvature of the stomach and the antimesenteric edge of the jejunum over a distance of 8 cm and shown in panel **(A)**. The stomach and the jejunum are then opened with the electrosurgical device in panel **(B)**.

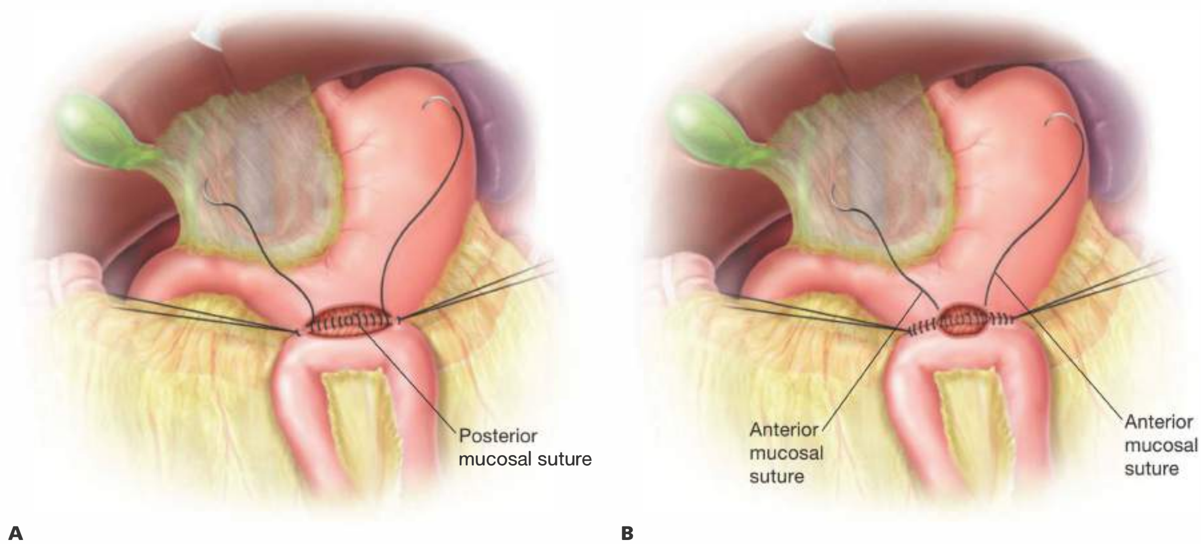

FIG 10 ● A double-armed suture is placed in the center of the back row of the anastomosis and run to the corners of each side as shown in panel **(A)**. This same suture is then run to the middle of the anterior row as shown in panel **(B)**. The anterior row can either be Connell sutures or simple sutures based on surgeon preference.

LAPAROSCOPIC PYLOROPLASTY

Port Placement and Liver Retraction

- We use a standard four-trocar approach for gastric procedures, with a 5-mm port in the left upper quadrant, a second 5-mm trocar just to the left of the umbilicus, a 12-mm trocar at the level of the umbilicus in the midclavicular line, and a 5-mm trocar in the right upper quadrant. A Nathanson liver retractor is placed to elevate the left lobe of the liver (**FIG 11**).

Identification of the Pylorus and Pyloric Incision

- The pylorus is identified either visually or by performing an EGD with CO_2 insufflation. Placing a 3-0 silk seromuscular stay suture at the superior and inferior edge of the duodenum at the level of the pylorus will facilitate the rest of the operation. Beginning roughly 2 cm proximal to the pylorus on the gastric antrum, incise the gastric wall, enter the lumen, and extend the incision distally parallel to the long axis of the bowel across the pylorus onto the duodenum to a total distance of roughly 5 cm using the electrosurgical device or an ultrasonic dissector (**FIG 12**).

Closure of the Pyloroplasty

- The assistant grasps the superior stay suture and applies cranial and leftward traction to convert the longitudinal incision into a transversely oriented closure. The surgeon then begins at the superior aspect of the duodenum and begins the closure. The easiest method is a running closure with 3-0 or 2-0 silk or polyglycolic suture. The surgeon should run this suture toward the inferior aspect of the duodenum stopping about two-thirds of the way down. A laparoscopic clip is placed on the suture to maintain tension while the surgeon focuses on the lower aspect of the closure. A second suture is then run

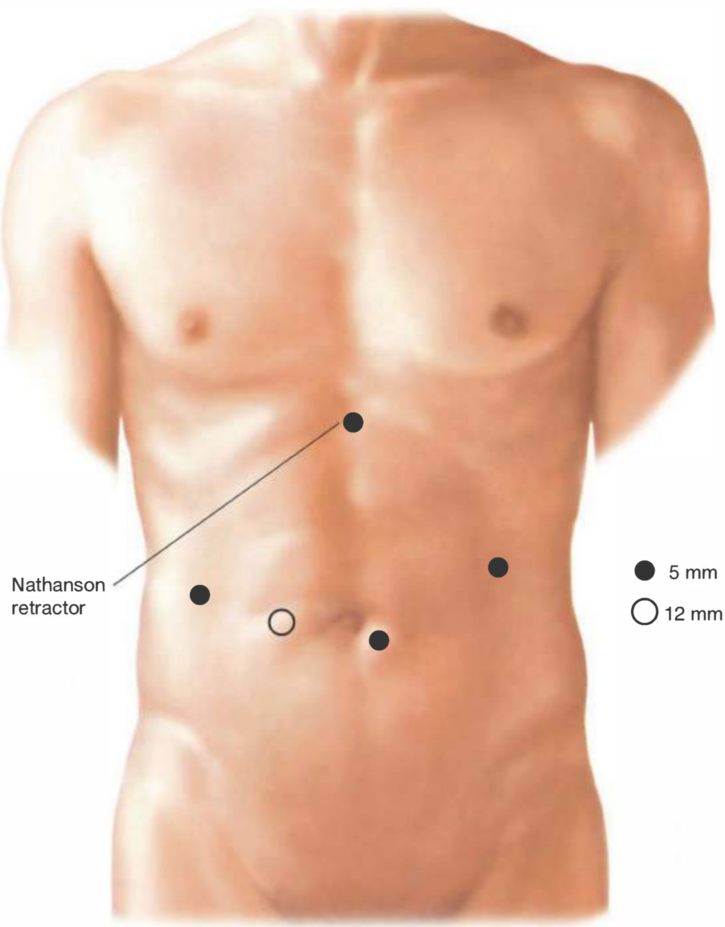

FIG 11 ● Shown is the standard port placement used for all laparoscopic drainage procedures. The surgeon stands on the patient's right. The first port placed is the left upper quadrant 5-mm port, which will be the assistant's instrument. The left periumbilical port is for the camera, and right 12-mm port is for the surgeon's dominant hand instrument. The lateral right port is for the surgeon's nondominant hand. A Nathanson liver retractor is placed in the subxiphoid position to retract the left lobe of the liver. (From Nussbaum MS. *Master Techniques in Surgery: Gastric Surgery*. Philadelphia, PA: Lippincott Williams & Wilkins; 2013.)

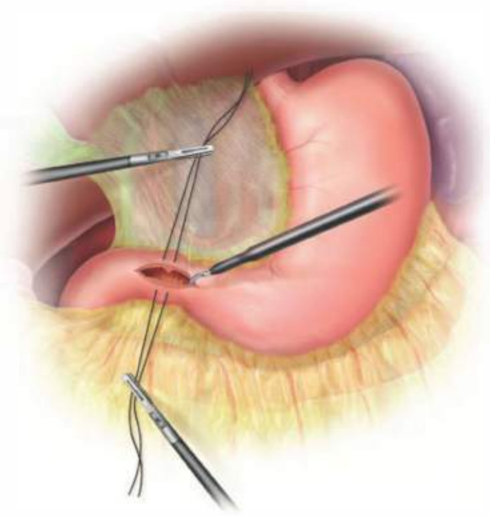

FIG 12 ● Two stay sutures are placed above and below the proposed pyloroplasty incision. The surgeon retracts the superior suture with their nondominant hand, and the assistant retracts the inferior suture from the far left port. A hooked cautery is then used to incise the pylorus beginning from the gastric side.

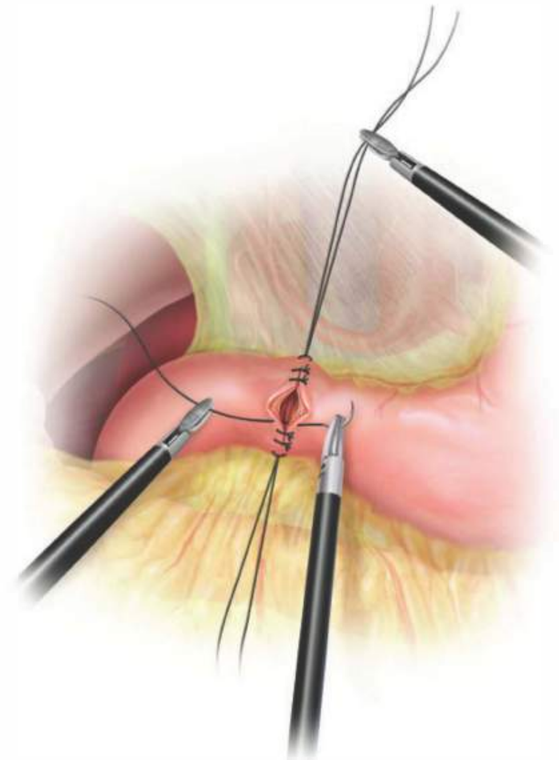

FIG 13 ● Although the assistant provides cranial traction on the superior stay suture to convert the longitudinal pyloroplasty incision into a transversely oriented incision, the surgeon closes the pyloroplasty with either interrupted or running sutures.

from the inferior edge of the pyloroplasty to the middle and tied to the upper suture after first removing the clip from the suture. The assistant can facilitate the suturing angles by retracting the inferior stay suture caudal and rightward. An alternative approach is to perform an interrupted closure. This allows for more precise suture placement but requires more intracorporeal knot tying (**FIG 13**). With an interrupted closure, alternating sutures from the either end and tying after placing each suture allows for precise suture placement. The last suture will be placed blindly, but if the assistant applies cranial traction on the tail of the suture just superior to the last one, it reduces the likelihood of back-walling the duodenum. Methylene blue can be placed into the distal stomach via the EGD scope to ensure the pyloroplasty closure is water tight.

Omental Patch

- The author then covers the completed pyloroplasty suture line with a vascularized pedicle of omentum, which is secured in place by tying the superior and inferior stay sutures over the pedicle in the fashion of a Graham patch. This is easier to perform and less likely to narrow the pyloric outlet than a second layer of seromuscular sutures.

LAPAROSCOPIC GASTROJEJUNOSTOMY

Port Placement

- We use a standard four-trocar approach for most gastric procedures, with a 5-mm port in the left upper quadrant, a second 5-mm trocar just to the left of the umbilicus, a 12-mm trocar at the level of the umbilicus in the midclavicular line, and a 12-mm trocar in the right upper quadrant. A Nathanson liver retractor is sometimes placed to elevate the left lobe of the liver and facilitate exposure of the anterior and inferior gastric wall (**FIG 11**).

Preparation of the Stomach and Identification of Proximal Jejunum

- First, identify the pylorus by either palpation with a grasper or by performing an intraoperative EGD. Identify a point 5 cm proximal to the pylorus, and then select a section of the jejunum 15 to 30 cm distal to the ligament of Treitz, which will easily reach the distal stomach without tension in an antecolic fashion.

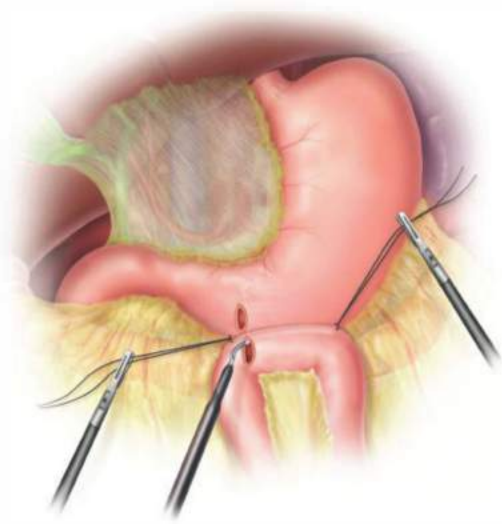

FIG 14 ● Two sutures are used to approximate the selected segment of jejunum to the greater curvature of the stomach in an antecolic, isoperistaltic fashion. With the assistant providing cranial traction from the left on the proximal suture and the surgeon providing caudal and rightward traction, the hooked cautery is used to make a full thickness open in the stomach and jejunum for insertion of a linear endocutting stapler.

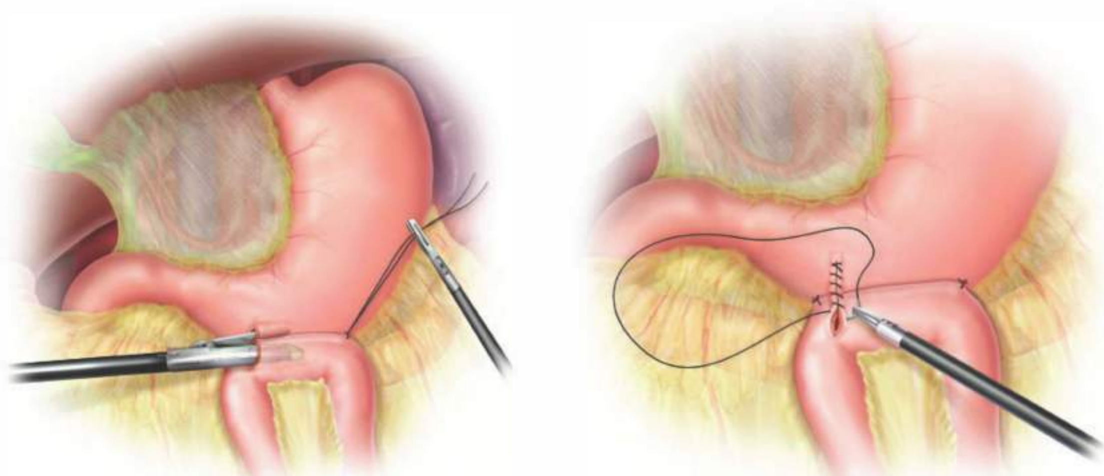
Construction of the Anastomosis

- A stapled side-to-side gastrojejunostomy is then constructed in an isoperistaltic fashion by aligning the distal portion of the small bowel with the pyloric side of the stomach. Placement of two interrupted 2-0 silk seromuscular sutures between the greater curvature of the stomach and the small bowel 6 cm apart serves to align the bowel for the stapled anastomosis. Using the electrosurgical device, an enterotomy is made in the stomach and small bowel (**FIG 14**). A 60-mm Endo GIA stapler is inserted via the most lateral right side port and fired to construct the anastomosis (**FIG 15A**). A blue or green load of the stapler device should be used depending on the thickness of the stomach. The common enterotomy is then closed using two 3-0 polyglycolic acid sutures in either a running fashion or an interrupted fashion as described for pyloroplasty (**FIG 15B**). A second layer of seromuscular 3-0 silk Lembert sutures is placed to complete the closure of the common enterotomy.



A B

FIG 15 ● In panel **(A)**, a blue or green load 60-mm endostapler is fired to construct the anastomosis. In panel **(B)**, the common enterotomy defect is then closed in two layers with sutures. The assistant can facilitate the suturing with cranial traction on the distal stay suture.

PEARLS AND PITFALLS

Indications	■ When performing a drainage procedure for delayed gastric emptying with a fundoplication, documentation of poor emptying with a gastric emptying study is strongly recommended prior to surgery. ■ When operating for GI bleeding, being present at the initial endoscopy to see the precise bleeding location will help avoid having to make an excessively large pyloroplasty incision.
Pyloroplasty incision	■ Incisions longer than 7 or 8 cm are difficult to close in a Heineke-Mikulicz fashion without narrowing the pyloric lumen and may require a Finney closure.
Kocher manuever	■ Is not always necessary with a short pyloroplasty and a Heineke-Mikulicz closure but is always required with a Finney closure
Pyloromyotomy	■ Is very hard to perform without mucosal perforation in the setting of any duodenal inflammation. If a significant mucosa perforation occurs during pyloromyotomy, the safest approach is to convert to pyloroplasty.
Gastrojejunostomy	■ Predisposes to marginal ulceration if a vagotomy is not performed. Patients undergoing gastrojejunostomy drainage without vagotomy will require lifetime proton pump inhibitor therapy. ■ In the setting of a prior gastric outlet obstruction, a prolonged period of delayed gastric emptying may be encountered despite an adequate anastomotic lumen.

POSTOPERATIVE CARE

- Most patients will require nasogastric decompression for 24 to 48 hours after a drainage procedure.

OUTCOMES

- When performed in conjunction with fundoplication in patients with delayed gastric emptying, 80% of patients report an improvement in bloating symptoms.[3]
- The incidence of diarrhea reported when pyloroplasty is performed in conjunction with fundoplication in the setting of delayed gastric emptying is reported to be as high as 25%.[4]
- The incidence of clinically significant dumping syndrome after drainage procedures is less than 10%.[5]

COMPLICATIONS

- Leak from suture or staple line
- Delayed gastric emptying
- Surgical site infection
- Dumping syndrome
- Diarrhea
- Duodenogastric reflux is quite rare after pyloroplasty.
- Bile reflux gastritis following gastrojejunostomy

Chapter 10 Antrectomy

J. Spencer Liles   John D. Christein

DEFINITION

- By strict definition, antrectomy refers to removal of the gastrin-secreting portion of the stomach and when combined with a vagotomy results in an 85% reduction in gastric acid secretion.[1,2] In the 1960s and 1970s, antrectomy with or without vagotomy was routinely performed for treatment of benign gastric and duodenal ulcers but, due to pharmacologic developments in reducing acid secretion and elucidation of the role of *Helicobacter pylori* in ulcer development, is now rarely performed for ulcer disease.[3,4]
- Today, the term antrectomy is loosely applied to any distal gastric resection and is indicated in recurrent or persistent gastric ulcers to rule out malignancy, complicated peptic ulcer disease (i.e., obstruction, hemorrhage, perforation), and for resection of certain neoplasms of the antrum and pyloric channel (Table 1).[3]
- When an antrectomy is performed for complicated peptic ulcer disease, a vagotomy may be included to reduce the chance of anastomotic ulcer formation in patients who are not candidates for *H. pylori* treatment and lifelong proton pump inhibitor therapy due to unreliability, noncompliance, or medication side effects.[5,6]
- Antrectomy is named by the type of gastrointestinal (GI) anastomosis performed.
  - Billroth I procedure—antrectomy and gastroduodenostomy
  - Billroth II procedure—antrectomy and gastrojejunostomy
    - A modification of the Billroth II procedure that involves a gastrojejunostomy via a Roux limb and is known as a Roux-en-Y gastrojejunostomy

DIFFERENTIAL DIAGNOSIS

- Complicated peptic ulcer disease and distal gastric neoplasms, both benign and malignant, account for the vast majority of the antral resections performed today. These diagnoses will be discussed separately.
- Peptic ulcer disease
  - Peptic ulcer disease refers to irritation of GI mucosa from gastric acid due to either increased acid presence or weakness in the mucosal protection and typically presents with epigastric pain.[2,4] Peptic ulcers can occur anywhere in the GI tract, but duodenal and gastric ulcers are most common. Duodenal ulcers typically arise within 2 cm of the pylorus, are highly associated with *H. pylori* infection (>90%), and frequently resolve with appropriate *H. pylori* therapy. Gastric ulcers are less likely to be associated with *H. pylori* infection and are classified into five types based on their location and association with acid secretion (Table 2).[7]
  - The differential diagnosis of epigastric pain similar to that found in complicated peptic ulcer disease is chronic cholecystitis, acute pancreatitis, chronic pancreatitis, functional indigestion or dyspepsia, gastritis, and reflux esophagitis. Complicated peptic ulcer disease can also present with upper GI hemorrhage, and a differential should include esophagitis (reflux and infectious); gastroesophageal varices, arteriovenous malformations; Mallory-Weiss tear; stress gastritis; and neoplasm of the esophagus, stomach, duodenum, pancreas, and biliary tree.
  - Lastly, pyloric obstruction due to chronic inflammation and scarring will cause nausea, emesis, and early satiety. The differential for these symptoms includes gastric motility disorders (i.e., gastroparesis), gastroenteritis, small bowel obstruction, electrolyte abnormalities, and extrinsic compression from pancreatic pseudocysts or neoplasms.
- Distal gastric neoplasms—Gastric neoplasms include benign polyps, adenocarcinoma, neuroendocrine tumors, lymphoma, B-cell mucosa-associated lymphoid tissue (MALT) lymphomas, GI stromal tumors, leiomyomas, and leiomyosarcomas. Any gastric neoplastic process can cause upper GI bleeding, epigastric pain, and luminal obstruction, and a differential similar to peptic ulcer disease should be considered.

Table 1: Indications for Antrectomy

Peptic ulcer disease
- Intractability—persistent or recurrent gastric ulcers in order to rule out malignancy
- Perforation—distal gastric or duodenal ulcer
- Bleeding—type I, II, or III gastric ulcer
- Obstruction—any gastric outlet or duodenal obstruction due to chronic ulcer scarring

Neoplasm
- Benign—single giant gastric polyp or multiple gastric polyps not amenable to endoscopic resection, leiomyoma, lipoma
- Malignant—leiomyosarcoma, gastrointestinal stromal tumor, early-stage adenocarcinoma, neuroendocrine tumor
- Gastroparesis—role is debated in chronic gastroparesis only after extensive workup

PATIENT HISTORY AND PHYSICAL FINDINGS

- All patients should undergo a thorough history and physical exam with questions focusing on the nature of the symptoms, specifically determining the relationship between symptoms and eating, deciphering whether symptoms are acute or chronic, and determining the severity of the symptoms. A vast majority of patients will have abdominal pain. Pain related to peptic ulcer disease that results from the corrosive effect of gastric acid on vulnerable GI mucosa and typically occurs in the epigastrium is described as gnawing or burning and follows a daily cycle. This pain typically arises shortly after eating breakfast and persists until lunch at which time the oral intake alleviates the pain. Relief is transient and pain recurs in the early afternoon and again persists until dinner. Meals, specifically ones consisting of milk and dairy products, and antacids provide temporary relief from ulcer pain. Acute, severe epigastric pain can signify ulcer perforation, whereas back pain suggests ulcer penetration into the pancreas.[8]

Table 2: Peptic Ulcer Disease

Location			Common Complications	Acid Secretion	Other
Esophageal		Gastroesophageal junction and distal esophagus	Hemorrhage	High	
Gastric					
I		Gastric body on lesser curvature near the angularis incisura	Perforation	Normal or low	• Older patients • Associated with *Helicobacter pylori*
II		Two ulcers; gastric body and duodenal ulcer	Hemorrhage, obstruction, or perforation	High	• Younger patients • Association with active or quiescent duodenal ulcers
III		Prepyloric	Hemorrhage, perforation	High	• Younger patients • Similar to type II gastric ulcers and duodenal ulcers
IV		High on lesser curvature	Hemorrhage	Low	• Likely a variant of type I gastric ulcers • Difficult to treat surgically
V		Anywhere	Perforation	Normal	• Related to NSAID use
Duodenal		95% occur within 2 cm of pylorus	Hemorrhage, obstruction, or perforation	Normal or high	

NSAID, nonsteroidal antiinflammatory drug.

- Nausea and vomiting can be seen with ulcer disease even in the absence of pyloric obstruction. Nausea that is chronic in nature and associated with early satiety and weight loss suggests inflammation and scarring of the pyloric channel due to chronic ulceration.
- It is not uncommon for complicated peptic ulcers to present with upper GI bleeding, perforation, or obstruction in a patient with no history of peptic ulcer disease.
  - Bleeding—hematemesis, melena, recent diagnosis of anemia
  - Perforation—acute onset upper abdominal pain and peritonitis
  - Obstruction—nausea, emesis, food regurgitation, early satiety, weight loss
- Acute or chronic upper GI bleeding can signify complicated ulcer disease and may present as melena, weakness, fatigue, general malaise, or a recent diagnosis of anemia.
- Risk factors for developing ulcer disease include a history of *H. pylori* infection; smoking; Zollinger-Ellison syndrome; and use of nonsteroidal antiinflammatory drugs (NSAIDs), steroids, and other immunosuppressive medications.[1,8] Therefore, an accurate medication list should be obtained and reviewed with the patient. History of previous ulcer disease should be elicited, and the success and timing of previous treatment modalities should be documented. Presence of *H. pylori* infection, completion of antibiotic therapy, and documentation of eradication is crucial (Table 3). Ulcers that persist despite appropriate

Table 3: *Helicobacter pylori* Testing

	Sensitivity	Specificity	Other
Noninvasive			
Urease breath test	>95%	>90%	Determines active infection but must stop PPI 2 wk prior; takes 30–60 min and is used to confirm eradication
Fecal antigen detection	>90%	>95%	Determines active infection but is positive for up to 12 wk after eradication
Serology	85%	79%	Cannot be used to confirm eradication because antibodies persist
Invasive (endoscopic)			
Biopsy urease test	>90%	>95%	Decreased sensitivity with ongoing PPI, H2 antagonist, antibiotic, and bismuth compound use or with recent GI bleeding
Histology	>90%	>95%	Multiple available stains and widely used; increased sensitivity with increased biopsies
Culture	80%	100%	Difficult and expensive; reserved for persistent infections and antibiotic sensitivity testing

PPI, proton pump inhibitor; GI, gastrointestinal.

treatment of *H. pylori*, cessation of NSAID use, or are found in *H. pylori*–negative patients should raise suspicion for underlying malignancy.

- A gastric lesion can also present with epigastric pain and obstruction. This pain is typically vaguer in nature and lacks a gnawing or burning component. Furthermore, these patients may describe a sensation of persistent fullness and early satiety despite hunger.
- A subjective assessment of nutrition and functional status is necessary to evaluate the patient's ability to tolerate a major surgical procedure.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Diagnostic evaluation of suspected peptic ulceration and upper GI lesions can include endoscopy, contrast radiography, and computed tomography (CT) (**FIG 1**).
- Endoscopy is felt to be superior because it allows for tissue sampling. Sampling of gastric mucosa can be used to confirm the presence of *H. pylori*. On endoscopy, ulcers are sharply demarcated; often have exposed underlying submucosa; and frequently occur in the first portion of the duodenum, the prepyloric area, and the pyloric channel. All gastric ulcers should be biopsied at least six times at the ulcer edge and brush biopsied to evaluate for underlying malignancy. Even if negative for malignancy, repeat endoscopy after medical treatment is indicated to evaluate for therapeutic response, and in instances of persistent or intractable disease, ulcer resection is indicated.[8]
- Other relevant imaging modalities include contrast radiography and CT. Double-contrast radiography of the upper GI tract detects roughly 90% of gastric and duodenal ulcers but does not allow for tissue sampling. In the acute setting, CT is helpful in identifying gastric or duodenal ulcer perforation. Additionally, CT can identify wall thickening in chronic ulcer inflammation or neoplastic situations but again lacks the ability to provide tissue sampling.
- Zollinger-Ellison syndrome is a rare condition of increased serum gastrin levels secondary to a gastrinoma with resulting severe ulcer disease. In nonsmoking patients who are negative for *H. pylori*, serum fasting gastrin levels should be obtained to evaluate for Zollinger-Ellison syndrome. Normal basal gastrin levels average to 50 to 100 pg/mL, and levels over 200 pg/mL can almost always be considered high. Diagnosis of Zollinger-Ellison syndrome can alter your treatment approach.[9]

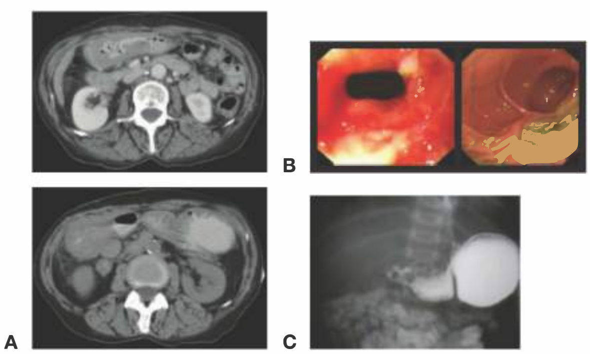

FIG 1 • Radiology. **A.** CT scan of pyloric obstruction from chronic pyloric inflammation. **B.** Endoscopic image of near-complete pyloric obstruction from chronic pyloric inflammation **(left)**; endoscopic image of a large gastric ulcer with a central necrotic region **(right)**. **C.** Contrast radiography demonstrating pyloric obstruction from chronic pyloric inflammation.

SURGICAL MANAGEMENT

- The indications for antrectomy are listed in Table 1. As explained earlier, an antrectomy is rarely performed for its original purpose of removing the antrum and reducing acid secretion.
- Antrectomy is not the primary treatment option for bleeding or perforated peptic ulcers. A vast majority of bleeding ulcers is controlled endoscopically and, in the 5% to 10% that require operative intervention, a formal antrectomy is rarely needed. Roughly 90% of perforated ulcers can be safely controlled with primary closure and omental patching. Thus, antrectomy for bleeding or perforated ulcers is reserved for cases when less invasive treatment options are ineffective.

Preoperative Planning

- All patients should undergo preoperative endoscopy to identify the extent of disease and preoperative nutritional assessment. All patients should receive preoperative antibiotics in a timely fashion to reduce the risks of perioperative infectious complications from gram-positive cocci and enteric gram-negative bacilli pathogens.

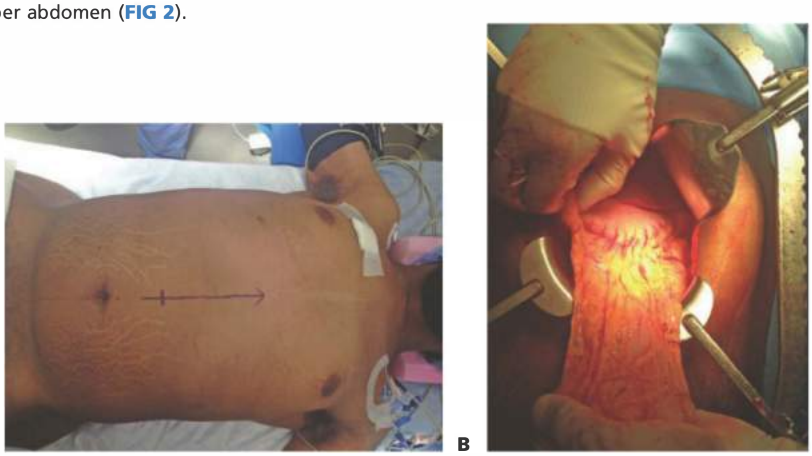
- Several factors must be considered when deciding between performing a Billroth I and Billroth II procedure. The advantage to a Billroth I procedure is that the anatomic arrangement of the GI tract is preserved, which maintains the innate regulatory pathways of bicarbonate and pancreatic enzymes and significantly decreases the rate of postprandial dumping. Unfortunately, the lack of a pylorus results in bile reflux gastritis in a majority of patients. A Billroth I procedure cannot always be performed due to inflammation and scarring from prepyloric, pyloric, or duodenal ulcers. In these instances, the Billroth II procedure allows for a tension-free anastomosis of noninflamed tissue but introduces the problems of potential afferent loop syndrome and bile reflux gastritis, whereas a Roux-en-Y gastrojejunostomy diminishes the occurrence of bile reflux at the cost of a second anastomosis. Lastly, in cases of invasive neoplasms or concerning gastric masses, a Billroth II procedure with or without reconstruction with a Roux-en-Y gastrojejunostomy is preferred as it allows for dissection of much wider margins and is less likely to obstruct in the unfortunate setting of recurrent disease.[10,11]

Positioning

- The patient should be positioned supine with arms out. A urinary catheter and a nasogastric tube should be placed to decompress the stomach. Positioning should allow for attachment of a self-retaining retractor system to the operating room table.

EXPOSURE

- A midline supraumbilical incision is made and carried to the level of the xiphoid. The falciform ligament is divided and a self-retaining retractor system is placed to widely expose the upper abdomen (**FIG 2**).



A B

FIG 2 ● **A.** A midline upper abdominal incision is used. **B.** Division of the falciform ligament and placement of self-retaining retractor allows adequate exposure of the upper abdomen.

GASTRIC MOBILIZATION

- Mobilization of the distal stomach is best achieved by starting on the greater curvature. The gastrocolic ligament is identified and incised to enter the lesser sac (**FIG 3**). Downward traction on the transverse colon and upward traction on the stomach will help expose this plane (**FIG 4**). Identification of the right and left gastroepiploic vessels along the greater curvature is essential. In benign disease, the plane of dissection can be very close to the stomach inside the gastroepiploic vessels. A large part of this plane is avascular and can be divided with electrocautery, whereas encountered vessels should be divided between clamps and ligated with 3-0 silk ligatures. Once the lesser sac is identified, electrosurgical devices can be used to further mobilize the greater curvature (**FIG 5**). Proximally, dissection is carried to the midpoint of the greater curvature preserving the left gastroepiploic artery. Distally, the plane is developed beyond the pylorus to the duodenum and, once identified, the right gastroepiploic artery should be clamped, ligated with 2-0 silk ligatures, and divided. Here, one should be aware of the underlying pancreatic tissue and dissection should be meticulous.
- Dissection along the greater curvature allows entrance to the lesser sac, and the stomach can be lifted superiorly exposing its posterior surface and the congenital

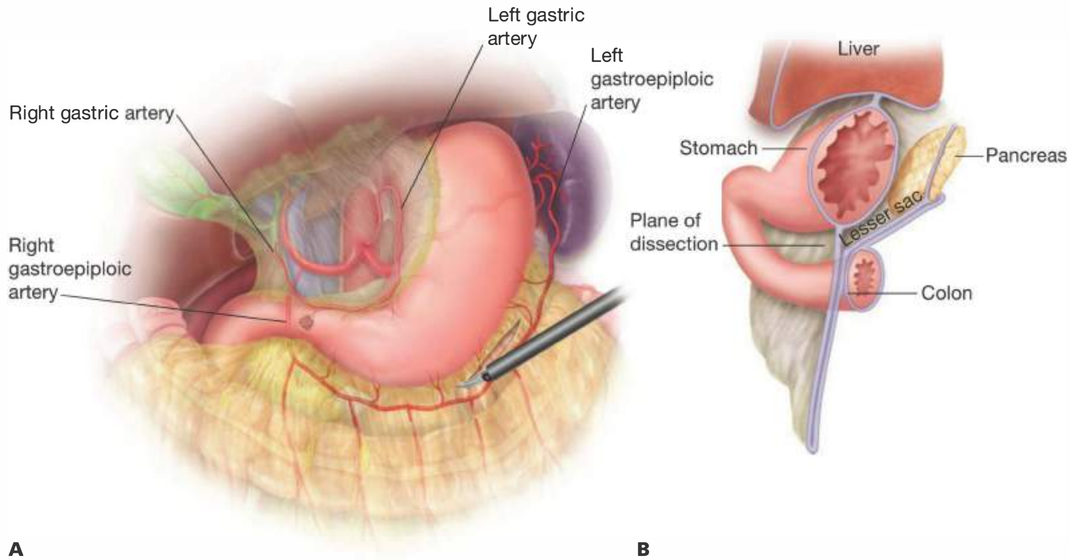


FIG 3 ● Dissection of the greater curvature. **A.** Division of the greater omentum along the greater curvature will allow access to the lesser sac. The gastroepiploic vessels should be identified and care should be taken to not damage the transverse colon and its mesentery. **B.** Cross-sectional view of the upper abdomen demonstrating the plane of dissection that allows entrance to the lesser sac and mobilization of the greater curvature.

attachments to the underlying pancreatic capsule (**FIG 6**). These attachments should be sharply divided. As this plane is developed in a superior direction, great care should be taken to not injure the left gastric artery at its origin from the celiac axis. Inflammation and scarring can be encountered in the setting of posterior gastric wall ulcers.

- Attention is then turned to division of the gastrohepatic ligament along the lesser curvature. Retracting the stomach inferiorly and to the patient's left facilitates exposure of the lesser curvature. This dissection can start in the transparent pars flaccida and is carried proximally to the incisura and distally to the right gastric artery, which should be clamped, ligated with 2-0 silk ligatures, and divided (**FIG 7**). Again, electrocautery or electrosurgical devices can be used along the lesser curvature. One must be aware of an aberrant or replaced left hepatic artery originating from the left gastric artery and traversing the gastrohepatic ligament. If encountered, attempts should be made to preserve this vessel. After clamping but before division of the right gastric artery, blood flow to the liver should be confirmed by palpation of the hepatoduodenal ligament.

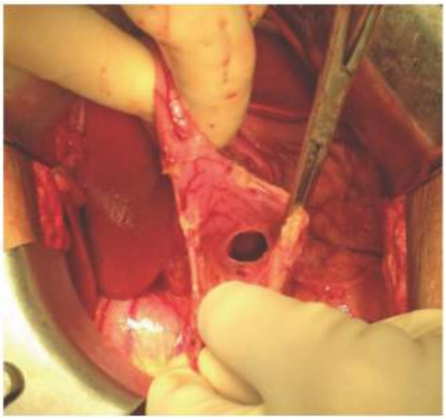

FIG 4 ● Traction on the stomach and the colon will aid dissection through the gastrocolic ligament allowing entrance to the lesser sac. As seen here, the lesser sac will be a true space that lies deep to the greater omentum.

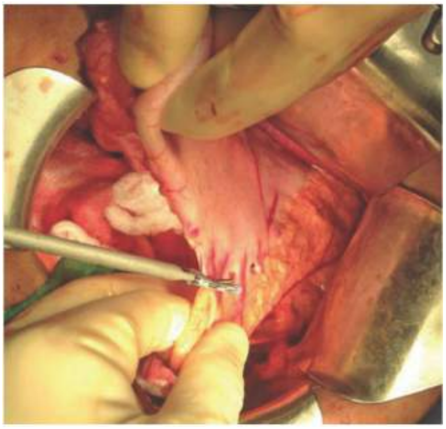

FIG 5 ● Once the lesser sac is identified, the greater curvature can be dissected both proximally and distally taking care to identify the gastroepiploic vessels.

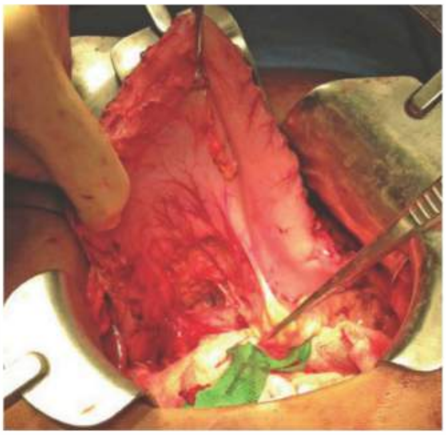

FIG 6 ● Dissection of the greater curvature allows for superior retraction of the stomach exposing its posterior surface and the underlying pancreas. Here, the lesser curvature and the left gastric artery are seen from the posterior aspect of the stomach.

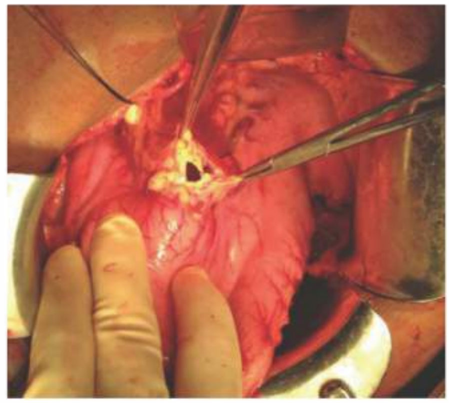

FIG 7 ● Dissection of the lesser curvature.

DIVISION OF THE STOMACH

- A stapling device is used to divide the stomach along a plane from just proximal to the incisura angularis on the lesser curvature to a point on the greater curvature two-thirds of the way from the gastroesophageal junction to the pylorus. Some recommend placing Babcock forceps distal to the staple line to prevent sliding or rotation of the gastric mucosa as the stapler is closed. This will help ensure a clean, even cut across the anterior and posterior layers of gastric mucosa (**FIG 8**).
- Division of the duodenum varies based on the type of reconstruction planned. The duodenum is divided between Potts clamps for a Billroth I procedure in order to facilitate the gastroduodenal anastomosis. If possible, a stapling device should be used to divide the duodenum in a Billroth II procedure.

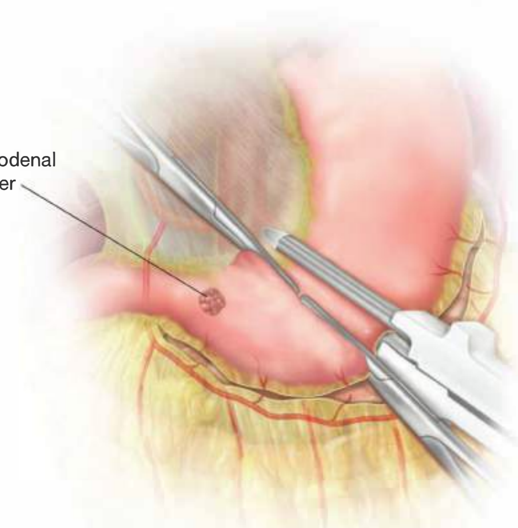

FIG 8 ● Division of the stomach.

RECONSTRUCTION: GASTRODUODENOSTOMY (BILLROTH I)

- If a Billroth I anastomosis is planned, a Kocher maneuver is needed to mobilize the duodenum.
- The duodenum is transected distal to the diseased area but proximal to the ampulla between Potts clamps, and the specimen is handed off the sterile field (**FIG 9**). It is essential that all gastric antrum be resected to prevent persistent ulcer disease from retained gastric antrum. If there is question, a frozen section can be sent to confirm duodenal tissue at the resection line.
- At this point, one can gauge the mobility of the stomach, and if limited, the attachments of the fundus to the base of the diaphragm can be divided along with the gastrosplenic ligament taking care to preserve the left gastroepiploic vessels. This further mobilization should allow for a tension-free gastroduodenal anastomosis. If there

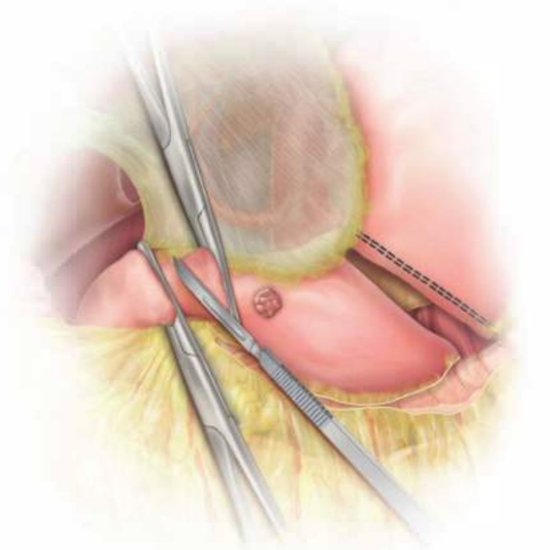

FIG 9 ● Division of proximal duodenum.

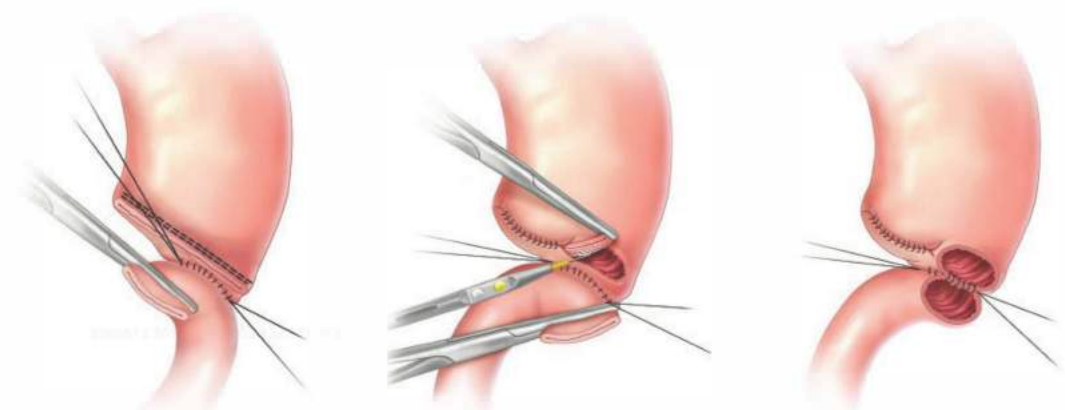
is concern about the ability to perform a tension-free anastomosis due to difficulty mobilizing the duodenum or the stomach, then a Billroth II procedure should be performed.

- For a Billroth I procedure, the duodenal stump is cleared of adjacent adipose tissue for roughly 1.5-cm distance in preparation for an end-to-end anastomosis. This anastomosis is constructed in standard two-layer fashion. Silk 3-0 seromuscular "stay" sutures are placed at the ends of the anastomosis to approximate the duodenum to the inferior aspect of the gastric staple line and the posterior layer is completed with interrupted 3-0 silk seromuscular sutures. Next, the inferior portion of the gastric staple line is removed using electrocautery for a length that correlates with the width of the duodenal stump. Two running 3-0 polydioxanone (PDS) sutures are used for the inner layer and an anterior layer of interrupted 3-0 silk seromuscular sutures completes the anastomosis. The remaining gastric staple line can be oversewed with interrupted 3-0 silk sutures (**FIG 10**).

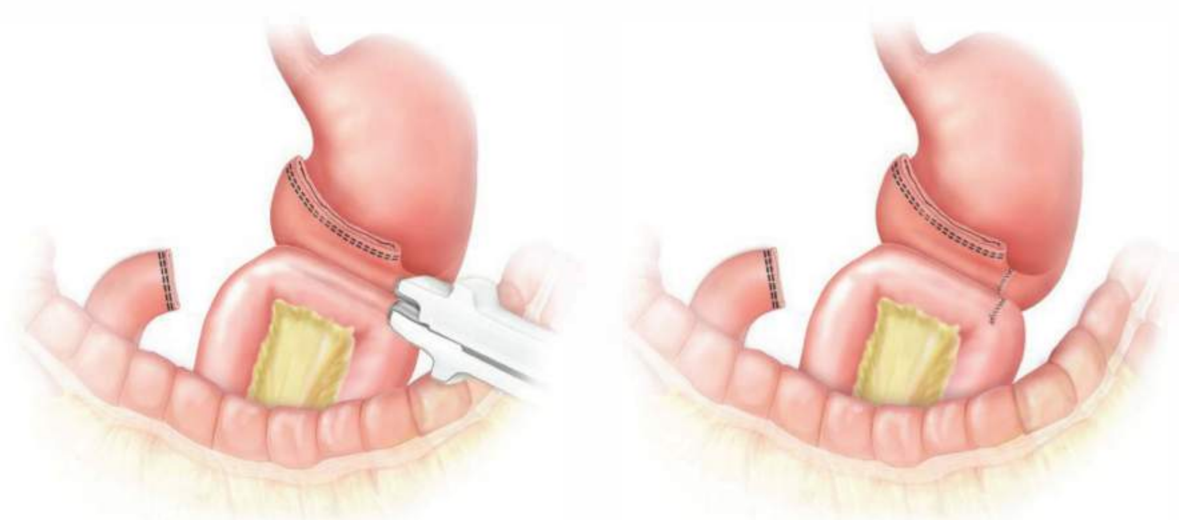


A B C

FIG 10 ● **A–C.** Billroth I.

RECONSTRUCTION: GASTROJEJUNOSTOMY (BILLROTH II)

- In performing a gastrojejunostomy, the gastric staple line is oversewed with interrupted 3-0 silk sutures.
- Next, the duodenum is divided distal to any disease with a stapling device. If it is not possible to fit a stapler into this plane, the duodenum can be divided with electrocautery and closed with a running 3-0 PDS. To buttress this closure, 3-0 silk full-thickness sutures can be placed and left untied. Omentum can be mobilized and loosely secured in place over the closure with the silk suture ends.
- We preferentially perform an isoperistaltic, retrocolic gastrojejunostomy, although an antecolic anastomosis is widely accepted. In the setting of malignancy, an antecolic approach may be favored as concern exists that progression of disease and future diffuse mesenteric lymphadenopathy may obstruct a retrocolic anastomosis. The anastomosis should be performed as close to the ligament of Treitz as possible (usually 10 to 15 cm), allowing for a tension-free anastomosis to minimize the risk of developing afferent limb syndrome.
- Although we prefer a stapled anastomosis, both stapled and hand-sewn techniques are widely accepted with similar rate of postoperative complications. A 45-mm stapled



A B

FIG 11 ● **A,B.** Billroth II.

gastrojejunal anastomosis is formed by creating a posterior wall gastrotomy and an antimesenteric enterotomy. Care is taken to ensure that the anastomosis is away from the prior gastric staple line on the posterior wall of the stomach. The common enterotomy is then closed with a 3-0 PDS full-thickness layer and an overlying layer of interrupted 3-0 silk sutures (**FIG 11**). Interrupted 3-0 silk sutures are then used to close the colonic mesentery defect to prevent bowel herniation (**FIG 12**).

FIG 12 ● Retrocolic gastrojejunostomy.

PEARLS AND PITFALLS

Indication	▪ Today, there is no role for antrectomy in treatment of noncomplicated peptic ulcer disease. ▪ A vast majority of peptic ulcers complicated by hemorrhage or perforation can be controlled with less invasive procedures.
Operative planning	▪ Preoperative endoscopy is essential to evaluate for the scope of disease and to allow biopsy of persistent gastric ulcers to rule out malignancy. ▪ In the setting of malignancy, preoperative staging is warranted and a more extensive, oncologic resection may be indicated.
Laparotomy	▪ Prior to extensive dissection, the extent of disease should be gauged to determine the operative plan and feasibility of a Billroth I anastomosis.
Gastric mobilization	▪ With mobilization of the greater curvature, the middle colic vein is at risk of injury. Caudal traction on the transverse colon during dissection can help prevent an inadvertent injury.
Duodenal transection	▪ Great care should be taken to not fracture or injure the head of the pancreas, which can be closely adherent due to chronic inflammation. ▪ If the common bile duct is difficult to identify, a cholecystectomy can be performed and a catheter can be placed in the cystic duct. Palpation of the catheter can aid in safely identifying the portal structures during dissection of the duodenum.

Reconstruction	■ Billroth I and II procedures are performed with acceptable postoperative morbidity. ■ A Billroth II anastomosis should be performed if there is concern about mobility of the duodenum or the stomach. ■ A short afferent limb (10 to 15 cm from the ligament of Treitz) can help minimize the likelihood of significant postoperative complications.

POSTOPERATIVE CARE

- Unless concerning comorbidities exist, patients can be monitored on the hospital floor/ward. A nasogastric tube is positioned intraoperatively in the proximal stomach and typically can be removed on postoperative day (POD) 1. There is no role for postoperative antibiotic prophylaxis. Unless contraindicated, all patients receive chemical prophylaxis for deep vein thrombosis and are encouraged to ambulate on POD 1 and begin pulmonary toilet with incentive spirometry. There is no convincing evidence for routinely placing abdominal drains after Billroth I and Billroth II procedures. If there is concern for the GI anastomosis or adequate closure of the duodenal stump, a closed suction abdominal drain can be placed. Oral intake is reintroduced on POD 3 and advanced as tolerated.

OUTCOMES

- Serious morbidity from postgastrectomy syndromes develops in 3% to 5% of patients.
- Thirty-day mortality for uncomplicated gastric ulcer disease is 1% to 2% and increases in emergency settings.[11]

COMPLICATIONS

- After an antrectomy, short-term complications include delayed gastric emptying, anastomotic leak, bleeding, and pancreatitis. Long-term complications include the postgastrectomy syndromes (described below) and anastomotic stricture. Additionally, chronic anemia, neuropathy, and osteopenia can result from iron, copper, and calcium malabsorption due to bypassing of the proximal small bowel in a Billroth II procedure.[12]
- Postgastrectomy syndromes
  - Afferent loop syndrome
    - Postprandial right upper abdominal colicky pain that accumulates in bilious emesis that alleviates the pain
    - Results from chronic dilation, obstruction, or stasis of the duodenum (afferent limb) after a Billroth II procedure
    - Rarely occurs but can be corrected by revision of the Billroth II, conversion to a Roux-en-Y reconstruction, or performing an afferent to efferent bypass (Braun enteroenterostomy)
  - Reflux gastritis—Patients report epigastric burning pain resulting from reflux of bile into the stomach. As expected, bile reflux is more common after Billroth I and Billroth II procedures than Roux-en-Y reconstruction and if severe can be treated by conversion to a Roux-en-Y reconstruction.
  - Dumping—Early dumping presents as crampy abdominal pain and diarrhea shortly after eating due to the large hyperosmolar load of simple sugars which quickly enter the small bowel in the absence of a pylorus. Late dumping occurs roughly 2 hours postprandial with the symptoms of hypoglycemia likely due to insulin response to the large sugar bolus. Dumping occurs in 5% of postgastrectomy and is controlled with diet modifications, and rarely, octreotide is given with success in severe and refractory cases.
  - Retained gastric antrum—Incomplete antrectomy with retained G cells within the duodenal stump can result in recurrent ulceration from continued intense gastrin secretion. Exposure of the jejunum to high levels of acid results in an anastomotic or marginal ulcer. A sodium 99m technetium scan identifies antral tissue and reexcision is needed for complete symptom relief.

Chapter 11

Subtotal Gastrectomy for Cancer

Vikas Dudeja   Patrick G. Jackson   Waddah B. Al-Refaie

DEFINITION

- Subtotal gastrectomy is removal of 70% to 80% of distal stomach. This is performed when the necessary 5- to 6-cm proximal margin can be obtained while maintaining a gastric remnant of reasonable size.

PATIENT HISTORY AND PHYSICAL FINDINGS

Presentation

- In United States, gastric cancer is often diagnosed at an advanced stage and nearly 65% of patients harbor node-positive disease.[1,2] The most common symptoms are weight loss, anorexia, and early satiety. Some of these symptoms overlap with those of benign peptic ulcer disease. Patients with distal gastric cancer may present with symptoms of gastric outlet obstruction, including postprandial vomiting and weight loss. Patients may also present with progressive abdominal distension secondary to malignant ascites.
  - Special attention should be paid to weight loss. Although this may reflect metastatic disease or gastric outlet obstruction, in patients with resectable disease, it signifies a need for preoperative nutritional optimization. Specifically, patients with more than 10% weight loss are at increased risk of perioperative complications.
  - Attention to pretherapy performance status is critical, as this correlates well with ability to tolerate various oncologic therapies including major surgical resection and systemic therapy.
- Patients presenting with gastric outlet obstruction may have dehydration and electrolyte imbalances. Placement of a nasogastric (NG) tube, volume replacement (initially with normal saline), and correction of electrolyte imbalance is paramount.

Physical Findings

- Most patients with early stage disease will have a normal physical examination. However, signs of malnutrition, cachexia, and jaundice should be sought. Patients with advanced stage disease may present with supraclavicular lymphadenopathy, pleural effusion, abdominal mass, hepatomegaly, malignant ascites, or drop metastases in the cul-de-sac known as "Blumer's shelf." Presence of any of these physical findings suggest unresectability.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Laboratory Tests

- A baseline hemoglobin will assess whether iron deficiency anemia is present. Patient's renal function and hydration status should be assessed by measuring serum blood urea nitrogen (BUN) and creatinine in preparation for cross-sectional imaging. Evaluation and correction of abnormalities in electrolytes are important in patients with gastric outlet obstruction. Serum albumin and prealbumin are essential tools for assessing nutritional status.

Diagnostic Studies and Staging Evaluation

- The evaluation of any upper gastrointestinal (GI) symptomatology begins with an upper GI endoscopy, especially if gastric cancer is suspected. Endoscopy provides histopathologic diagnosis as well as guidance toward the location and extent of the gastric tumor (**FIG 1A,B**). For example, the endoscopist needs to comment on the location of the tumor as well as the relationship to the first portion of the duodenum. Additionally, it is important to exclude the presence of linitis plastica by insufflating the stomach and evaluating its distensibility, as patients with linitis plastica carry a higher risk of metastatic disease and a median survival of approximately only 14 to 16 months.
- Endoscopic ultrasound performed at the time of or subsequent to diagnostic endoscopy provides the most accurate estimation of the tumor depth (T stage) and needle biopsy of surrounding lymph nodes can be performed.[3]
- Pretherapy cross-sectional imaging (contrast computed tomography [CT] scan or magnetic resonance imaging [MRI] of abdomen and pelvis) is important to exclude distant metastatic disease to the liver or omentum (**FIG 2A**). In patients with proximal gastric cancer, the addition of chest cross-sectional imaging is helpful to exclude the presence of metastases to the lung. The presence of bulky adenopathy adds prognostic value but should not preclude resection unless it is outside the area of resection, such as the periportal area or mesenteric vessels. Fewer than 15% of patients present with locally advanced disease extending to the pancreas. In these patients, we perform staging laparoscopy to exclude M1 disease and then recommend neoadjuvant chemotherapy.

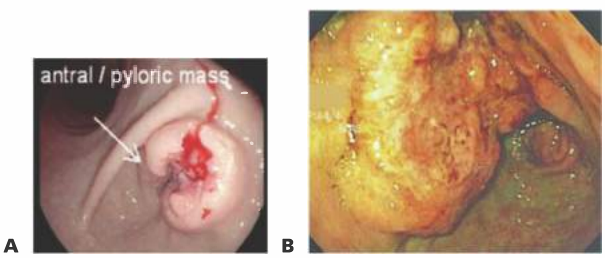

FIG 1 • Esophagogastroduodenoscopy helps with histologic diagnosis as well as provides information about extent of tumor. **A.** Biopsy-proven poorly differentiated adenocarcinoma with signet cell features in the antral/prepyloric region of stomach. **B.** Fungating adenocarcinoma of the distal third of the stomach in a 75-year-old male who presented with iron deficiency anemia.

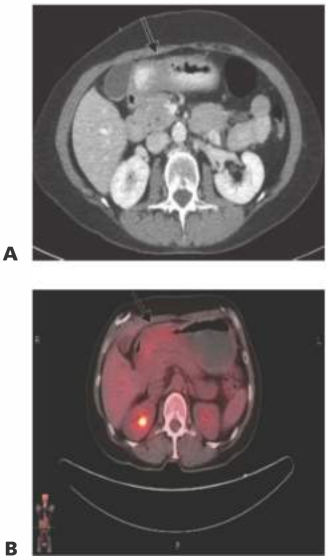

FIG 2 ● Cross-sectional imaging in the form of CT and CT/PET helps to evaluate for distant metastatic disease as well as extent of locoregional disease. **A.** CT scan in a patient with gastric cancer demonstrates thickening of the gastric antrum with nodularity in the gastrocolic ligament suggestive of direct spread to the transverse colon. **B.** PET/CT corroborated with CT scan to suggest involvement of gastrocolic ligament. No metastatic disease was observed.

- Positron emission tomography (PET)/CT scan has evolved as a noninvasive radiographic staging modality to exclude the presence of metastatic disease (**FIG 2B**).
- **Staging laparoscopy:** Due to the natural history of gastric cancer, up to a third of patients who have localized disease on staging evaluation have unsuspected hepatic and/or peritoneal disease.[4] Thus, all patients should undergo staging laparoscopy to detect "subradiologic" disease. Staging laparoscopy is typically performed in a reverse TNM fashion. The operating surgeon should inspect the intraabdominal cavity for presence of peritoneal, omental, or hepatic metastases. The addition of peritoneal washing for cytology is an area of debate.[5,6] It may have a place in patients at risk of undeclared metastatic disease or suboptimal performance status, as patients with positive peritoneal cytology have unfavorable overall prognosis.[6] In the absence of concerning radiographic features, staging laparoscopy is typically performed at the time of the intended resection.

SURGICAL MANAGEMENT

- Margin-negative resection along with an adequate lymphadenectomy are the most critical components of the surgical resection.

Preoperative Planning

- **Addressing preoperative malnutrition:** Gastric outlet obstruction caused by tumor as well as anorexia associated with malignancy contribute to malnutrition. As such, these patients may benefit from a placement of a preoperative nasojejunal tube and enteral nutrition. In patients presenting with malignant distal gastric obstruction, an endoscopic transpyloric stent may address the gastric outlet obstruction and thus help in optimizing the nutrition. Staging laparoscopy and placement of a feeding jejunostomy tube is another option.
- **Evaluation of the patient's functional status:** A careful review and optimization of underlying comorbidities (e.g., cardiac, pulmonary, diabetes) and performance status should be performed. A subset of high-risk individuals may benefit from preoperative admission to optimize the nutrition, electrolytes imbalance, and improve performance status (e.g., physical therapy) in preparation for the oncologic resection.
- **Preoperative antibiotics:** Patients should have preoperative first- or second-generation cephalosporins prior to incision to reduce the risk of wound infection.
- **Deep venous thrombosis (DVT) prophylaxis:** All patients should have a sequential compression device applied during the procedure. Use of subcutaneous heparin/low-molecular-weight heparin is initiated on postoperative day 1 and continued throughout the hospitalization unless contraindicated.

Positioning

- The patient is placed in supine position with both arms out at 90 degrees. Nipples to upper thigh should be prepped and draped in the operative field.

STAGING LAPAROSCOPY

- Pneumoperitoneum is created by either open technique or Veress needle. A 30-degree scope is inserted at the umbilicus. One to two additional 5-mm ports on left or right side of the abdomen are needed for additional visualization, grasping, and biopsy of suspicious tissue. A complete survey of the peritoneal cavity is performed, including undersurface of the diaphragm, liver surface, spleen, lining of peritoneal cavity, pelvis, small bowel surface, and omentum, for metastatic disease. If suspicious disease is observed, it is sent for frozen section. In the setting of biopsy-proven peritoneal disease, gastrectomy should not be considered and nonsurgical treatments should be initiated. However, selective palliative surgical procedures may be indicated, for example, in bleeding or obstructing cancers that cannot be palliated by endoscopic procedures. These decisions need to be individualized based on the performance status of the patient, extent of metastatic burden, and the projected survival.
- If the staging laparoscopy is negative for peritoneal spread of the disease, operative resection is performed.

EXPLORATORY LAPAROTOMY

- Abdomen is entered through a midline incision extending from the xiphoid process to just below the umbilicus. A bilateral subcostal incision, approximately 2 cm below the costal margin, also provides good exposure. During entry into the abdomen, the falciform ligament should be preserved as it can be used to buttress the duodenal closure.
- A careful exploration of the peritoneal cavity is performed to exclude presence of subradiographic peritoneal or metastatic disease. The liver is carefully examined for any suspicious nodules.

MOBILIZATION OF THE GREATER CURVATURE OF THE STOMACH

- In this step, the transverse colon is separated from the greater omentum in an avascular plane (**FIG 3**). The stomach and the greater omentum are reflected superiorly, and the transverse colon is reflected inferiorly. The plane of fusion between the greater omentum and the transverse mesocolon is identified as a faint white line. This plane is incised with electrocautery to enter the lesser sac. This plane is advanced proximally and distally along the transverse colon.
- The dissection proceeds to the proximal greater curvature of the stomach using either clamps and ties or an energy device, such as Harmonic™ or LigaSure™, to divide the short gastric vessels. When performing a subtotal gastrectomy, this dissection should stop at the beginning of the short gastric vessels as short gastric arteries provide the blood supply to the proximal gastric remnant.

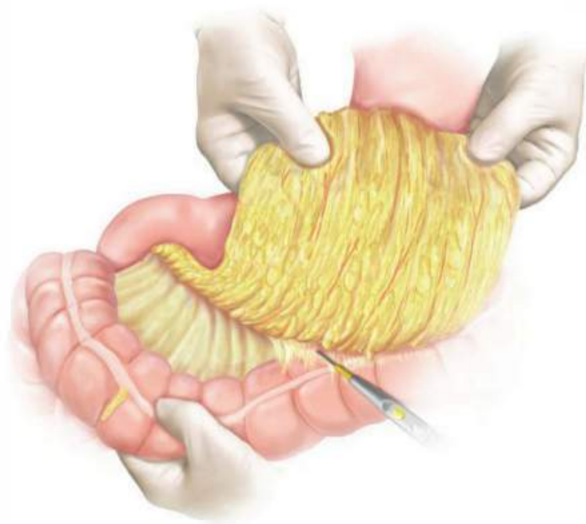

FIG 3 ● Separation of the omentum from the transverse colon. Omentum is separated from the transverse colon along the avascular embryonic planes of fusion thus allowing access to the lesser sac.

DUODENAL MOBILIZATION AND TRANSECTION

- The hepatic flexure of the colon is mobilized by dividing the avascular attachment of the right colon to the retroperitoneum. The separation of the greater omentum from the transverse mesocolon is continued to the hepatic flexure. This exposes the gastrocolic trunk, which is formed by the confluence of right gastroepiploic vein with a colonic vein and drains into the superior mesenteric vein (**FIG 4**). The right gastroepiploic vein is divided at its junction with the gastrocolic trunk. Alternatively, the gastrocolic trunk can be divided with a single fire of

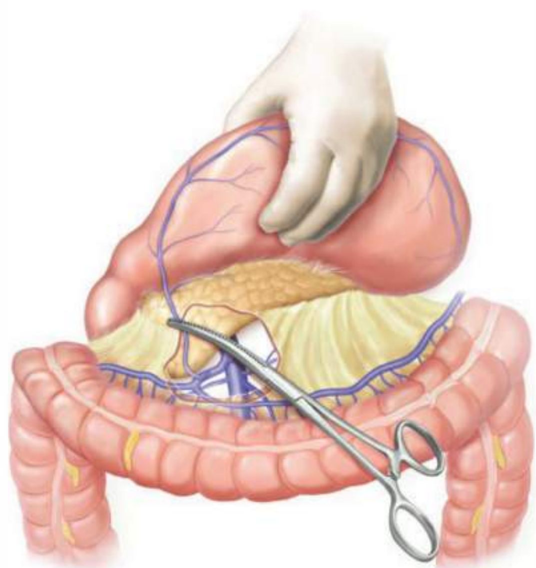

FIG 4 ● Ligation of the right gastroepiploic vein. Right gastroepiploic vein is ligated at its junction with the colonic veins. Alternatively, the gastrocolic trunk can be divided with a single fire of a vascular stapler load.

FIG 5 ● Dissection of the infrapyloric nodal packet at the level of right gastroepiploic vessels.

vascular stapler. At this stage, the right gastroepiploic artery is divided at its origin at the infraduodenal level. The infrapyloric nodes, located adjacent to the origin of gastroduodenal artery, are mobilized with the specimen (**FIG 5**).

- The lesser curvature is mobilized by dividing the lesser omentum as close to the liver as possible (**FIG 6**). If a replaced or accessory left hepatic artery is identified, it should be temporarily ligated, and the perfusion of the left lobe of the liver should be assessed prior to transecting the vessel. The dissection is carried distally to the portal triad. The right gastric artery arising from the common hepatic artery is divided including the lymphatic tissue with the specimen. The duodenum is circumferentially dissected about 2 to 3 cm distal to the pylorus, encircled with a Penrose drain and divided with either a stapler or in between straight bowel clamps (**FIG 7**). Care is taken not to injure the bile duct, hepatic artery, or portal vein when encircling the duodenum. The stapled duodenal line is oversewn with 3-0 silk Lembert sutures and can be buttressed with the falciform ligament (Moossa's patch). However, in the setting of extensive inflammation around the periduodenal area, consideration should be given to dividing the duodenal stump in between two straight bowel clamps and suture closure of the duodenal stump.

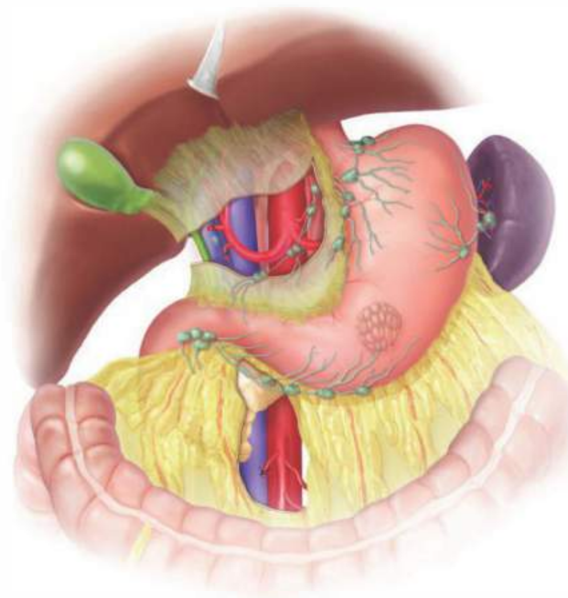

FIG 6 ● Mobilization of the lesser curvature of the stomach. Lesser omentum is divided as close to the liver as possible. Presence of replaced or accessory left hepatic artery is carefully sought for.

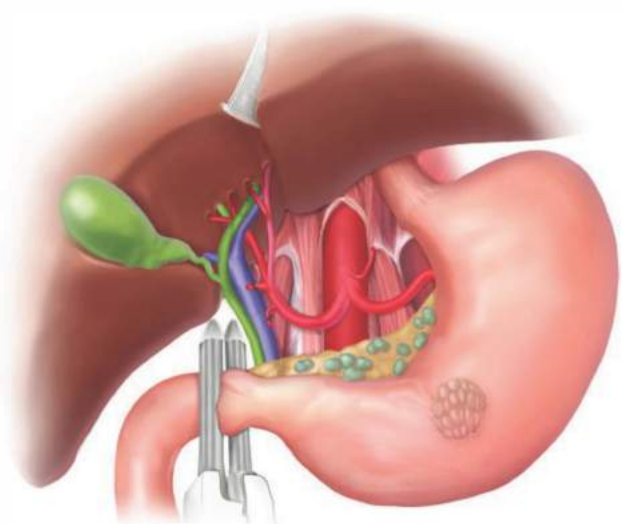

FIG 7 ● Division of duodenum. Duodenum is encircled with a Penrose and divided with a blue GIA stapler load. Care is taken to avoid injury to portal vein, bile duct, and hepatic artery.

- The gastrectomy specimen, now disconnected distally, is lifted upward. The left gastric artery is identified, suture ligated, and divided at its origin (**FIG 8**). The lymph–areolar tissue with the left gastric artery is mobilized with the specimen.

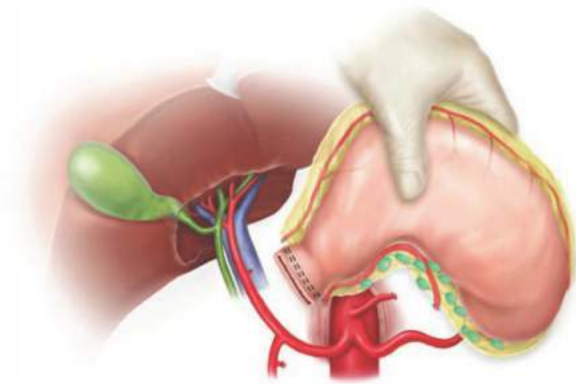

FIG 8 ● Division of left gastric artery. Stomach is lifted upward, left gastric artery is identified, and suture ligated. The lymph node packet along the left gastric artery is mobilized along with the specimen.

GASTRIC TRANSECTION

- Next, the stomach is divided about 4 to 6 cm proximal to the gastric cancer (**FIG 9**). Our preference is to use several green loads of a GI stapler.
- We send the resected specimen in separate containers in the following manner: (1) stomach with a marking stitch on proximal end, (2) greater omentum, (3) infrapyloric nodal packet, and (4) lesser curvature nodal packet with a long stitch on the left gastric artery. The operating surgeon should communicate with the pathologist to orient him/her to the specimen and indicate the proximal and distal margins for frozen section assessment.

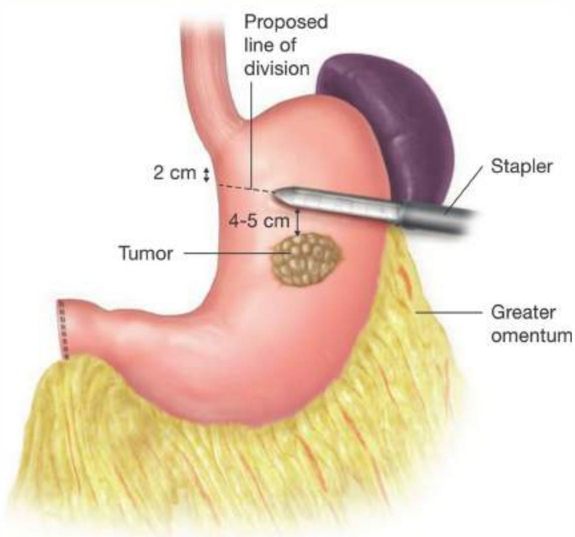

FIG 9 ● Division of the stomach. Stomach is divided 5 to 6 cm proximal to the most proximal extent of the tumor along a line extending from 2 cm distal the gastroesophageal (GE) junction to the greater curvature.

EXTENT OF LYMPHADENECTOMY

- The extent of lymphadenectomy in patients with operable gastric cancer is an area of controversy.[7,8] To ensure adequate lymphadenectomy, the gastric arteries need to be divided at their origin. We typically perform a pancreas- and spleen-preserving lymphadenectomy. That is, taking the right gastric artery, right gastroepiploic artery, and left gastric arteries at their origin along with celiac axis nodal dissection. We acknowledge that the addition of a celiac axis dissection is an area of controversy.

RECONSTRUCTION

- Restoration of GI continuity can be achieved by performing a Billroth II loop gastrojejunostomy or Roux-en-Y gastrojejunostomy. Our preference is Roux-en-Y gastrojejunostomy.
- **Roux-en-Y reconstruction:** While awaiting frozen section on the gastric margins, we proceed with the reconstruction. A loop of jejunum distal to the ligament of Treitz that reaches the stomach pouch without tension is identified. The jejunum is divided at this point

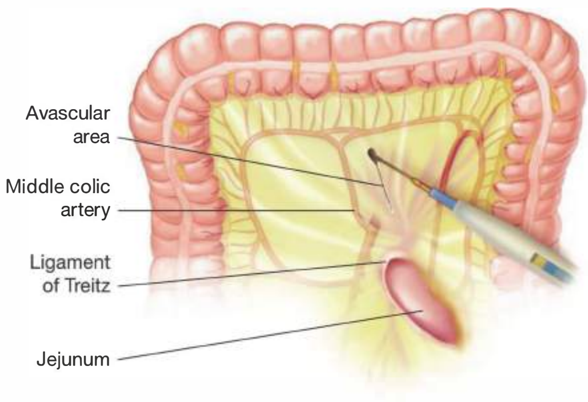

FIG 10 ● Creation of defect in transverse mesocolon. A defect is created in the transverse mesocolon to the left of middle colic veins. The Roux limb is taken to the gastric remnant in a retrocolic fashion.

with a blue gastrointestinal anastomosis (GIA) stapler. The staple line on the end of the Roux limb is oversewn with 3-0 silk stitches in Lembert fashion. The Roux limb needs to be at least 40 cm (i.e., from its beginning at the level of stomach to the jejunojejunostomy). A defect is created in the transverse mesocolon to the left of the middle colic vessels (**FIG 10**). We then confirm that the Roux limb can easily reach the stomach without tension when placed in the retrocolic position. Our preference is to first perform a stapled side-to-side anastomosis between the biliopancreatic limb and the jejunum. Our rationale behind this order of reconstruction is to allow for an easier reconstruction of this anastomosis away from the transverse mesocolon defect. Stay sutures are placed between the biliopancreatic limb and the jejunum. Enterotomies are made in the biliopancreatic limb and the jejunum. One limb of the blue GIA stapler is introduced into the biliopancreatic limb and the other in the jejunum. The blue load is fired and the common enterotomy is closed either in a hand-sewn fashion or with a single fire of GIA or thoracoabdominal (TA) stapler.

- Then, the Roux limb is navigated through the defect in the transverse mesocolon. A two-layered side-to-side anastomosis is created between the anterior surface of the gastric pouch and the Roux limb. A posterior layer of interrupted 3-0 silk seromuscular (Lembert) sutures are placed (**FIG 11A**). Two opposing enterotomies are made on the stomach and the antimesenteric border of the Roux limb. The length of the opening in jejunum should be shorter than that made in the stomach as the opening in the small bowel tends to expand. Next, an inner posterior layer of full-thickness interrupted 3-0 silk (or absorbable) sutures are placed, followed by an anterior layer of interrupted 3-0 silk (or absorbable) full-thickness stitches (**FIG 11B**). Prior to completion of anterior layer, the anesthesiologist advances the NG tube into the afferent limb of the jejunum. Following completion of the inner layer of the two-layered anastomosis, an anterior layer of interrupted 3-0 silk seromuscular (Lembert) sutures are placed (**FIG 12**). Alternatively, the surgeon can perform this anastomosis as a stapled anastomosis. The Roux limb is sutured to the transverse mesocolon to prevent herniation of small bowel through this defect.

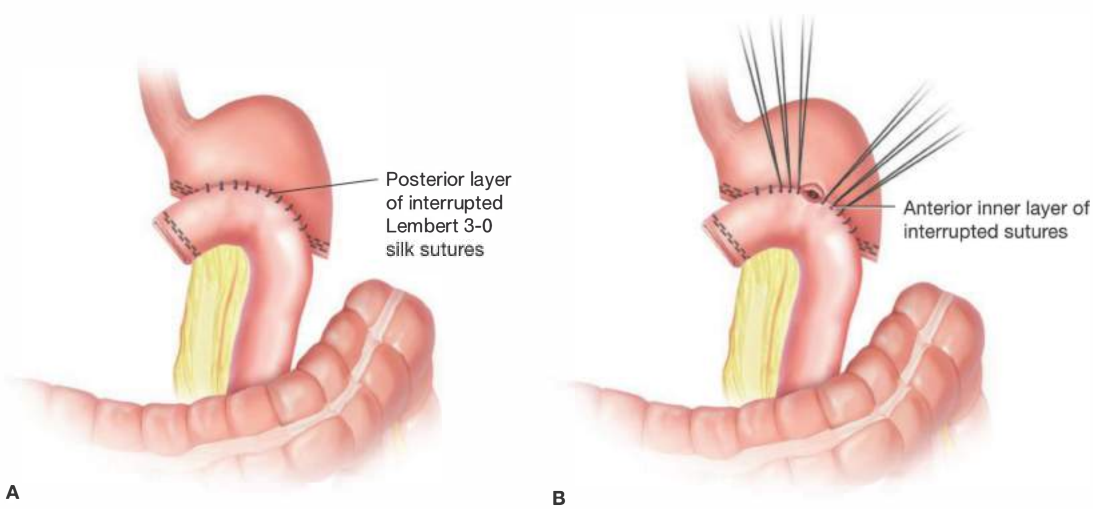

FIG 11 ● Construction of two-layered hand-sewn gastrojejunal anastomosis. **A.** A series of posterior layer of interrupted 3-0 silk sutures are placed. **B.** Anterior inner layer also consists of interrupted 4-0 absorbable full-thickness stitches. Prior to completion of anterior layer, an NG tube is advanced into the afferent limb of the jejunum. Following completion of the inner layer of the two-layered anastomosis, an anterior layer of interrupted 3-0 silk is placed.

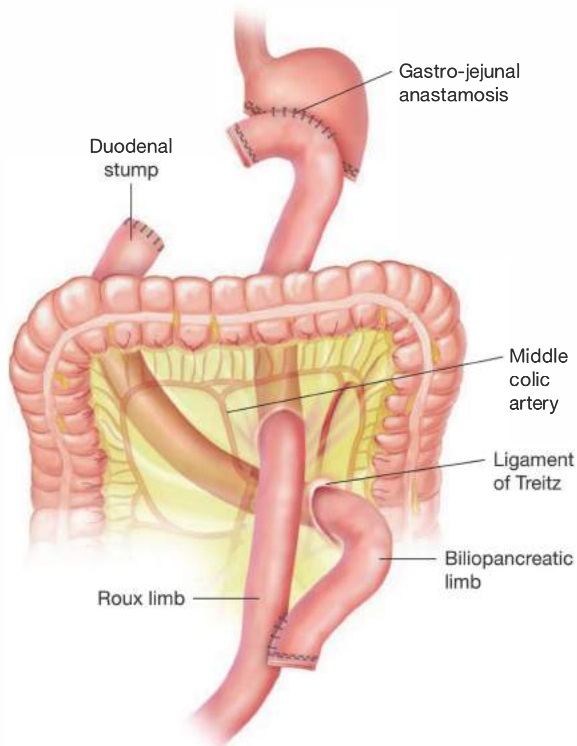

FIG 12 ● Final anatomy after completion of gastrojejunal anastomosis.

CLOSURE

- At this point, abdomen is irrigated and the fascia closed with a running no. 1 absorbable monofilament suture.

The skin is closed with staples or running subcuticular absorbable suture.

PEARLS AND PITFALLS

Diagnostic studies	■ The endoscopy should be performed or personally discussed with the endoscopist for better operative planning and intraoperative localization of the tumor.
Staging laparoscopy	■ Staging laparoscopy is critical to avoid nontherapeutic laparotomy. Up to a third of the patients with localized disease on imaging will have subradiologic peritoneal spread.
Preoperative nutrition	■ Preoperative nutrition should be addressed by nasojejunal tube placement and enteral nutrition. Addressing gastric outlet obstruction by endoscopic means (e.g., stenting) or placement of a jejunostomy tube (J tube) at the time of staging laparoscopy also helps with nutritional optimization.
Mobilization of greater curvature of the stomach	■ Greater curvature of the stomach should be mobilized, taking care to avoid unnecessary traction on splenic adhesions thus avoiding splenic injury and splenectomy. The blood supply to the proximal gastric pouch is from short gastric vessels, which should be preserved above the point of transection. If injury to spleen requires a splenectomy then total gastrectomy should be performed, as the removal of spleen jeopardizes the vascular supply of the proximal gastric remnant.
Circumferential dissection of duodenum	■ Careful dissection around the duodenum in the infrapyloric area is a key step to ensure adequate lymphadenectomy and avoid injury to common bile duct and portal vein.
Left gastric pedicle dissection	■ Identification and ligation of left gastric vein should be done with care to avoid bleeding or venous tear propagating to the portal vein.

Reconstruction of the gastrointestinal continuity	■ Before constructing the gastrojejunal anastomosis, the orientation of the Roux limb should be carefully checked to prevent twisting or undue tension on the anastomosis.
Delayed gastric emptying	■ Up to 15% to 20% of the patients demonstrate delayed gastric emptying after gastric surgery. Early recognition of symptomatology, by not mistaking vomiting or early satiety as postoperative ileus, is important. Treatment is supportive with gastric decompression and trial of prokinetic agents (e.g., metoclopramide or intravenous [IV] erythromycin).

POSTOPERATIVE CARE

- **General management:** Similar to other intraabdominal operation, patients with subtotal gastrectomy should undergo a regimen of aggressive pulmonary hygiene, early ambulation, and physical therapy. Careful attention should be paid to the volume status, electrolytes, and input/output balance.
- **DVT prophylaxis:** We start patients on DVT prophylaxis within 24 hours after completion of the procedure unless contraindicated.
- **NG tube:** We keep the NG tube until 2 to 3 days postoperatively. If the tube gets dislodged accidently, we do not replace it. If replacement of an NG tube is necessary, it should be performed under fluoroscopy to avoid accidental disruption of the anastomosis by a blindly placed NG tube.
- **Diet:** A clear liquid diet is initiated on postoperative day 3 or 4 and advanced as tolerated. We consult a dietitian to educate patients on issues related to postgastrectomy diet.

OUTCOMES

- **Prognosis:** 5-year survival is 70% for stage IA, 57% for stage IB, 45% for stage IIA, 32% for stage IIB, 20% for stage IIIA, 14% for stage IIIB, 9% for stage IIIC, and 4% for stage IV.[9]
- In a landmark study,[10] adjuvant chemoradiation therapy for the treatment of stage IB to IV M0 (AJCC 1988) resectable gastric cancer improved the 3-year overall and relapse-free survival from 41% to 50% and 31% to 48%, respectively.
- Similarly, perioperative chemotherapy without radiation[11] for gastric cancer led to an improvement of overall 5-year survival from 23% to 36%.

COMPLICATIONS

- **Pulmonary complications**
  - Pulmonary complications are frequent after upper abdominal surgery including atelectasis, aspiration, pneumonia, DVT, and pulmonary embolism. Good pulmonary toilet, early mobilization, elevation of the head of the bed, close attention to fluid balance, and early initiation of DVT prophylaxis are paramount to minimize the occurrences.
- **Postoperative bleeding**
  - **Presentation:** Postoperative bleeding can occur intraluminal or intraabdominal. Intraluminal bleeding presents with fresh blood in NG tube, melena, falling hemoglobin, and if severe, as hemodynamic instability. Bleeding from the anastomosis line is the major cause of the intraluminal bleeding and usually occurs around postoperative days 5 to 7.[12] Intraabdominal bleeding presents with hypotension, tachycardia, dropping hemoglobin, and abdominal distension. Intraabdominal bleeding usually presents in the first 12 to 24 hours following surgery. Unrecognized splenic injuries in the form of capsular tears and lacerations and/or inadequate control of short gastric vessels are the major causes of postoperative intraabdominal bleeding.[12]
  - **Management:** Intraluminal bleeding can generally be managed by supportive measures in the form of correction of coagulopathy and volume resuscitation. Bleeding that causes hemodynamic compromise or does not respond to supportive measures requires careful endoscopic therapeutic measures. Reoperation for bleeding not controlled with endoscopy is rare. Intraabdominal bleeding requires volume resuscitation and correction of coagulopathy. Patients with hemodynamic compromise or who do not immediately respond to supportive measures (suggesting ongoing bleeding) should return to the operating room for definitive control of the bleeding source.
- **Anastomotic leak**
  - **Presentation:** The overall incidence of anastomotic leak after subtotal gastrectomy is much less as compared to esophagojejunal anastomosis leak after total gastrectomy and is about less than 2%. Anastomotic leak presents with intraabdominal sepsis with fever and leukocytosis.
  - **Management:** When anastomotic leak or intraabdominal sepsis is suspected, a CT scan of the abdomen and pelvis with oral and IV contrast is performed. CT scan may suggest the presence of anastomotic leak and would demonstrate the presence of any drainable abdominal collection. The anastomotic leak can further be confirmed and characterized with a Gastrografin swallow study. Most leaks can be managed by making the patient NPO, parenteral nutrition, and drainage of any intraabdominal collection. Weekly Gastrografin swallow studies can document when the leak is healed. Rarely is surgical intervention required. Small leaks can be closed primarily and buttressed with an omental patch. Larger leaks may require a revision of anastomosis with wide drainage and jejunostomy tube for enteral feeding.
- **Duodenal stump blowout**
  - **Presentation:** Duodenal stump blowout can present as either peritonitis and hemodynamic instability or in a more localized fashion as signs and symptoms of intraabdominal abscess. Overzealous dissection of duodenum leading to its devascularization, chronic scarring of duodenum complicating its closure, and obstruction of the biliopancreatic limb are potential etiologies.
  - **Management:** A CT scan will demonstrate an abscess in the right upper quadrant and will not contain oral contrast. A percutaneous drain with a contrast study through the drain will confirm connection with duodenum. Management is largely through supportive measures

including NPO, parenteral or enteral nutrition, and replacement of fluid losses. A percutaneous transhepatic duodenal diversion can assist with closure of the leak by diverting the bile and pancreatic juices away from the fistula. Operative management might be required if the fistula does not close. If the duodenal blowout presents as acute abdomen, then exploratory laparotomy, placement of a tube duodenostomy, and wide drainage of right upper quadrant is performed.

- **Delayed complications:**
  - **Delayed gastric emptying**
    - **Presentation:** Disruption of normal mechanisms of gastric emptying and motility with gastric surgery leads to delayed gastric emptying. Delayed gastric emptying presents as nausea, vomiting, bloating, hiccoughs, and continued high NG tube output in presence of antegrade bowel function. The diagnosis is clinical and can be confirmed by slow emptying of stomach on contrast study or nuclear medicine gastric emptying study.
    - **Management:** Treatment is largely supportive and includes gastric decompression with NG and trial of promotility agents such as metoclopramide (10 mg three times daily) and/or erythromycin (up to 250 mg four times a day).
  - **Alkaline reflux gastritis**
    - **Presentation:** Contact of gastric mucosa with biliary contents causes alkaline reflux gastritis and presents as epigastric pain unrelieved by antacids, nausea, and bilious vomiting. Diagnosis is clinical and one of exclusion. Anastomotic ulceration, afferent and efferent loop syndrome, and disease of the gallbladder and pancreas must be ruled out. Endoscopy demonstrates hyperemic gastric mucosa with biliary staining, which supports the diagnosis. Bile reflux can be further documented using a HIDA scan.
    - **Management:** Alkaline reflux gastritis does not respond well to medical therapy. However, a trial of medical therapy with cholestyramine, sucralfate, or antacid is still warranted. Surgical treatment involves diverting duodenal contents away from the stomach by converting loop gastrojejunostomy to a Roux-en-Y gastrojejunostomy with a 45- to 60-cm Roux limb. A vagotomy should be performed at the time of reoperation to reduce the risk of marginal ulcer.
  - **Afferent and efferent loop syndrome**
    - **Presentation:** Afferent or efferent loop syndrome occurs due to obstruction of the afferent or the efferent loop when a loop gastrojejunostomy has been used to restore GI continuity. This can present as an acute problem if the obstruction is complete or as a chronic problem due to partial obstruction. The potential causes are numerous and include internal herniation, volvulus, or kinking at the anastomosis. Acute afferent limb obstruction is the most common cause of duodenal stump blowout and is a surgical emergency. Patient presents with severe epigastric and right upper quadrant pain associated with nausea and vomiting. Physical examination may reveal an intraabdominal mass, and CT scan of the abdomen reveals the diagnosis. When the afferent limb is partially blocked, then it presents as chronic afferent loop syndrome where patients complain of postprandial abdominal pain with nausea and projectile vomiting, which typically does not contain food and relieves the pain. Diagnosis is clinical and is complemented with endoscopy and upper GI fluoroscopy studies. Obstruction of the efferent loop is less common and presents as abdominal pain, nausea, and bilious vomiting with food particles in it. The diagnosis can be confirmed by Gastrografin study, which shows a holdup in the passage of contrast into the efferent limb. Potential causes include retroanastomotic hernia, adhesions, and stricture.
    - **Management:** Acute afferent loop syndrome is an emergency and requires immediate operative exploration. If the duodenum and afferent limb are viable, then addressing the etiology may include shortening the redundant afferent limb, reducing internal herniation, closing the mesenteric defects, or revision of gastrojejunal anastomosis. However, necrosis of the duodenum in this condition is a difficult problem and may require a pancreaticoduodenectomy. In case of chronic afferent loop syndrome, conversion of a loop gastrojejunostomy to Roux-en-Y anastomosis addresses the problem. Surgery is usually required for efferent loop obstruction and involves correction of the underlying cause.
  - **Nutritional consequences:** Gastrectomy is associated with specific mineral and vitamin deficiencies[12] as described below.
    - **Iron deficiency:** Iron deficiency is the most common cause of anemia after gastrectomy. Iron malabsorption, decreased intake, and increased losses from friable mucosa are reasons for iron deficiency. Daily supplementation of 150 to 300 mg per day in divided doses should be provided.
    - **Vitamin B_{12} deficiency:** Reduction in production of intrinsic factor and decrease in stomach acidity thus decreasing absorption of vitamin B_{12} leads to vitamin B_{12} deficiency. Daily supplementation of 100 μg of oral vitamin B_{12} or a monthly 1 mg intramuscular vitamin B_{12} injection is recommended following subtotal gastrectomy.
    - **Other mineral and vitamin supplementation:** Decreased oral intake and decreased absorption due to decreased gastric acid secretion can contribute to folate deficiency thus supplementation of folate is also recommended. Supplementation of vitamin D and calcium is also recommended after gastric surgery.

Chapter 12

Minimally Invasive Total Gastrectomy

Elliot Newman Marcovalerio Melis

DEFINITION

- Please refer to the *Minimally Invasive Distal Gastrectomy* chapter for details on definitions and indications.
- Currently, total gastrectomy is indicated for adenocarcinoma of the stomach where the proximal location precludes a lesser resection with a proximal 5- to 6-cm grossly negative margin.
- Randomized trials have shown that total gastrectomy offers no oncologic value over a distal gastrectomy as long as a negative margin can be obtained.[1,2]
- Occasionally, gastrointestinal stromal tumors located near the gastroesophageal junction may also require a total gastrectomy to achieve negative resection margins.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Following the diagnosis of gastric adenocarcinoma, accurate clinical staging is necessary.
- Endoscopic ultrasound will evaluate depth of tumor invasion and possible lymph node metastases
- Computed tomography (CT) scan of the chest abdomen and pelvis will evaluate for metastatic disease.
- Positron emission tomography (PET)/CT is recommended if no metastatic disease is detected by the CT.
- Diagnostic laparoscopy can be considered for advanced tumors (e.g., T3N1) to rule out subradiographic peritoneal dissemination.

SURGICAL MANAGEMENT

Preoperative Planning

- Same as *Minimally Invasive Distal Gastrectomy*. Please refer to the appropriate chapter.

Positioning

- Same as *Minimally Invasive Distal Gastrectomy* (**FIG 1**)
- Please refer to the appropriate chapter for further details.

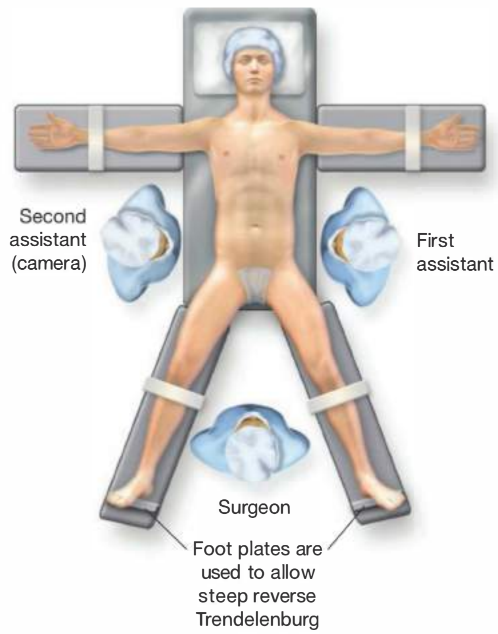

FIG 1 • Positioning of the patient on the operative table.

TECHNIQUES

ACCESS AND PORT PLACEMENT

- Same as *Minimally Invasive Distal Gastrectomy*, except for the camera port, which is placed routinely two to three fingerbreadths above the umbilicus and to the left of the midline, and a 15-mm trocar used for the most lateral trocar site on the left (**FIG 2**).
- Please refer to the appropriate chapter for further details.

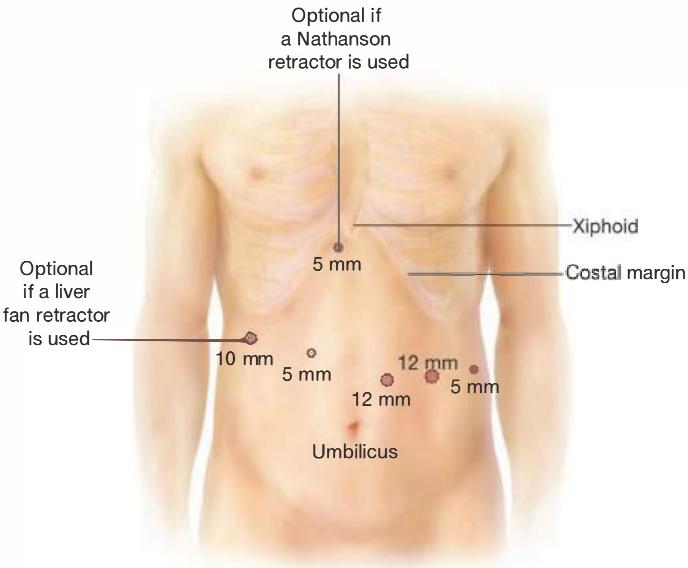

FIG 2 ● Port placement for laparoscopic distal gastrectomy. Depending on surgeon's preference for liver retraction, either a 5-mm trocar is placed at the epigastrium for a Nathanson retractor or a 10-mm trocar is placed in the lateral right upper quadrant for a fan retractor.

DISSECTION OF THE GREATER CURVE

- Retract the transverse colon and the greater omentum caudally.
- Access the lesser sac by entering the gastrocolic ligament in an avascular area with ultrasonic shears.
- Extend the dissection of the gastrocolic ligament distally toward the pylorus and cephalad toward the spleen with the ultrasonic shears.
- Continue the dissection of the gastrocolic ligament along the upper third of the greater curvature with the division of the left gastroepiploic vessels and then the gastrosplenic ligament including the short gastric vessels. This portion of the dissection is greatly facilitated by bringing the stomach down and rolling it up to expose the back wall of the stomach.
- By performing the dissection of the greater curvature lateral to the gastroepiploic arcade, the lymph nodes along the gastroepiploic vessels (stations 4d and 4sb) are included in the specimen.
- In order to expose the lesser cavity in its entirety, divide the avascular posterior gastropancreatic adhesions that are almost always present between the posterior wall of the stomach and the anterior surface of the pancreas. Division of those adhesions will also facilitate anterior retraction of the stomach (**FIG 3**).

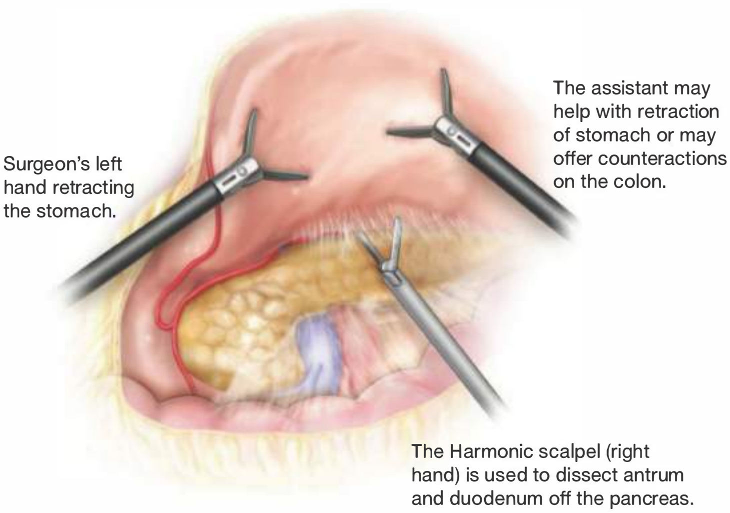

FIG 3 ● The stomach is retracted anteriorly to the patient's right, and adhesions between pancreas and posterior aspect of the stomach are divided.

- Next, continue the dissection more cranially along the greater gastric curvature, until all of the short gastric vessels are divided and the fundus is completely mobilized. At this time, the left crus and the hiatus with the distal esophagus should be visualized (**FIG 4**). Having the operating surgeon retract the anterior fundus toward the anterior abdominal wall and to the patient's right with the assistant retracting the posterior fundus in the same direction can improve the exposure.
- Using the ultrasonic dissector, divide the lateral portion of the phrenoesophageal ligament and expose the fibers of the left crus.

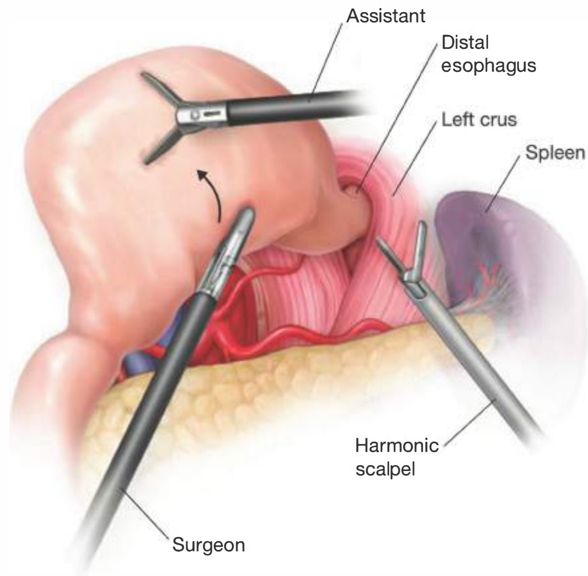

FIG 4 ● The greater curvature is completely dissected off the spleen and the stomach is elevated and rotated to the right, exposing the diaphragmatic hiatus.

ANTRAL DISSECTION

- Firm anterior retraction of the stomach aids in the duodenal dissection. While retracting the antrum toward the abdominal wall, separate bluntly or with Endoshear the posterior wall of the duodenum off the anterior surface of the pancreatic head. The gastroduodenal artery marks the limit of this pancreaticoduodenal dissection (**FIG 5**).
- Identify the origin of the right gastroepiploic artery. This is usually a direct continuation of the gastroduodenal

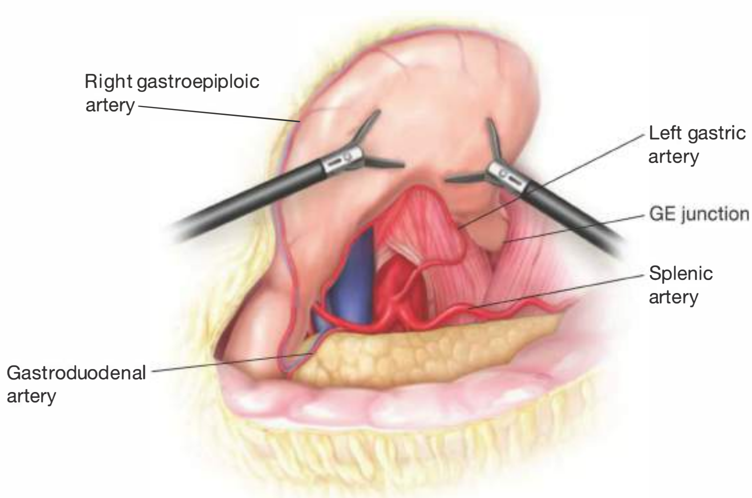

FIG 5 ● The antrum and the first portion of the duodenum are dissected off the pancreas. The gastroduodenal artery marks the limit of the duodenal dissection. The right gastroepiploic artery is identified at its takeoff from the gastroduodenal artery.

artery caudally emanating from the inferior edge of the pancreas. Use the lower border of the pancreas as a guide for where to divide the right gastroepiploic artery.

- Sweep the lymphatic tissue around the right gastroepiploic vessels (infrapyloric nodes, station 6) toward the specimen. Now, divide the right gastroepiploic vessels between clips or using a vascular load stapler. If clips have been used in proximity of the vessels, take great care to ensure they are not included in the stapler line.
- The right gastric artery can be dissected from behind the stomach and duodenum with good visualization. Dissect the filmy adhesions superior and posterior the first portion of the duodenum until the right gastric artery is visualized. Sweep the lymphatic tissue around the right gastric artery toward the specimen. This maneuver clears the suprapyloric lymph nodes (station 5).
- You can also retract the duodenum caudally and visualize the right gastric artery anteriorly at its takeoff from the common hepatic artery. Dissect it free, doubly clip, and divide it.

DIVISION OF THE DUODENUM

- Remove nasogastric tubes and/or temperature probes from the patient's mouth to prevent their inclusion in the jaws of the stapler.
- Make sure adequate length of duodenum is mobilized to easily allow placement of a linear stapler across the first portion of the duodenum, just distal to the pylorus.
- Place an Endo GIA with 3.5-mm cartridge close to the level of the duodenal dissection to avoid the pyloric ring and minimize duodenal ischemia. We often use a staple line reinforcement of biologic material, although usefulness of this device for prevention of postoperative leakage has not been proven. Before firing, make sure that any esophageal tube has been removed and that the portal structures are excluded from your stapler line.
- Make every attempt to divide the duodenum in one firing. Carefully inspect the integrity of duodenal staple line.

DISSECTION OF THE HEPATODUODENAL LIGAMENT

- Incise the peritoneum overlying the common hepatic artery and the bile duct with the hook electrocautery. Divide the gastrohepatic ligament, remaining along the left lobe of the liver and paying attention to identify and preserve an accessory or replaced left hepatic artery.
- Identify the base of the right crus.
- The lymph nodes along the common hepatic (station 8) and proper hepatic (station 12) arteries are removed en bloc just anterior to the portal vein. Our preference is to use the hook for dissection and the ultrasonic scalpel for division of larger vessels. Frequently, a vessel loop around the hepatic artery aids in retraction.

DISSECTION OF THE INTRAABDOMINAL ESOPHAGUS

- Have the assistant retract the stomach down and to the patient's left. This will improve exposure to the right crus, which had been previously identified.
- Free the gastroesophageal junction from the hiatus by dissecting up the right crus with ultrasonic shears.
- Take down the phrenoesophageal ligament and proceed through the connective tissue posterior to the esophagus to extend the dissection toward the left crus.
- Divide the right and left vagus nerves when identified.
- The gastroesophageal junction is now dissected circumferentially. Guide a 2-cm wide Penrose drain around the esophagus. Secure the two ends of the Penrose together with an Endo GIA stapler (Covidien, Norwalk, CT) or an Endo loop, leaving little space between the drain and the esophageal wall.
- The assistant may now use the Penrose drain to retract the esophagus caudally and increase exposure of the hiatal region. Complete the dissection of the lower esophagus using blunt and ultrasonic dissection.

DIVISION OF THE LEFT GASTRIC ARTERY

- Use either the Nathanson liver retractor or a handheld retractor to elevate the stomach and identify the left gastric artery and the celiac trunk.
- The left gastric vessels at this time should be readily identifiable caudad to the Penrose drain, between the two "windows" created by the hiatal dissection, and by the opening of the gastrohepatic ligament.
- Once the celiac anatomy is evident, dissect the left gastric artery and skeletonize its takeoff from the celiac trunk, therefore mobilizing nodal tissue of station 7 (left gastric artery) and 9 (celiac artery) anteriorly toward the specimen. Once the left gastric pedicle is skeletonized, divide it at its origin, using a 2.5-mm Endo GIA cartridge flush, with the anterior pancreatic body. Our practice is to take the coronary vein and the left gastric together in a single fire of the stapler.
- Once the left gastric artery is divided, skeletonize the splenic artery thus mobilizing station 11 nodes. Again, vessel loops may aid in retraction of the larger arteries in concert with gentle downward retraction of the

pancreatic body. Care must be taken to identify and preserve the splenic vein.

- We do not routinely include the peritoneum covering the anterior surface of the pancreas in our dissection.
- We do not routinely perform a splenectomy or a distal pancreatectomy, because in the western literature, potential benefits of a complete dissection of the lymph nodes in station 11 is outweighed by a significant increase in postoperative morbidity (specifically pancreatic leaks) without measurable effect in long-term survival.

PROXIMAL DIVISION

- Division of the left gastric artery will increase exposure to the hiatus.
- With the assistant pulling on the Penrose to retract the stomach caudally, complete (if necessary) the mobilization of the intraabdominal esophagus using ultrasonic shears.
- Place two stay sutures on each side of the esophagus, proximally to the planned division. Those sutures will facilitate retrieval of the esophagus should it retract in the mediastinum after removal of the specimen.
- Transect the distal esophagus using a 3.5-mm Endo GIA of appropriate length.
- The specimen is placed in a 15-mm endo bag and extracted by enlarging as needed the most lateral trocar site on the left. If you have to make a large incision to remove the specimen, you may need to use a ballooned trocar for this site to seal the peritoneal cavity and avoid loss of the pneumoperitoneum.
- Obtain hemostasis.
- The stump of the excised portion of esophagus may be submitted for frozen section examination to assure a microscopically negative margin.

RECONSTRUCTION WITH STAPLED ESOPHAGOJEJUNOSTOMY

- Our choice for the reconstruction is a Roux-en-Y esophagojejunostomy in an antecolic fashion, using an end-to-end anastomosis (EEA) OrVil™ stapler device with a 25-mm diameter. Alternatively, a 21-mm diameter EEA stapler can be used for a smaller caliber esophagus.
- The OrVil™ is a device prepared with an EEA anvil head fastened in a tilted state to a long polyester tube.
- End-to-side esophagojejunostomy
  - Exposure of the distal esophagus is facilitated by gentle tension on the stay sutures previously placed.
  - Insert the OrVil™ device through the patient's mouth and guide it into the esophagus until the tip reaches the stapled line at its blinded end.
  - Create a small esophagotomy in the midportion of the stapled line, and let the tip of the OrVil™ pass through it.
  - Use a grasper inserted through a left trocar to pull the tube outside the esophagus, until the anvil is seen effacing the stapled line at the end of the esophageal stump. You must pay extreme attention during this maneuver, as it is relatively easy to tear the esophagus. Maneuvers that assist in passing the OrVil™ include adequate paralysis, jaw thrust, and deflating the balloon in the endotracheal tube.
  - The anvil head and the tube are kept connected by two pieces of polyester yarns; while securing the anvil, cut one thread and detach the tube from the anvil.
  - Identify the ligament of Treitz at the base of the transverse mesocolon. Proper anatomy is confirmed by visualization of the inferior mesenteric vein.
  - Divide the jejunum 20 cm away from the ligament of Treitz with a 3.5-mm Endo GIA.
  - Starting from the mesenteric side, remove most of the stapled line from the distal limb of the divided jejunum. Make sure not to completely excise the stapled line from the jejunum, but leave it attached to the antimesenteric side; you can use it as a handle to facilitate maneuvering this loop of bowel over the stapler.
  - Remove the trocar from the left lateral incision and use this opening to insert the EEA stapler into the abdomen. Enlarge this incision as needed to accommodate the EEA. Usually, two fingerbreadths are sufficient. Your assistant should now use two graspers to grab the mesenteric side and the thin strip of jejunum with the staples still attached to the antimesenteric side. While your assistant provides adequate exposure of the jejunal lumen with the two graspers, guide the EEA inside the lumen of the jejunum.
  - Select an appropriate site on the antimesenteric side of the jejunum for the esophagojejunostomy. Make sure it can easily reach the esophageal stump without tension.
  - Once you are satisfied with the site for the anastomosis, advance the spike of the EEA through the antimesenteric wall of the jejunum.
  - Ask your assistance to maintain tension on the jejunum, so that it does not retract off the EEA. Paying extreme attention to keep the spike of the EEA through the jejunotomy, advance the EEA toward the esophageal stump (**FIG 6**).
  - Firmly hold the anvil with a right-angle grasper, and use the other hand to progressively guide the spike of the EEA into the anvil until the two parts of the stapler click together.
  - Now close the EEA while advancing it toward the esophagus in order to avoid excessive tension of the anvil against the esophageal stapled line.
  - The anvil and the main unit are now connected. Make sure that nothing is caught between the esophagus and the jejunum while you fire the EEA stapler. Fire the stapler to complete the anastomosis.

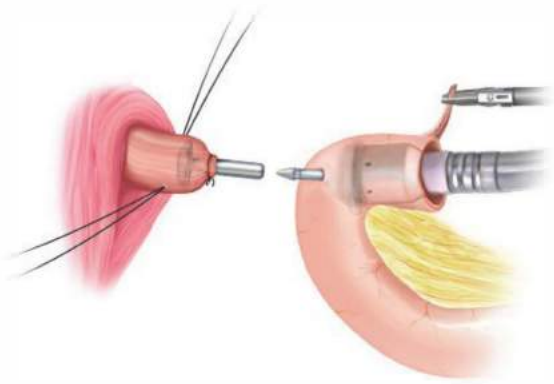

FIG 6 ● An end-to-side esophagojejunostomy is created with a mechanical stapler. The assistant holds the jejunum to avoid its displacement off the stapler. The surgeon advances the stapler over the colon toward the anvil while avoiding excessive tension of the anvil against the esophageal stapled line.

  - Use a 3.5-mm Endo GIA to close the open end of the jejunum. Our practice is to leave approximately 3 cm of jejunum as blind end.
- Side-to-side jejunojejunostomy
  - The jejunojejunostomy is typically created 40 to 50 cm distal to the esophagojejunostomy.
  - Use stay sutures to secure in a side-to-side fashion the stapled end of the biliopancreatic limb to the alimentary limb of the jejunum, just caudal to the transverse colon and avoiding any tension.
  - Use the ultrasonic shears to make a small enterotomy in the antimesenteric side of each limb.
  - Insert the jaws of a 3.5-mm Endo GIA in the enterotomies. Make sure that no mesentery or other loops of bowel are caught in the stapler prior to firing.
  - Once the stapler is fired, the staple line is inspected for bleeding.
  - Close the remaining anastomotic defect, which corresponds to the proximal end of the staple rows in two layers using running nonabsorbable suture.

CLOSING

- Complete a final inspection of all staple lines and vascular pedicles for hemostasis and well-formed staples. Bleeding points and areas of malformed staples should be oversewn with absorbable suture.
- Closed suction drainage is optional.
- Abdominal fascia is closed for all port sites larger than 5 mm.

POSTOPERATIVE CARE

- We usually keep a nasojejunal tube for 24 hours in order to avoid distension of the proximal jejunum, which may compromise the integrity of the anastomosis. Whether this decreases the leak rate has not been proven.
- Immediately after surgery, the patient is instructed to use incentive spirometry, cough, and take deep breaths. Patients are encouraged to stay out of bed and ambulate within 6 hours from surgery.
- Prophylactic antibiotics are not indicated in the postoperative period.
- Unless an epidural catheter is used for analgesia, the Foley catheter is removed in postoperative day 1.
- If the patient is able to protect his or her airway and the abdomen is not distended, clear liquids are allowed on postoperative day 1, then diet is advanced to a postgastrectomy diet as tolerated.

OUTCOMES

- Minimally invasive total gastrectomy is a safe and effective treatment of gastric cancer.
- Available evidence shows no major differences in morbidity, mortality, number of nodes harvested, or disease-free survival.
- The addition of a D2 dissection elevates this operation to much higher difficulty level.
- Oncologic principles and safety are paramount and should not be sacrificed for a less invasive approach.

COMPLICATIONS

- The postoperative complications observed after minimally invasive total gastrectomy generally are comparable with those of an open procedure.
- *Intraoperative*
  - Bleeding
  - Splenic injury
  - Iatrogenic enterotomy
- *Early postoperative*
  - Esophagojejunal leak
  - Duodenal leak
  - Bleeding
- *Late postoperative*
  - Dumping
  - Afferent limb syndrome
  - Malnutrition
  - Anastomotic stricture

Chapter 13

Minimally Invasive Distal Gastrectomy

John K. Saunders Marcovalerio Melis

DEFINITION

- The indications for minimally invasive distal gastrectomy (MIDG) do not differ from the indications for open gastrectomy and include both benign and malignant diseases.
- Gastric malignancies (adenocarcinomas, neuroendocrine tumors, gastrointestinal stromal tumors [GIST], and other submucosal neoplasms) account for the single largest indication for gastric resection and will be the focus of this chapter.
- MIDG performed for malignancies should follow the same standard oncologic principles generally followed during open resections.
- For adenocarcinomas, gastric resection should be extended proximally for 5 to 6 cm from the gross tumor margins. For tumors of the distal stomach, this is generally achievable with a partial gastrectomy. Randomized trials have shown that total gastrectomy offers no oncologic value over a distal gastrectomy as long as a negative margin can be obtained.[1,2] Appropriate extent of lymphadenectomy for gastric adenocarcinoma in the western population is a topic of great debate and beyond the scope of the present chapter. In our practice, we usually perform a D2 lymph node dissection. A recent meta-analysis has shown that MIDG for gastric adenocarcinoma is safe and associated with reduced overall morbidity.[3] Comparative studies with long-term follow-up are still lacking, but available evidence suggests that oncologic outcomes are comparable after either MIDG or open distal gastrectomy. Perioperative chemotherapy is indicated for any gastric adenocarcinoma stage T2N0M0 or greater as recommended by National Comprehensive Cancer Network (NCCN) guidelines.
- For GIST, gastric resection follows different oncologic principles. A lymph node dissection is not required and surgery is considered curative as long as the resection margins are negative. Therefore, more limited resections (e.g., wedge resections) are appropriate for GIST. Partial gastrectomies may still be required for large tumors or when the gastroesophageal junction or the pylorus is involved.
- Although decreasing in frequency, complications of peptic ulcer disease (bleeding, gastric outlet obstruction, failure of medical treatment) are still significant indications for distal gastrectomy. The same technique described in this chapter may be used for benign pathologies, omitting the lymphadenectomy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Following the diagnosis of gastric adenocarcinoma, accurate clinical staging is necessary.
- Endoscopic ultrasound will evaluate depth of tumor invasion and possible lymph node metastases.
- Computed tomography (CT) scan of the chest abdomen and pelvis will assess metastatic disease.
- Positron emission tomography (PET)/CT is recommended if no metastatic disease is detected by the CT.
- Diagnostic laparoscopy can be considered for advanced tumors (e.g., T3N1) to rule out subradiographic peritoneal dissemination but not routinely indicated.

SURGICAL MANAGEMENT

Preoperative Planning

- The choice of laparoscopic versus open techniques should be at the discretion of the surgeon.
- Regardless of the technique, the primary goals of the operation are the same: resection of the cancer with negative margins and restoration of intestinal continuity.
- The patient should be medically optimized for surgery. Special attention needs to be given to malnourished patients.
- Preoperative nutritional panels are mandatory, and occasionally, the placement of a preoperative feeding jejunostomy is warranted. Consider preoperative tube feedings in patients with significant weight loss or other evidence of malnutrition, especially if candidates for neoadjuvant treatment.
- Consider neoadjuvant treatment for lesions T2 or greater and/or for suspected lymph node involvement.
- Insist on smoking cessation to reduce postoperative pulmonary and wound complications.
- Consider a preoperative liquid protein diet to improve steatohepatitis in obese patients.
- Perioperative antibiotic should be given within 30 minutes prior to the initial skin incision.
- Deep vein thrombosis (DVT) prophylaxis with calf length pneumatic compression devices or subcutaneous heparin (or both) should be instituted prior to induction of anesthesia.
- General anesthesia may be supplemented with epidural analgesia.
- The bladder is decompressed with a Foley catheter.
- An orogastric or a nasogastric tube is inserted.

Positioning

- Use an operating room (OR) table that may accommodate very steep reverse Trendelenburg position.
- Preferred position is supine split leg with foot plate attachments to prevent patient migration. The foot plates should be snugly placed with the toes pointing slightly outward (**FIG 1**).
- Pad pressure points along arms and legs and secure the knees in the locked position. Pillow cases or folded sheets and 2-in silk tape can be used to keep the knees from buckling. Arms are secured either by Kerlix™ gauze wrapped around the armboard or by commercially made arm straps.
- Prior to prepping and draping, check the positioning by manipulating the bed in all of the positions that will be used during the operation.

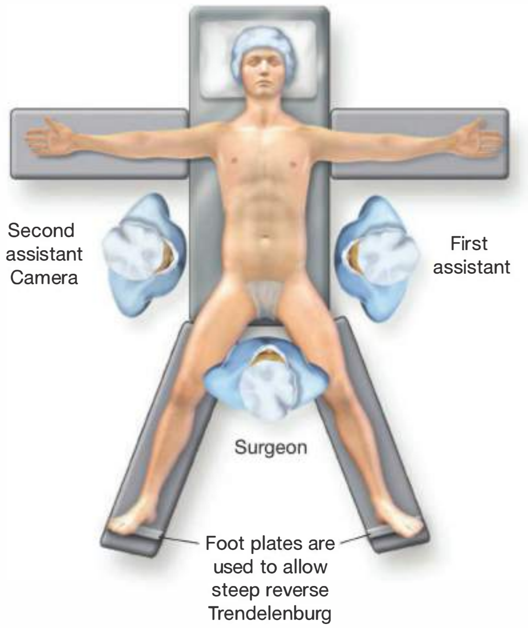

FIG 1 ● Positioning of the patient on the operative table.

ACCESS AND PORT PLACEMENT

- Port placement is dictated by the body habitus of the patient. The umbilical trocar is generally used for the camera. In obese patients, or with an unusually low umbilicus, the camera port may need to be more cephalad, often two or three fingerbreadths above the umbilicus and left to the midline.
- Place a 10-mm trocar at the umbilicus with usual Hassan technique.
- Establish a 15 mmHg pneumoperitoneum and perform a diagnostic laparoscopy to rule out peritoneal or hepatic metastases. If metastatic lesions are suspected, they should be biopsied and sent for frozen section prior to committing to gastrectomy. If ascites is present, washings should be performed.
- Identify the neoplasm by visualization or by palpation. If unsuccessful, intraoperative endoscopy is encouraged.
- Place the patient in steep reverse Trendelenburg position and insert the trocars under direct visualization and in a direction that minimize torque. Our typical port setup is shown in **FIG 2**.
- Retract the liver with a subxiphoid Nathanson retractor. However, stiff or floppy livers are best retracted with a 10-mm handheld fan retractor from the patient's right side.

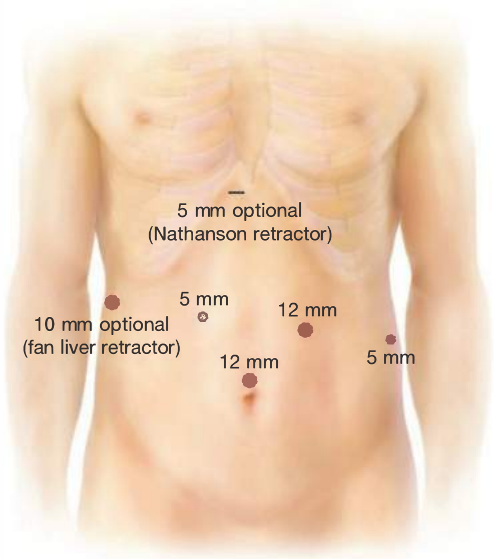

FIG 2 ● Port placement for laparoscopic distal gastrectomy. Depending on surgeon's preference for liver retraction, either a 5-mm trocar is placed at the epigastrium for a Nathanson retractor or a 10-mm trocar is placed in the lateral right upper quadrant for a fan retractor.

GASTROCOLIC DISSECTION

- Reflect the greater omentum cephalad. Retract the transverse colon caudally.
- Mobilize the omentum off of the transverse colon using ultrasonic scissors. In the course of this mobilization, the lesser sac is entered. It is helpful to widely open the lesser sac in order to aid the anterior retraction of the distal stomach.
- Care must be taken to preserve at least the most proximal short gastric vessels to assure adequate perfusion to the remnant stomach.
- Lysing the gastropancreatic adhesions is helpful in obtaining the proper retraction.

ANTRAL DISSECTION

- Once the greater curvature is fully mobilized, complete the gastric dissection by dividing sharply any gastropancreatic or retrogastric adhesions until the entire posterior wall of the stomach are visualized in its entirety (**FIG 3**).
- Firm anterior retraction of the stomach aids in the duodenal dissection. By retracting the antrum toward the abdominal wall, the duodenum may be freed from the anterior surface of the pancreatic head. The gastroduodenal artery marks the limit of this pancreaticoduodenal dissection.
- Identify the origin of the right gastroepiploic artery (which corresponds to lymph node station 6 [**FIG 4**]). This is usually a direct continuation of the gastroduodenal artery, caudally emanating from the inferior edge of the pancreas. Use the lower border of the pancreas as a guide for where to divide the right gastroepiploic artery.
- Sweep the lymphatic tissue around the right gastroepiploic vessels toward the specimen. Then divide the right gastroepiploic vessels between clips or using a vascular load stapler. If clips have been used in proximity of the vessels, take great care to ensure they are not included in the stapler line.
- The right gastric artery can be dissected from behind the stomach and duodenum with good visualization. Dissect the filmy adhesions superior and posterior to the first portion of the duodenum until the right gastric artery is visualized. You can also retract the duodenum caudally and visualize the right gastric anteriorly at its takeoff from the common hepatic artery. Dissect it free, doubly clip, and divide it.

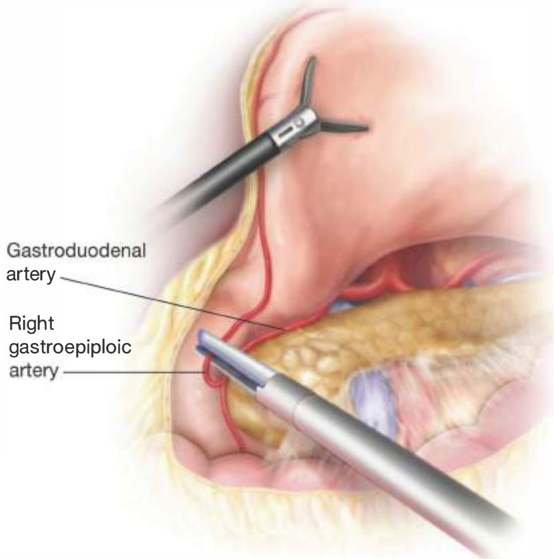

FIG 4 ● The right gastroepiploic artery is divided between clips or using a stapler or energy-sealing device.

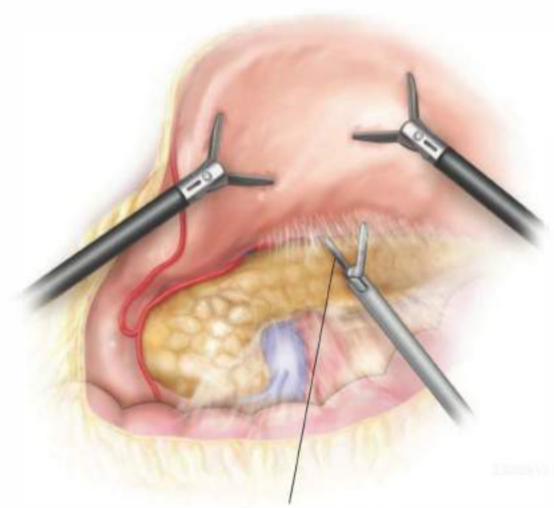

FIG 3 ● Posterior dissection of the antrum. The stomach is retracted anteriorly to the patient's right, and adhesions between pancreas and posterior aspect of the stomach are divided. The first portion of the duodenum has to be completely mobilized in order to allow safe use of the Endo GIA stapler for its transection.

DIVISION OF THE DUODENUM

- Remove nasogastric tubes and/or temperature probes from the patient's mouth to prevent their inclusion in the jaws of the stapler.
- Make sure adequate length of duodenum is mobilized to easily allow placement of a linear stapler across the first portion of the duodenum, just distal to the pylorus.
- Place an Endo GIA with 3.5-mm cartridge close to the level of the duodenal dissection to avoid the pyloric ring and minimize duodenal ischemia. We often use a staple line reinforcement of biologic material, although usefulness of this device for prevention of postoperative leakage has not been proven. Before firing, make sure again that any esophageal tube has been removed and that portal structures are excluded from your stapler line.
- Make every attempt to divide the duodenum in one firing. Carefully inspect the integrity of the duodenal staple line.

DISSECTION OF THE HEPATODUODENAL LIGAMENT

- Incise the peritoneum overlying the common hepatic artery and the bile duct with the hook electrocautery. Take care to identify aberrant left hepatic arteries. Divide the entire lesser omentum remaining along the left lobe of the liver.
- The base of the right crus is identified.
- Identify the hepatic artery and skeletonize it, mobilizing stations 12, 5, and 8. Our preference is to use the hook for dissection and the ultrasonic scalpel for division of larger vessels. Frequently, a vessel loop around the hepatic artery aids in retraction.

DIVISION OF THE LEFT GASTRIC ARTERY

- Use either the Nathanson liver retractor or a handheld retractor to elevate the stomach and identify the left gastric artery and the celiac trunk.
- Once the celiac anatomy is evident, dissect the left gastric artery and skeletonize its takeoff from the celiac trunk by mobilizing station 9 nodal tissue anteriorly. Once the left gastric pedicle is skeletonized, divide it at its origin using a 2.5-mm Endo GIA cartridge flush with the anterior pancreatic body (**FIG 5**). Our practice is to take the coronary vein and the left gastric together in a single fire.
- Once the left gastric artery is divided, skeletonize the splenic artery thus mobilizing station 11 nodes. Again, vessel loops may aid in retraction of the larger arteries in concert with gentle downward retraction of the pancreatic body. Care must be taken to identify and preserve the splenic vein.

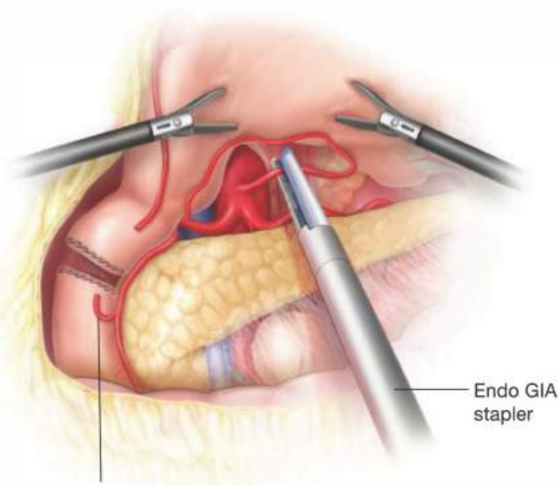

FIG 5 ● Elevating the stomach toward the abdominal wall and to the patient's right helps identification and isolation of the left gastric artery, which is then divided with a vascular stapler. Hepatic and splenic arteries should also be identified prior to firing the stapler.

PROXIMAL DIVISION OF THE STOMACH

- Divide the greater omentum and the gastroepiploic arcade (may use a vascular stapler) at the level chosen on the greater curvature for the proximal resection margin.
- Divide the stomach, taking care to achieve a minimum of 5- to 6-cm margin of normal stomach from the tumor. Our choice is Endo GIA 4.8-mm cartridge with bioabsorbable buttressing.
- The specimen is placed in a 15-mm endo bag and extracted via the 15-mm trocar in the right midclavicular line.
- Oversew any bleeding points with absorbable suture.

RECONSTRUCTION WITH STAPLED ANASTOMOSIS

- Our choice for the reconstruction is a stapled antecolic isoperistaltic gastrojejunostomy.
- Identify the ligament of Treitz at the base of the transverse mesocolon. Proper anatomy is confirmed by visualization of the inferior mesenteric vein.
- Use an umbilical tape cut to 40 cm to identify the jejunal loop to be used for the anastomosis. Make sure that this loop of jejunum can lie next to the gastric pouch without tension. If tension is encountered, the approach should be converted to a retrocolic position. If additional length is required, consider a Roux-en-Y reconstruction and/or mobilization of the intraabdominal esophagus and esophageal hiatus to decrease the anastomotic tension.
- Use stay sutures to secure the jejunum to the lesser curvature of the stomach. The planned line of the gastrojejunal anastomosis should be 2 to 3 cm from distal resection margin to ensure adequate blood supply.
- Use the ultrasonic shears to make a small enterotomy and a small gastrotomy that can accommodate the Endo GIA stapler.
- At this point, you should have an idea regarding the thickness of the stomach. A thicker stomach requires a 4.8-mm stapler; otherwise, use a 3.5-mm cartridge (**FIG 6**).
- Once the stapler is fired, the staple line is inspected for bleeding.
- Close the remaining anastomotic defect which corresponds to the proximal end of the staple anastomosis in two layers using running absorbable suture.

Reconstruction With Hand-Sewn Anastomosis

- Depending on the skill set of the surgeon, a hand-sewn gastrojejunostomy may be accomplished either intracorporeally or through a carefully positioned midline or subcostal small incision. For extracorporeal anastomoses, it is our practice to use a wound protector; this incision can also be used to extract the operative specimen.

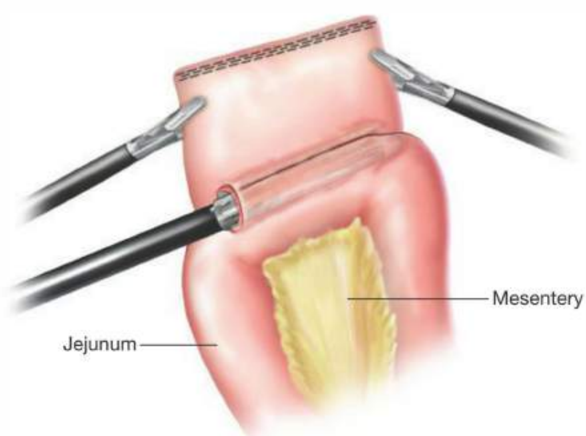

FIG 6 ● A mechanical linear stapler is used for the hepaticojejunostomy. The stapler should be introduced from the afferent limb side. This maneuver minimizes the risk of anastomotic stricture of the efferent limb when closing the anastomotic defect used for introduction of the stapler.

CLOSING

- Complete a final inspection of all staple lines and vascular pedicles for hemostasis and integrity. Bleeding points and areas of malformed staples should be oversewn with absorbable suture.
- Closed suction drainage is optional.
- Abdominal fascia is closed for all port sites larger than 5 mm.

POSTOPERATIVE CARE

- We usually keep a nasogastric tube for 24 hours in order to decrease gastric distension, which may compromise the integrity of the anastomosis. Whether this decreases the leak rate has not been proven.
- Immediately after surgery, the patient is instructed to use an incentive spirometer, cough, and take deep breaths. Also, patients are encouraged to ambulate within 6 hours from surgery.
- Prophylactic antibiotics are not indicated in the postoperative period.
- Unless an epidural catheter is used for analgesia, the Foley catheter is removed in postoperative day 1.
- If the patient is able to protect his or her airway and the abdomen is not distended, clear liquids are allowed on postoperative day 1, then diet is advanced as tolerated.

OUTCOMES

- Available evidence shows no major differences in morbidity, mortality, number of nodes harvested, or disease-free survival.
- MIDG is a safe and effective treatment of gastric cancer.
- The addition of a D2 dissection elevates this operation to much higher difficulty level.
- Oncologic principles and safety are paramount and should not be sacrificed for a less invasive approach.

COMPLICATIONS

- The postoperative complications observed after MIDG generally are comparable with those of an open procedure.
- *Intraoperative*
  - Bleeding
  - Splenic injury
  - Iatrogenic enterotomy
- *Early postoperative*
  - Gastrojejunal anastomotic leak
  - Duodenal leak
  - Bleeding
  - Delayed gastric emptying
- *Late postoperative*
  - Dumping
  - Afferent limb syndrome
  - Marginal ulcer
  - Bile reflux gastritis
  - Malnutrition

Chapter 14

Proximal Gastrectomy

Sushanth Reddy Martin J. Heslin

DEFINITION

- Proximal gastrectomy is defined as a procedure to remove the upper third to one-half of the stomach and the distal portion of the esophagus. This is a procedure to remove cancers or premalignant lesions in the cardia of the stomach, the gastroesophageal (GE) junction, or the distal esophagus. Proximal gastrectomy is usually used in conjunction with systemic chemotherapy and external beam radiation for malignant lesions in this area.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present with difficulty swallowing, dysphagia, upper gastrointestinal (GI) bleeding, or reflux symptoms, especially in the setting of unexplained weight loss. Initial diagnostic evaluation typically includes an esophagogastroduodenoscopy (EGD) with biopsy showing malignancy.
- A thorough history and physical examination should be performed prior to surgery. Particular attention should be paid to cardiac and pulmonary comorbidities and nutritional status. Risk factors for cancer including acid reflux disease, history of Barrett's esophagus, and tobacco use should be identified.
- Patients who have disease in the proximal to midesophagus should not undergo proximal gastrectomy.[1] These patients should be considered for either an Ivor-Lewis (Part 1, Chapter 30) or transhiatal esophagectomy (Part 1, Chapter 29).
- All patients with cancer should undergo staging prior to consideration for surgery.
- Patients with high-grade dysplasia or T1 tumors without lymph node metastases should be considered for surgery first. Patients with advanced tumors (T2 or greater) or those with lymph node involvement should be considered for upfront (neoadjuvant) chemotherapy and radiation therapy.[2,3] Those patients who are nutritionally depleted should have a feeding jejunostomy tube placed prior to initiating therapy.[4]
- Following completion of chemotherapy and radiation therapy, patients should be restaged. The presence of distant metastases is a contraindication for surgery.
- The period of upfront therapy allows for optimization of cardiac and pulmonary comorbidities prior to surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients should undergo staging evaluation prior to surgery. Endoscopic ultrasound (EUS) is used to identify tumor depth (T stage) and regional lymph node metastases (N stage). Computed tomography (CT) scan or positron emission tomography (PET) scan is used to identify distant metastases. The liver is the most common site of distant metastases for adenocarcinoma and squamous cell carcinoma (the two most common tumor histologies).
- Staging should be repeated after the completion of upfront chemotherapy prior to surgery.
- The celiac axis anatomy should be carefully studied prior to surgery to look for anomalies. Specific attention should be paid toward an accessory or replaced left hepatic artery within the gastrohepatic ligament.

SURGICAL MANAGEMENT

Preoperative Planning

- Many patients with gastric or esophageal malignancy have comorbid conditions related to age or tobacco use. These patients should undergo optimization of their comorbidities prior to surgery.
- Anesthesia should consider placement of an arterial monitoring catheter and/or a central venous catheter. During hiatal dissection, the heart may be compressed and invasive monitoring can be useful in guiding resuscitation in the operating room.
- A nasogastric (NG) tube will be placed during the operation. It may not be possible to pass an NG tube prior to removal of the tumor (if it is obstructing). The surgeon should have good communication with anesthesia in regard to NG tube position as it will be manipulated through the operation.

Positioning

- The patient is positioned with both arms at 90 degrees with the torso. This will facilitate with exposure by spreading the lower ribs laterally. Alternatively the right arm can be tucked to the patient's side to aid in attachment of the self-retaining retractor device to the operating room table. If a feeding jejunostomy tube has already been placed, the tube should be prepped into the sterile field.

TECHNIQUES

DIAGNOSTIC LAPAROSCOPY

- The abdomen is entered through the supraumbilical midline and a laparoscope placed (Part 2, Chapter 13). The entire abdomen should be evaluated with specific attention to the liver and the peritoneal surfaces for the presence of metastatic disease. Any suspicious lesions should be biopsied and sent for frozen section analysis in the pathology. The presence of metastatic disease is a contraindication for surgical resection.

MOBILIZATION OF THE STOMACH

- A formal laparotomy is performed and a self-retaining retractor is placed. Excision of the xiphoid process may be used to aid with retraction (this allows for wider retraction of the costal margin).
- The lesser sac is entered along the avascular plane that separates the gastrocolic omentum from the transverse mesocolon. The dissection should proceed away from the greater curve of the stomach to avoid injury to the right gastroepiploic artery. The right gastroepiploic artery will be the primary blood supply of the residual stomach (**FIG 1**). The right gastric artery can be spared to keep the gastric conduit well vascularized. Mobilization of the stomach is usually sufficient for resection and reconstruction for a proximal gastrectomy without the need for ligation of the right gastric artery and a Kocher maneuver to mobilize the duodenum (needed for transhiatal esophagectomy [Part 1, Chapter 29] or Ivor-Lewis esophagectomy [Part 1, Chapter 30]).
- The left lateral section of the liver is mobilized to expose the lesser curve of the stomach and the esophageal hiatus: The left triangular ligament is incised. This is avascular. The falciform ligament may also be incised to aid with visualization of the left triangular ligament (**FIG 2**). The ligament need not be mobilized to its confluence with the falciform to avoid injury to the left hepatic vein. The gastrohepatic ligament is divided. This structure is typically also avascular, but attention should be paid for any accessory or replaced left hepatic artery (**FIG 3**). This will allow exposure of the esophageal crura.
- The gastrosplenic ligament is divided between clamps and ties. The *vasa brevia* are individually dissected and divided between ties. Alternative strategies for division of this structure would include an advanced energy device or an articulating 45-mm stapler with vascular loads.
- The distal esophagus is circumferentially freed using a combination of sharp and blunt dissection. A Penrose drain is placed around the esophagus to aid with retraction (**FIG 4**). The Penrose drain can be used to retract the esophagus to expose the diaphragmatic hiatus and aid with lower mediastinal dissection. The hiatal attachments of the esophagus are taken down with an advanced energy device. The hiatus should be opened to facilitate dissection of the esophagus. During this dissection, it may be necessary to put pressure on the heart to free the mediastinal attachments of the esophagus. The proximal extent of the tumor and the length of the intraabdominal esophagus will dictate the amount of mediastinal dissection necessary.
- With the stomach reflected anteriorly, the left gastric vessels are ligated (**FIG 5**). Prior to ligation, the left gastric artery is test clamped to make sure that flow remains in both the common hepatic artery and the splenic artery. The left gastric artery is ligated at its root off the celiac trunk to facilitate appropriate lymphadenectomy.

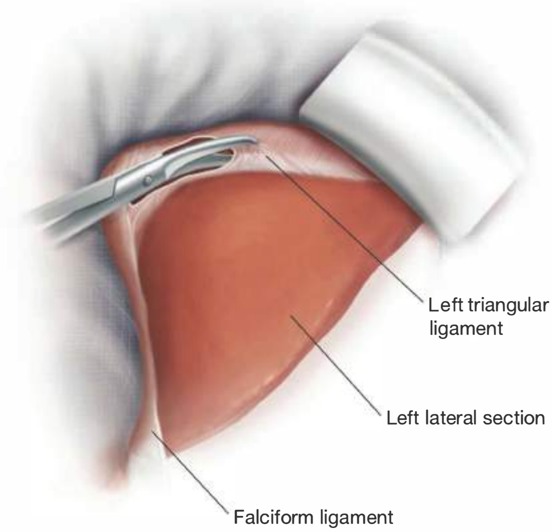

FIG 2 ● The left lobe of the liver is mobilized. The falciform ligament has already been divided and the left triangular ligament is being incised. Both of these structures are avascular. The falciform ligament should be divided near the liver. As dissection proceeds cephalad, the falciform will divide into the right and left triangular ligaments when dissection is closer to the liver. If dissection is closer to the abdominal wall, division of the falciform will lead into the hepatic venous confluence. Injury to one of these vessels can lead to catastrophic blood loss.

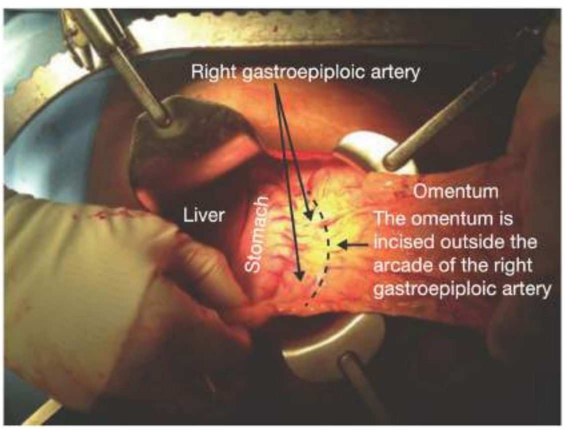

FIG 1 ● The greater curve of the stomach is mobilized. Care is taken to stay outside the right gastroepiploic artery as this is the vascular pedicle of the gastric conduit. This portion of the gastrocolic omentum is typically avascular, although small blood vessels may be encountered requiring ligation. The vasa brevia should be ligated as dissection proceeds cephalad.

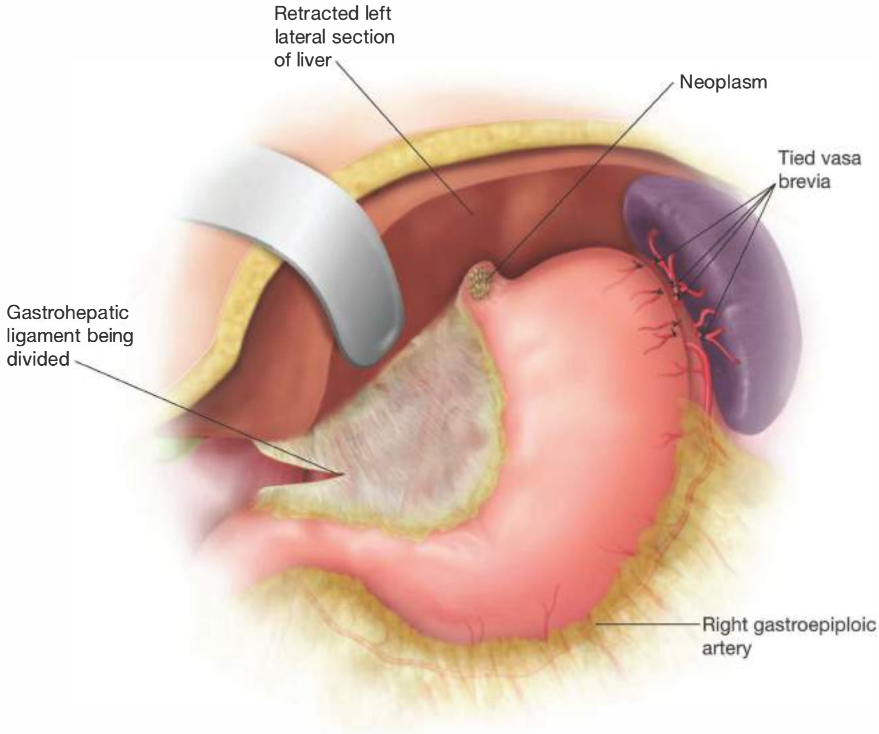

FIG 3 ● The lesser curve of the stomach is mobilized. By mobilizing the left lobe of the liver, the left lateral section can be retracted to expose the gastrohepatic ligament. This is also typically avascular. Attention should be given in case there is an accessory or replaced left hepatic artery. This can usually be seen on preoperative contrast CT scans. By opening the gastrohepatic ligament, the diaphragmatic crura can be visualized.

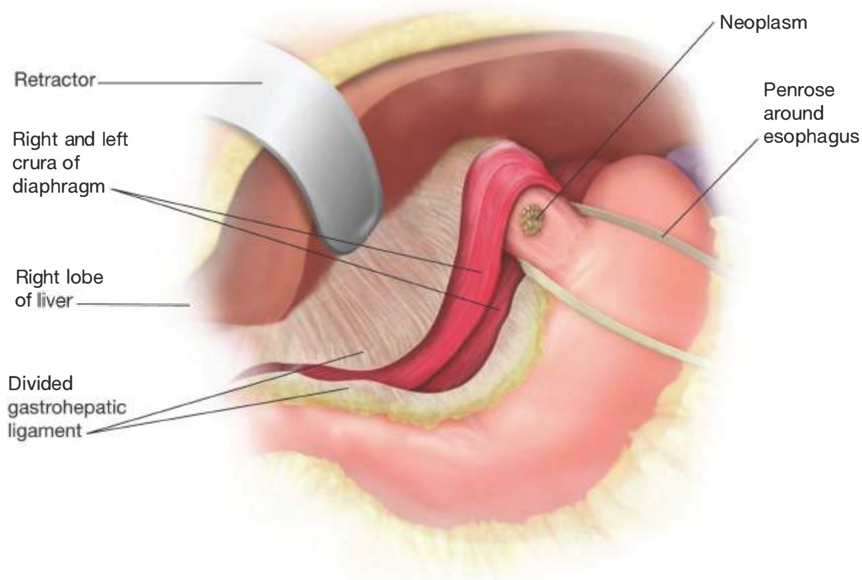

FIG 4 ● The distal esophagus and GE junction are dissected. Once the stomach's greater and lesser curve have been mobilized, this dissection can be performed bluntly. In patients who have undergone preoperative radiation therapy, scarring in this region can make dissection difficult. A Penrose drain is placed around the esophagus. This drain allows the esophagus to be manipulated in all directions to aid with transhiatal dissection. A sufficient length of esophagus should be mobilized into the abdomen so that the proximal esophageal margin is grossly clear from the tumor. A high-energy device can be used to aid with distal esophageal mobilization (minimizing blood loss seen with blunt or cautery dissection).

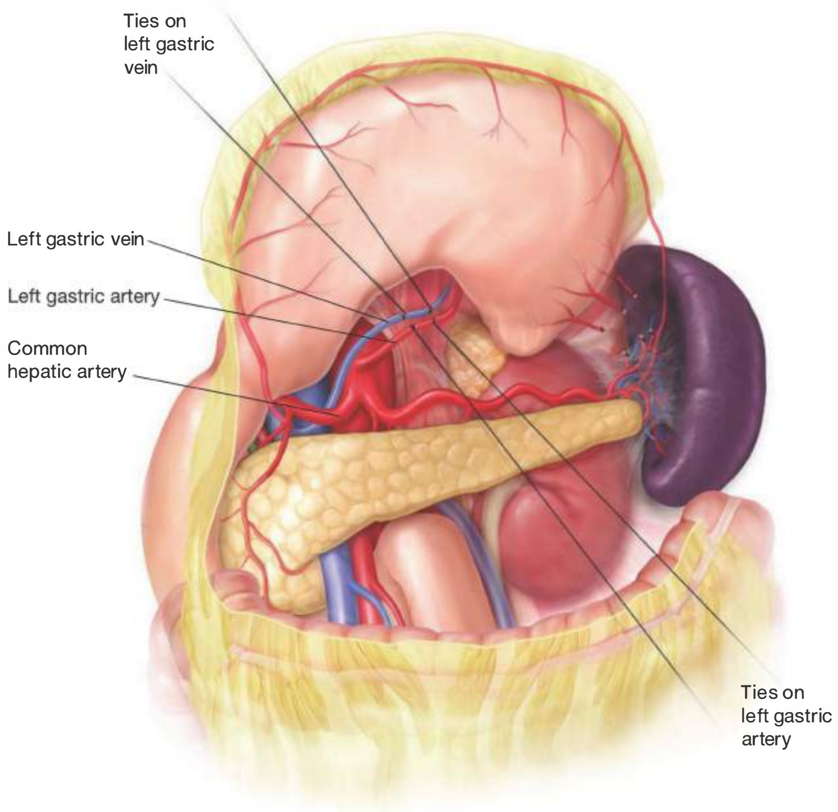

FIG 5 ● The left gastric pedicle is divided. The stomach should be reflected to expose the lesser sac. This will facilitate exposure of the left gastric artery near its origin at the celiac axis. This structure should be test clamped prior to ligation (pulses should be assessed in both the common hepatic and splenic arteries). Ligation of the left gastric artery near its origin will facilitate with lymphadenectomy (for patients with malignancy).

GASTROESOPHAGEAL RESECTION AND RECONSTRUCTION

- Using the NG tube as a guide, place two purse-string sutures in the esophagus proximal to the neoplasm (**FIG 6**). These will be an alternating horizontal mattress to ensure complete donuts after stapling. Do not allow the sutures to go through the NG tube.
- Anesthesia should retract the NG tube into the esophagus. Partially divide the esophagus with electrocautery below the purse-string sutures and above the neoplasm. The posterior wall of the esophagus and the purse-string sutures are used to keep the proximal esophagus in an intraabdominal position. The anvil of a circular linear stapling device is placed in the esophagus and the purse-string sutures are tied. The division of the esophagus is completed. The GE junction can now be delivered extracorporally. A proximal surgical margin is sent for frozen section analysis. Typically, a 25-mm circular stapler will be sufficient for reconstruction.
- Multiple firings of the gastrointestinal anastomosis (GIA) linear stapler are used to both resect the proximal stomach while tubularizing the remaining stomach for the reconstruction. The first staple load is deployed perpendicular to the greater curvature of the stomach. The stapler is fired sequentially toward the lesser curve, creating a gastric tube (**FIG 7**). The stomach should not be completely transected.
- A gastrotomy is created along the lesser curve to allow placement of the handle of a circular stapling device. This gastrotomy should be positioned so that it will be resected as part with additional firings of the GIA linear stapler to completely transect the proximal stomach. The stapler is attached to its anvil in the proximal esophagus and fired (**FIG 8**). The anastomotic donuts are examined to ensure that two intact rings are present. The esophagogastrectomy is completed with additional firings of the GIA stapler to excise the gastrotomy site, the proximal stomach, the tumor, and the distal esophagus. Tension from the proximal esophagus will usually retract the anastomosis into the thorax. A closed suction drain should be placed at the anastomosis. The NG tube should be advanced into the stomach.

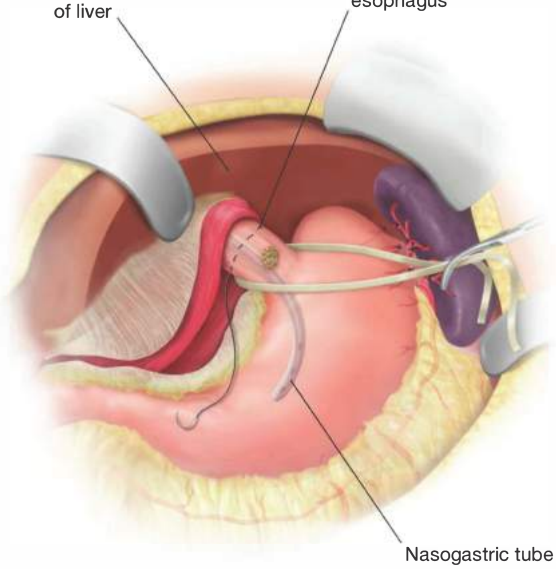

FIG 6 ● The resection margins are planned. The proximal resection margin can be grossly approximated based on the tumor's location. Two purse-string sutures are placed on the esophagus just above the planned proximal margin. The NG tube can be used as a guide to ensure the sutures are transmural (as the needle meets resistance from the NG tube, it should be rotated away from the tube). The suture should not pass through the NG tube. After the sutures are placed, the NG tube should be retracted into the esophagus above the sutures. The anterior wall of the esophagus is then transected, and the anvil of a 25-mm circular stapler is placed into the esophagus. The sutures are tied to keep the anvil in place. The posterior wall of the esophagus is then divided. The distal esophagus and stomach can now be delivered extracorporally. An esophageal margin should be sent for frozen section to ensure negative resection margins (this can be taken from the distal esophagus above the tumor).

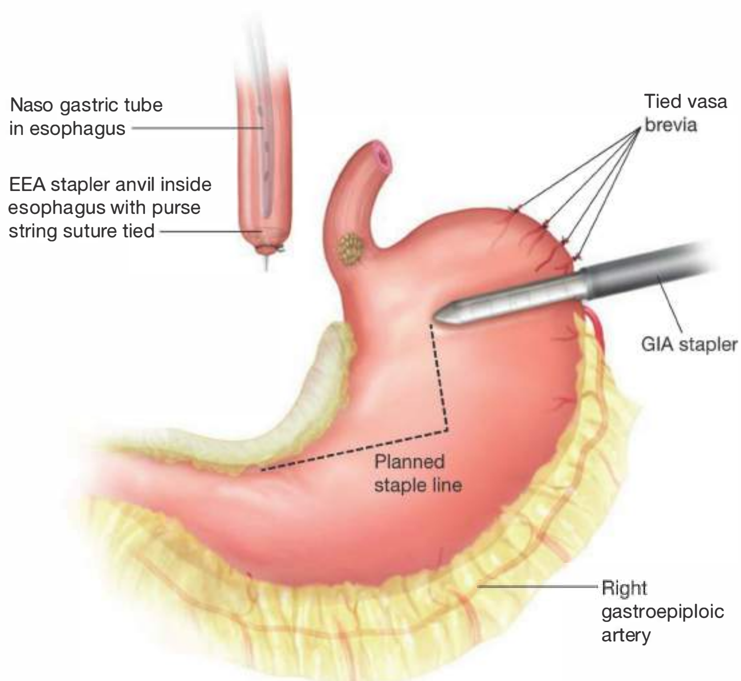

FIG 7 ● A GIA stapler is then used to begin gastric transection. The first staple load should be horizontally across the stomach just below the vasa brevia (to a portion of the stomach with vascular supply from the right gastroepiploic artery). Subsequent staple loads should be fired in a manner to create a gastric tube for the esophagogastrostomy anastomosis.

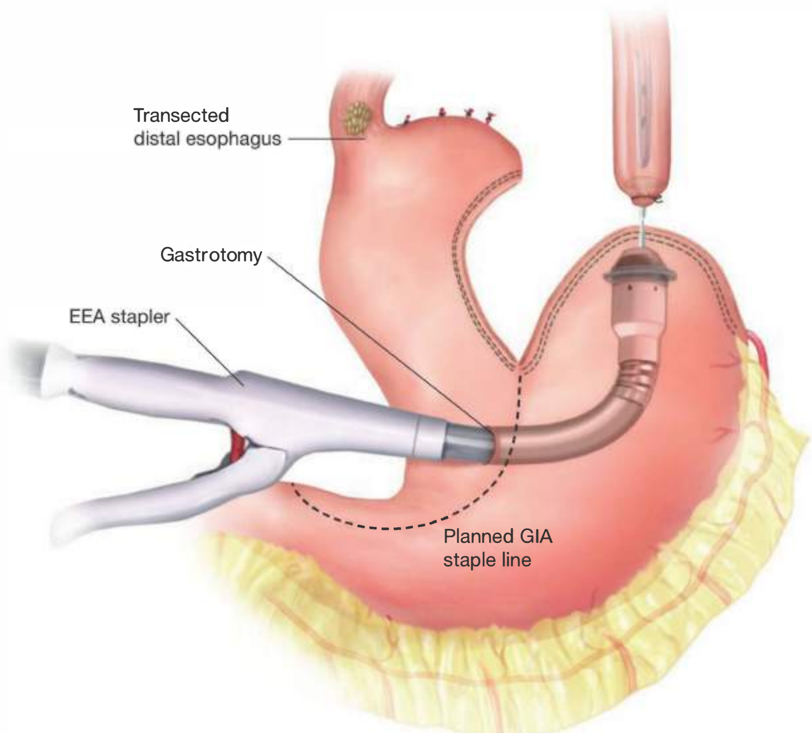

FIG 8 ● Prior to completing the gastric resection, a gastrotomy is made in the lesser curve in a portion of the stomach that will be transected with the GIA stapler. The handle of the circular stapler is inserted to create an end-to-side esophagogastrostomy. The handle is opened so that it can dock with the anvil in the proximal esophagus. This stapler is fired to create an end-to-side esophagogastric anastomosis. The stapler is removed and the anastomotic donuts are retrieved. Both donuts should be intact. After removing the circular stapler, additional firings of the GIA stapler are used to complete the gastric transection along the lesser curve. The NG tube is then advanced into the gastric conduit and secured at the nose. A closed suction drain is left in proximity of the anastomosis.

PYLOROMYECTOMY

- The pylorus is identified by palpation and the presence of the vein of Mayo. Stay sutures are placed at the 12 o'clock and 6 o'clock positions. The pylorus muscle is opened sharply and a piece of the muscle is removed with a 15 blade knife to the level of the mucosa without entering the GI tract.
- The pyloromyectomy is closed transversely with interrupted sutures (**FIG 9**).
- If the mucosa is opened inadvertently, a Heineke-Mikulicz–type pyloroplasty is performed instead (Part 2, Chapter 9). A drain should be left in Morrison's space (hepatorenal recess).[5]

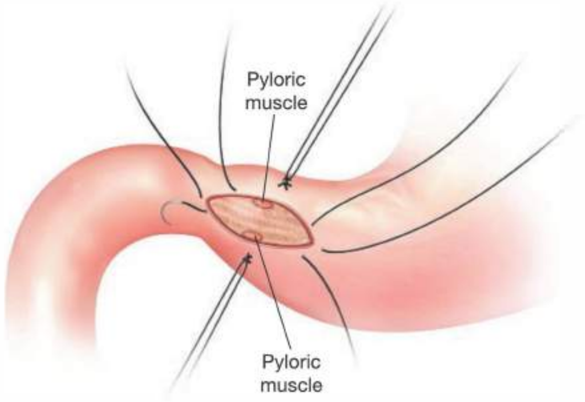

FIG 9 ● A pyloromyectomy is performed. First, stay sutures are placed at the 6 o'clock and 12 o'clock positions (to ligate the vein of Mayo). The serosa and submucosa of the pylorus are incised with a knife. The mucosa should not be entered. In most patients, the pyloric muscle can be visible after sharp transection. The pyloromyectomy should be closed transversely with interrupted sutures. If the mucosa is opened, a Heineke-Mikulicz pyloroplasty should be performed. A closed suction drain should be placed.

FEEDING JEJUNOSTOMY

- If a jejunal feeding tube has not already been placed, one should be created at this time (Part 2, Chapter 17).[4]

PEARLS AND PITFALLS

Workup	■ The nutritional status of the patients should be assessed prior to proximal gastrectomy with strong consideration of a feeding jejunostomy tube prior to attempting proximal gastrectomy. ■ Careful preoperative and intraoperative staging should take place to assure that there is no distant metastatic disease. ■ Patients with comorbid conditions should undergo optimization of their cardiopulmonary status prior to proximal gastrectomy.
Mobilization	■ Care should be taken to avoid injury to the right gastroepiploic artery when entering the lesser sac through the gastrocolic omentum. ■ While mobilizing the lesser curve of the stomach, attention should be paid for a replaced left hepatic artery. ■ The left gastric artery should be test clamped prior to ligation in case there is a celiac axis anomaly.
Postoperative care	■ The NG tube should not be manipulated or replaced blindly. ■ Most postoperative leaks can be managed with drainage alone. ■ Many patients will have symptoms of reflux requiring prolonged use of proton pump inhibitors.
Nutrition	■ The feeding jejunostomy tube should be left in place until the patient can demonstrate adequate oral intake to maintain nourishment—especially if the patient will undergo adjuvant therapy. ■ If the patient does not have a feeding jejunostomy placed prior to operation, there should be one placed in all cases of a proximal gastrectomy because leaks and delayed gastric emptying are two major complications.

POSTOPERATIVE CARE

- Most patients have medical comorbidities related to advanced age and tobacco use. Intensive care unit (ICU) care with special attention to aspiration precautions should be considered for the immediate postoperative period.
- The NG tube should remain in place until a contrast esophagogastrogram is performed. If the NG tube is inadvertently removed, it should not be blindly replaced.
- On postoperative days 4 to 5, the anastomosis should be studied with a contrast esophagogastrogram. A water-soluble contrast agent should be used initially followed by barium to evaluate for anastomotic leaks. After a successful swallow study, the patient may begin oral nutrition.
- The operative drain should be removed only after the patient starts an oral diet without clinical evidence of an anastomotic leak.

- The feeding jejunostomy tube should be left in place to supplement nutrition until the patient reliably demonstrates adequate oral intake to maintain nourishment.[4]

OUTCOMES

- Reflux esophagitis and anastomotic strictures are present in up to 40% of patients undergoing proximal gastrectomy.[6]
- The overall survival for patients undergoing proximal gastrectomy is similar to other gastric resections and is heavily dependent on tumor stage (5-year survivorship: stage I, 75% to 90%; stage II, 49%; stage III, 13% to 33%; stage IV, 11%).[7]

COMPLICATIONS

- If there is a small leak identified after the swallow study, replacement of an NG tube should almost never be considered. Keeping the patient NPO with enteral nutrition solves the majority of these leaks. Additional CT- or ultrasound-guided percutaneous drains should be considered if the surgical drain does not adequately drain the leak. A contrast esophagogastrogram should be repeated prior to initiating oral nutrition. An endoscopically placed covered stent may facilitate closure of a leak.
- If a large leak is identified on the initial contrast study, consider early reoperative intervention. Options can include wide drainage or conversion to an Ivor-Lewis or transhiatal esophagectomy. However, the majority of the time, simply widely draining the region and controlling abdominal sepsis is the primary focus of early reoperative surgery for leaks.

Chapter **15**

Total Gastrectomy for Cancer

Vikas Dudeja Eugene A. Choi Waddah B. Al-Refaie

DEFINITION

- Total gastrectomy is removal of the stomach in its entirety including the gastroesophageal (GE) junction. This is typically performed for patients with proximal gastric cancer, including Siewert type II and III GE junction cancers,[1] in whom a subtotal gastrectomy with 5- to 6-cm proximal margin does not leave a reasonable gastric remnant. Rarely, diffuse involvement of stomach with malignant processes other than gastric adenocarcinoma may warrant a total gastrectomy. Even though proximal gastric resection is widely performed in Asia and select U.S. cancer centers for proximal gastric tumors, this procedure has not gained wide adoption in western centers.[2]

PATIENT HISTORY AND PHYSICAL FINDINGS

- **Presentation:** In the United States, most patients with gastric cancer are diagnosed at advanced stages. Weight loss, anorexia, dyspepsia, progressive dysphagia, and early satiety are the most common symptoms. Unfortunately, some of these symptoms (dyspepsia, nausea, anorexia) overlap with those of benign reflux disease and explain the late presentation of proximal gastric cancers in the United States. Poor oral intake because of cancer-induced anorexia and dysphagia contributes to patients' weight loss. As such, patients with more than 10% weight loss are at increased risk of perioperative complications. Thus, quantification of weight loss in the preoperative period provides a meaningful estimate of nutritional status and helps in pretherapy planning in terms of preoperative nutrition. Patients may also present with iron deficiency anemia due to occult blood loss.
- Evaluation of the performance status and frailty is important for the formulation of a treatment plan. Eastern Cooperative Oncology Group's (ECOG) performance status scale provides a standardized method to assess and compare performance status of the patient.[3] Patients with ECOG performance score of 0 to 1 are generally able to tolerate major oncologic resections. Those with a score of 2 may require individualized decision making, factoring comorbidities into the overall treatment plan. Patients with a score of 3 and above are unable to tolerate any major oncologic resection. Attention to pretherapy performance status and frailty are critical, as these two important yet underassessed parameters correlate well with the ability to tolerate various oncologic therapies, including major oncologic resection and systemic therapy.
- **Physical findings:** In early stages, the physical examination is essentially normal. However, surgeons need to look for signs of malnutrition. Patients with advanced-stage gastric cancer may present with supraclavicular lymphadenopathy, pleural effusion, abdominal mass, hepatomegaly, malignant ascites, or drop metastases in the form of "Blumer's shelf" appreciated on rectal examination. Presences of any of these physical findings suggest unresectability.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- **Laboratory tests:** Baseline hemoglobin, platelet count, and complete metabolic profile should be obtained. Serum albumin and prealbumin are useful to guide assessment of nutritional status.
- **Diagnostic studies and staging evaluation:** The evaluation of any upper gastrointestinal symptomatology starts with an esophagogastroduodenoscopy (EGD), especially if gastric cancer is suspected. Endoscopy provides histopathologic diagnosis as well as gives information on location and extent of gastric tumor, GE junction involvement, presence of linitis plastica, and status of duodenal bulb (**FIG 1A,B**). Endoscopic

FIG 1 ● Endoscopy and EUS are critical for the diagnosis and staging of gastric cancer. **A.** Endoscopic findings in a 68-year-old male who presented with iron deficiency anemia and anorexia. An ulcerated adenocarcinoma of the proximal third of the stomach was discovered. Patient underwent R0 total gastrectomy with lymphadenectomy, and the final pathology report showed pT2 N0 (0/23) M0 disease. **B.** A retroflexed endoscopic view of T2 gastric adenocarcinoma in gastric fundus. **C.** EUS helps with accurate preoperative T staging of the lesion.

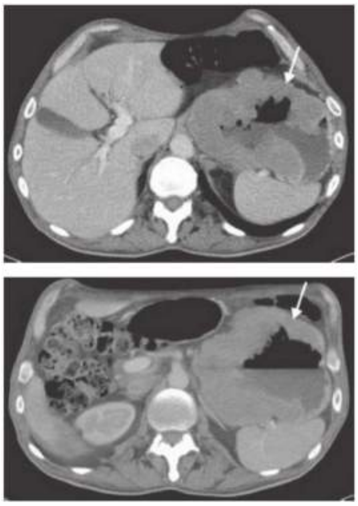

FIG 2 ● Cross-sectional imaging with CT or MRI evaluates for distant metastatic disease and bulky adenopathy. Abdominal CT scan in a patient with known high-grade neuroendocrine tumor. No liver metastases were noted. Note diffuse nodular heterogeneous thickening of the stomach *(white arrow)*.

ultrasound (EUS), performed at the time of or subsequent to diagnostic endoscopy, provides the most accurate estimation of the tumor depth (T stage) (**FIG 1C**) and can help in evaluation and needle biopsy of surrounding lymph nodes.[4] Furthermore, EUS provides information on the degree of distal esophageal involvement.

- Cross-sectional imaging of abdomen and pelvis, in the form of a computed tomography (CT) scan (**FIG 2**) with oral and intravenous (IV) contrast or magnetic resonance imaging (MRI), evaluates for presence of distant metastatic disease to the liver and bulky lymphadenopathy. Metastases to lungs should be evaluated by CT scan of the chest. The presence of bulky adenopathy has a prognostic value. However, it should not preclude resection unless patient presents with diffuse adenopathy involving the periportal area or mesenteric vessels. Positron emission tomography (PET)/CT scan has evolved as an additional radiographic staging modality to exclude the presence of distant metastatic disease (**FIG 3**).
- **Staging laparoscopy:** Peritoneal spread is part of the natural history of gastric cancer. Up to a third of the patients who have localized disease on staging evaluation have unsuspected hepatic and/or peritoneal disease.[5] Thus, staging laparoscopy can prevent a nontherapeutic laparotomy in the setting of M1 disease. The timing of staging laparoscopy may depend on the institutional preference with respect to neoadjuvant versus adjuvant therapy. We recommend neoadjuvant chemotherapy for patients with proximal gastric tumors and perform staging laparoscopy (with peritoneal cytology) before initiation of neoadjuvant therapy. We selectively place feeding jejunostomy during staging laparoscopy, especially in persons who are old, frail, have suboptimal performance status, or present with malnutrition. The patient then returns after completion of neoadjuvant chemotherapy for restaging and definitive surgical treatment (i.e., gastrectomy).
- **Peritoneal cytology:** The addition of peritoneal washing for cytology is an area of debate.[6,7] We use this diagnostic modality in patients at risk of undeclared metastatic disease or suboptimal performance status, as patients with positive peritoneal cytology have unfavorable overall prognosis compared to those with negative peritoneal cytology.

SURGICAL MANAGEMENT

- A complete margin-negative resection with an adequate lymphadenectomy is the most critical component of therapy for operable gastric cancer.

Preoperative Planning

- **Addressing preoperative malnutrition:** Patients with proximal gastric cancer are at an increased risk of being nutritionally compromised due to cancer-induced anorexia and dysphagia. These patients benefit from preoperative enteral nutrition through a jejunostomy tube placed preoperatively during the staging laparoscopy. The enteral nutrition through jejunostomy tube also helps with hydration and nutrition during neoadjuvant therapy. A consultation with a dietitian with regard to nutritional optimization is recommended.
- **Evaluation of the patient's ability to tolerate the surgery:** A careful review and optimization of underlying comorbidities (e.g., cardiac, pulmonary, diabetes) and perfor-

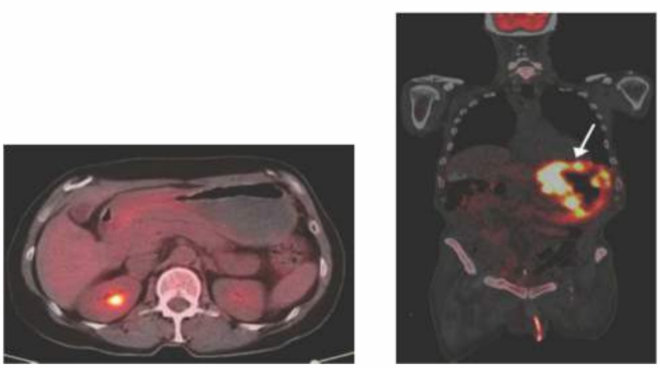

FIG 3 ● PET scan may help in the evaluation of disease spread. PET scan in a patient with known high-grade neuroendocrine tumor demonstrates hypermetabolic activity *(white arrow)* in the stomach but no other organ. This patient required total gastrectomy for complete disease clearance.

mance status should be considered in conjunction with other supporting specialties. A subset of high-risk individuals may benefit from preoperative admission to optimize nutrition, electrolyte imbalance, and performance status (e.g., physical therapy) in preparation for their oncologic resection.

- **Evaluation of response to neoadjuvant therapy:** At times, when neoadjuvant therapy is employed to increase rates of R0 resection or spare the GE junction, a repeat posttherapy preoperative EGD provides additional information on tumor response and the proximal extent of the tumor.
- **Preoperative antibiotics:** Patients should be given one dose of first- or second-generation cephalosporin for perioperative antibiotic prophylaxis.

Positioning

- In most patients, an upper midline incision provides optimal exposure for the procedure. The chest should be prepped into the operative field for the possibility of needing a thoracotomy for GE junction tumors. A sandbag can be placed under the left chest to facilitate thoracotomy.

STAGING LAPAROSCOPY

- Pneumoperitoneum is created by either an open technique or verse needle. A 30-degree scope is inserted at the umbilicus. One to two additional 5-mm ports on either side of the umbilicus are needed for optimal visualization, grasping of tissue, and biopsy of suspicious tissues. A complete survey of the peritoneal cavity is performed, including undersurface of the diaphragm, liver surface, spleen, lining of peritoneal cavity, pelvis, small bowel surface, and omentum for any metastatic disease. If any suspicious lesion is observed, it is biopsied and sent for frozen section. In the setting of biopsy-proven peritoneal disease, gastrectomy should not be performed and nonsurgical treatments should be initiated. However, at times, surgeons are faced with a situation to carefully and selectively consider palliative surgical procedures in the setting of metastatic disease, for example, bleeding or obstructing cancer not palliated by endoscopic means. These decisions need to be individualized based on the performance status of the patient, extent of metastatic burden, the projected survival, and the availability of adjunctive therapy such as endoluminal stenting.
- **Peritoneal cytology:** If the staging laparoscopy is negative for peritoneal spread, the procedure is continued. We perform peritoneal cytology in the patients who do not have gross peritoneal metastasis. For peritoneal cytology, 500 mL of normal saline is instilled into the abdominal cavity and allowed to dwell for 10 to 15 minutes. During this time, the patient's table is moved from left to right to expose the peritoneum to this fluid. After 10 to 15 minutes, the fluid is aspirated with a suction device, which has a mechanism to trap the fluid. The fluid is then sent to the pathology lab, and in those with positive peritoneal cytology, we favor not proceeding with resection.
- When a laparoscopic feeding jejunostomy is to be placed, it is imperative that the surgeon performing the staging laparoscopy and jejunostomy tube placement is cognizant of the need to construct a Roux limb for the restoration of gastrointestinal continuity at the time of definitive surgery. Thus, the loop of jejunum just distal to the ligament of Treitz, which would be used for fashioning the Roux limb, should not be used for the placement of jejunostomy tube.

EXPLORATORY LAPAROTOMY AND MOBILIZATION OF THE LIVER

- The abdomen is entered through a midline incision extending from the xiphoid process to just below the umbilicus. A bilateral subcostal incision, approximately 2 cm below the costal margin, also provides good exposure. During entry into the abdomen, the falciform ligament should be preserved as it can be used to buttress the duodenal closure. A careful exploration of the peritoneal cavity is performed to exclude the presence of subradiographic peritoneal or distant metastatic disease. The liver is carefully inspected and palpated for any suspicious nodules.
- For better access and visualization of the GE junction, we typically divide the left triangular ligament thus mobilizing the left lobe of the liver. Once mobilized, the left lobe of the liver can be folded on itself thus allowing better visualization of the GE junction and the right crus of the diaphragm.

MOBILIZATION OF THE GREATER CURVATURE OF THE STOMACH

- In this step, the attachments of the greater omentum to the transverse colon are divided in an avascular plane. The stomach and the greater omentum are reflected superiorly and the transverse colon is reflected inferiorly. The plane of fusion between the greater omentum and the transverse mesocolon is identified as a faint white line. This plane is entered by incising with electrocautery and, once properly developed, allows access to the lesser sac (**FIG 4**). This plane of separation is then developed toward both proximal and distal parts of the transverse colon thus completely separating the greater omentum from the transverse colon and mobilizing it with the specimen.

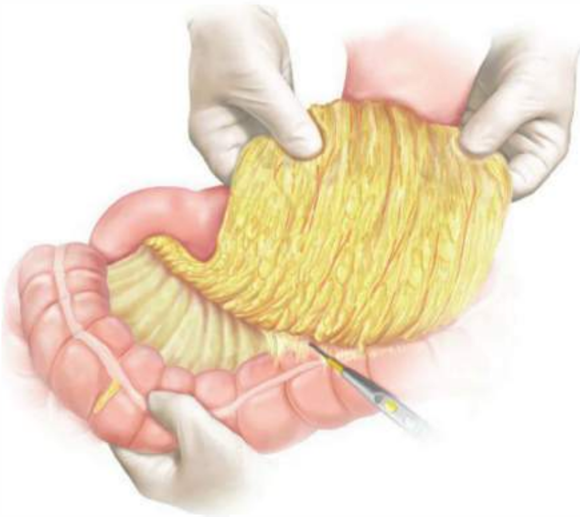

FIG 4 ● Division of attachments of greater omentum to the transverse colon. Incision of avascular fusion plane of greater omentum with the transverse colon/mesocolon separates greater omentum from the transverse colon and provides access to lesser sac.

FIG 6 ● Dissection of the infrapyloric nodal packet at the level of right gastroepiploic vessels.

- The hepatic flexure of the colon is mobilized by division of the avascular attachment of the hepatic flexure to the retroperitoneum. The separation of the greater omentum from the transverse mesocolon is carried toward the hepatic flexure. This exposes the gastrocolic trunk, which is formed by the confluence of right gastroepiploic vein with middle colic vein and drains into the superior mesenteric vein. The right gastroepiploic vein is divided at its junction with the gastrocolic trunk (FIG 5). Alternatively, the gastrocolic trunk can be divided with a single fire of a vascular stapler. At this stage, the right gastroepiploic artery is divided at its origin from the gastroduodenal artery at the infraduodenal level. We recommend additional time spent when performing this dissection in obese patients given the potential difficulty in identifying this artery. Infrapyloric nodes, located adjacent at the origin of gastroduodenal artery, are mobilized with the specimen (FIG 6).
- Toward the left, the greater curvature of the stomach is mobilized up to the GE junction by division of the short gastric vessels. These vessels are divided carefully to avoid troublesome bleeding or iatrogenic splenic injury that may lead to splenectomy (FIG 7).

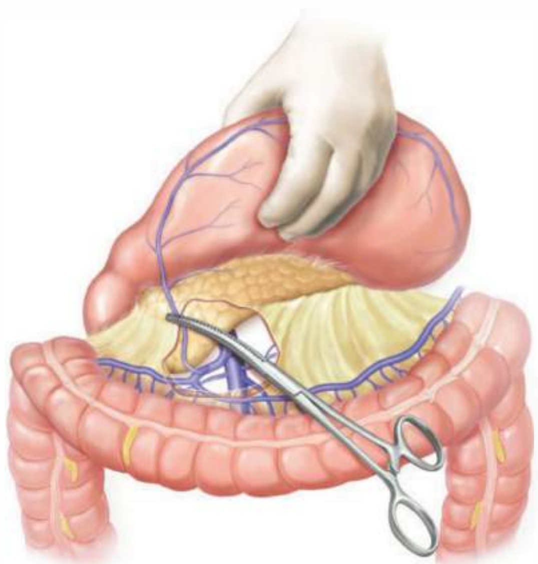

FIG 5 ● Ligation of right gastroepiploic vein at its confluence with colonic veins. Alternatively, the gastrocolic trunk can be divided with the single fire of a vascular stapler.

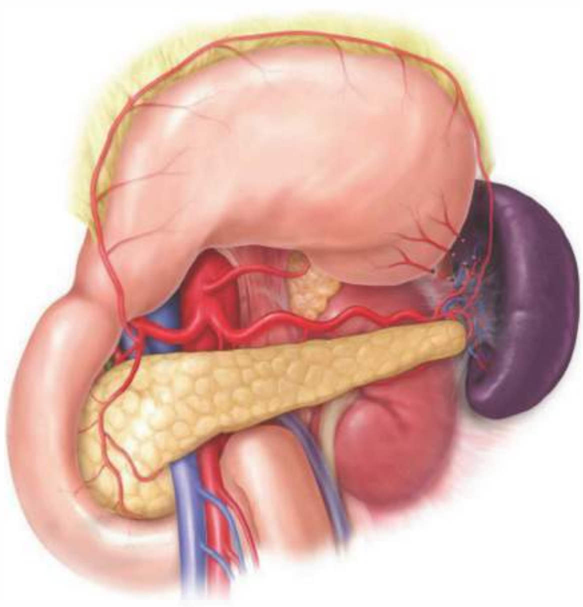

FIG 7 ● Division of short gastric arteries. Short gastric arteries are divided between ligatures or using energy devices. Care is taken to avoid iatrogenic splenic injury.

MOBILIZATION OF THE LESSER CURVATURE OF THE STOMACH

- Now, the lesser curvature is mobilized by dividing the lesser omentum as close to the liver as possible (**FIG 8**). Care is taken to identify the presence of a replaced or accessory left hepatic artery. This dissection is carried toward the portal triad. The right gastric artery arising from the common hepatic artery is divided carefully, mobilizing the lymphatic tissue toward the specimen. At this point, duodenum is circumferentially dissected about 2 to 3 cm distal to the pylorus, encircled with a Penrose drain and divided with a stapler (**FIG 9**). Care is taken not to injure the bile duct, hepatic artery, and portal vein while encircling the duodenum. The stapled duodenal line could be oversewn with 3-0 silk Lambert sutures and buttressed with a healthy piece of falciform ligament (Moossa's patch). However, in the setting of extensive inflammation around the periduodenal area (e.g., in the setting of chronic scarring due to duodenal ulcer), consideration should be given to dividing the duodenal stump in between two straight bowel clamps and suture closure of the duodenal stump.
- Next, the gastrectomy specimen, which is disconnected distally, and the right gastric and right gastroepiploic vessels have been divided, is lifted upward. The left gastric artery is identified, suture ligated, and divided at its origin (**FIG 10**). The lymph–areolar tissue with the left gastric artery is mobilized with the specimen.

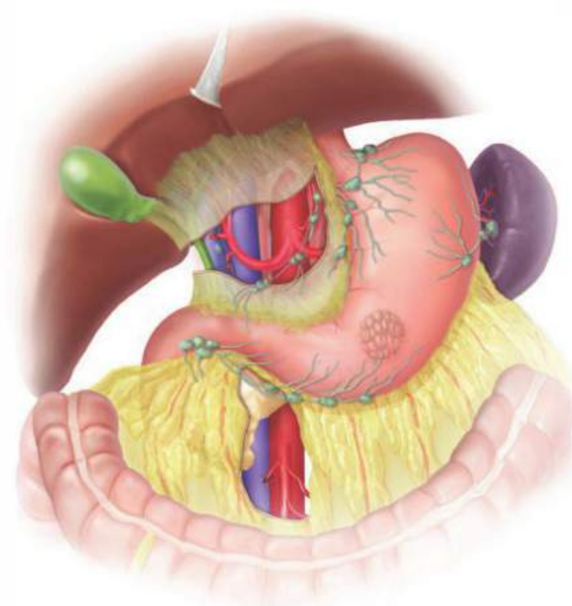

FIG 8 ● Division of lesser omentum. Lesser omentum is divided as close to the liver as possible. Presence of a replaced or accessory left hepatic artery arising from the left gastric artery is carefully sought for.

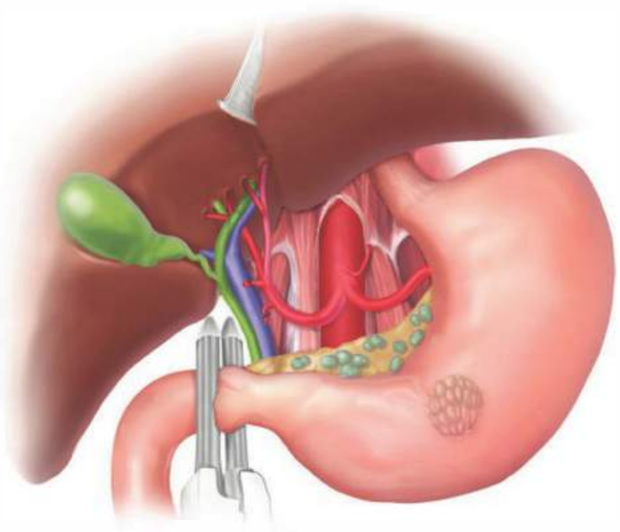

FIG 9 ● Division of the duodenum. Duodenum is circumferentially dissected, encircled with a Penrose, and divided with GIA stapler blue or green load.

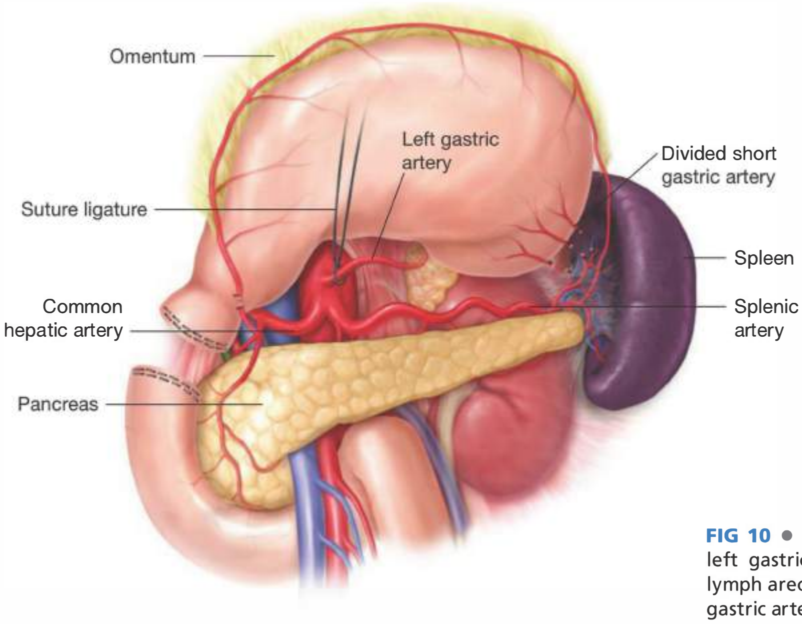

FIG 10 ● Division of the left gastric artery. The left gastric artery is divided at its origin. The lymph areolar tissue around the origin of the left gastric artery is mobilized with the specimen.

ESOPHAGEAL TRANSECTION

- After the division of the left gastric pedicle, the dissection continues upward, along the lesser curvature and the ascending branch of the left gastric artery. The peritoneum anterior to the GE junction is divided. The lymphoareolar tissue along and anterior to the upper part of the lesser curvature and the right aspect of abdominal esophagus is mobilized to the left with the specimen. At this point, the gastrectomy specimen is only anchored at the esophagus. Enough intrathoracic esophagus should be freed so that a proximal margin of 4 to 5 cm from the tumor can be obtained and an anastomosis can be fashioned without tension. At an appropriate point, the esophagus is divided between noncrushing clamps (**FIG 11**). We do not preserve the vagus nerve and both anterior and posterior vagi are divided with the esophagus. This allows for additional mobilization of the distal esophagus into the abdomen.

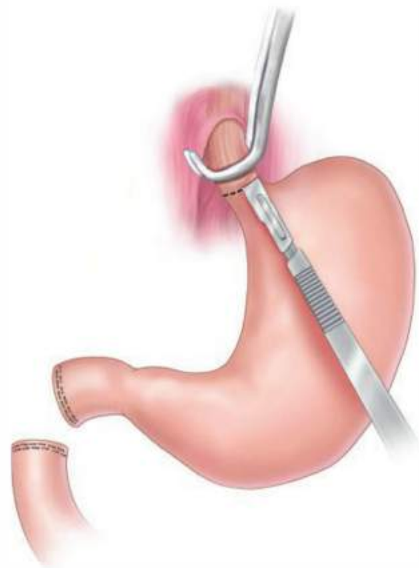

FIG 11 ● Division of esophagus. Esophagus is divided at least 5 cm proximal to the most proximal extent of the gastric tumor.

SPECIMEN PROCESSING

- The operating surgeon is encouraged to hand carry the specimen to the pathologist to orient him/her with the details of the resection and to perform frozen section assessments of the proximal and distal margins. We typically send the resected specimen in separate containers in the following manner: (1) stomach with a marking stitch on proximal end, (2) greater omentum, (3) infrapyloric nodal packet, and (4) lesser curvature nodal packet with a long stitch on the left gastric artery.
- Once the frozen section of the proximal margin comes back negative for malignancy, we proceed with restoration of intestinal continuity.

LYMPHADENECTOMY

- The extent of lymphadenectomy in patients with operable gastric cancer is an area of controversy. Western trials[8,9] did not demonstrate the same survival advantage of D2 lymphadenectomy over D1 lymphadenectomy as demonstrated in eastern gastric cancer surgery trials. However, it has been suggested that the excess mortality in the D2 lymphadenectomy arm in the Dutch gastric cancer trial[8] and the Medical Research Council Trial[9] was due to the distal pancreatectomy and splenectomy. Thus, at this time, we typically perform a pancreas–spleen-preserving D1 lymphadenectomy; that is, taking the right gastric, right gastroepiploic artery, and left gastric arteries at their origin. We acknowledge that the addition of a celiac axis dissection is an area of controversy.

RESTORATION OF INTESTINAL CONTINUITY

- After total gastrectomy, the intestinal continuity is restored by Roux-en-Y esophagojejunostomy. The length of the Roux limb from the esophagojejunal anastomosis to jejunojejunal anastomosis should be 40 to 60 cm to avoid biliary reflux esophagitis.
- **Construction of the Roux limb:** While the pathology team is performing their frozen section on the gastric margin, we simultaneously proceed with the reconstruction. A loop of jejunum distal to the ligament of Treitz that will reach the transected esophagus without any tension is identified. Jejunum at this point is divided with a blue gastrointestinal anastomosis (GIA) stapler. The staple line on the end of the Roux limb is oversewn with 3-0 silk stitches in Lambert fashion. The Roux limb needs to be at least 40 cm (i.e., from its beginning at the level of anastomosis with esophagus to the jejunojejunostomy). A defect is created in the transverse mesocolon to the left of the middle colic vessels (**FIG 12**). We then test that the Roux limb can easily reach the esophagus in retrocolic manner without tension. Our preference is to first perform the stapled side-to-side anastomosis between the biliopancreatic limb and the jejunum. Our rationale behind this order is to allow for an easier reconstruction of this anastomosis away from the mesenteric defect, which is typically the case once the Roux limb has been passed through the mesocolic defect and esophago-jejunostomy has been done. Stay sutures are placed between the biliopancreatic limb and the jejunum and enterotomies for insertion of the limbs of stapler are made. One limb of the blue GIA stapler is introduced into the biliopancreatic limb and the other in the jejunum. The blue load is fired, and the common enterotomy is either closed in a hand-sewn fashion or with a single fire of GIA or thoracoabdominal (TA) stapler.
- **Esophagojejunal anastomosis:** Next, the Roux limb is passed through the mesocolic defect to the left of middle colic vessels, and esophagojejunal anastomosis is performed. The esophagojejunal anastomosis can be fashioned either in hand-sewn or stapled fashion. We favor the hand-sewn anastomosis as it is consistent with our academic mission of training residents in complex intestinal anastomosis techniques. Also, we find the hand-sewn anastomosis more controlled with respect to placement of sutures.
- **Hand-sewn anastomosis:** Two seromuscular stay sutures, passing through the 3 o'clock and 9 o'clock position on the esophagus and antimesenteric aspect of Roux limb, are placed to keep esophagus and the Roux limb together while the anastomosis is being created. We prefer single-layer end-to-side anastomosis. An enterotomy is made on the antimesenteric border of the Roux limb with the help of the electrocautery. The opening in the jejunum is kept smaller than that of the esophagus because the jejunal opening tends to stretch and become bigger. A stay stitch on the anterior lip of the esophagus helps to keep it open thus facilitating the anastomosis. First, the posterior layer of equally spaced interrupted full-thickness 3-0 silk (or absorbable) sutures are placed (**FIG 13A**). Special attention should be given to the corner stitches. All the sutures should be placed before tying. Once the posterior layer is complete, the anterior layer is then performed with the placement of interrupted 3-0 silk (or absorbable) sutures (**FIG 13B**). The knots on the anterior-layer sutures can be extraluminal. Before completion of the anterior layer, a nasogastric (NG) tube is passed into the Roux limb and a small piece of Gelfoam is placed in the lumen to help with hemostasis and to prevent inadvertent placement of anterior stitches through the posterior wall. The jejunum could be tacked to the diaphragm to reduce the tension on the anastomosis from the weight of the Roux limb.

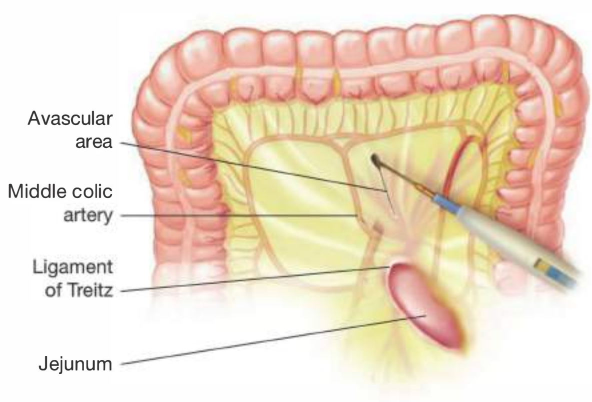

FIG 12 ● Creation of the defect in mesocolon. A defect is created in the mesocolon to the left of middle colic vessels. The Roux limb is passed through this defect in a retrocolic fashion.

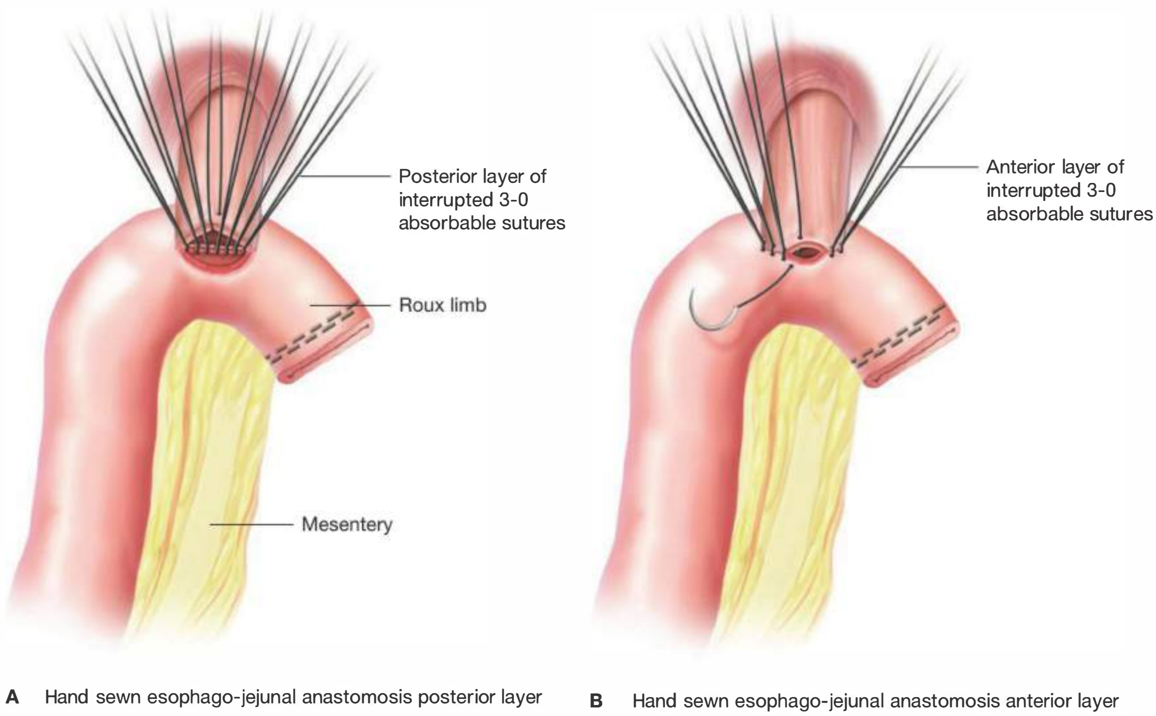

FIG 13 ● Hand-sewn esophagojejunal anastomosis. An end-to-side anastomosis is created between the esophagus and the Roux limb. An enterotomy, smaller than the opening in the esophagus, is made in the antimesenteric border of the Roux limb. First, the **(A)** posterior layer of interrupted absorbable sutures is placed followed by **(B)** anterior layer of sutures.

- **Stapled anastomosis:** For stapled anastomosis (FIG 14), an end-to-end anastomosis (EEA) stapler is used. First, the size of the esophageal opening is measured by using calibrated sizers and the EEA stapler is chosen on the basis of this measurement. Esophagus can also be gently dilated using a Foley, which is inserted into the esophagus and then withdrawn gently with balloon inflated. In general, a 25-mm EEA stapler is used for the esophagojejunostomy. A purse string is placed at the end of esophagus with a 2-0 Prolene (FIG 14A). The anvil of the EEA stapler is now introduced into the esophagus and the purse string is tied (FIG 14B). Next, the EEA stapler is introduced into the Roux limb preferably through the end of the jejunum or through an opening created in the Roux limb and directed toward the antimesenteric border of the Roux limb (FIG 14C). The pin of the EEA stapler is now opened with anticlockwise rotation of the knob and brought out through the point on the antimesenteric border of the Roux limb where the anastomosis is planned. This pin is attached to the anvil, stapler closed, and fired. The operator of the stapler should familiarize himself/herself to the operation of the stapler as these may differ from one company to the other. The doughnuts are checked for completeness and integrity. If the stapler was inserted through the blind end of the jejunum, this can be stapled close after the anastomosis is created.
- Although we do not routinely employ the following additional step, some surgeons assess the integrity of the anastomosis using an instilled methylene blue or air into the esophagus (through a tube in the esophagus) while the Roux limb is clamped.

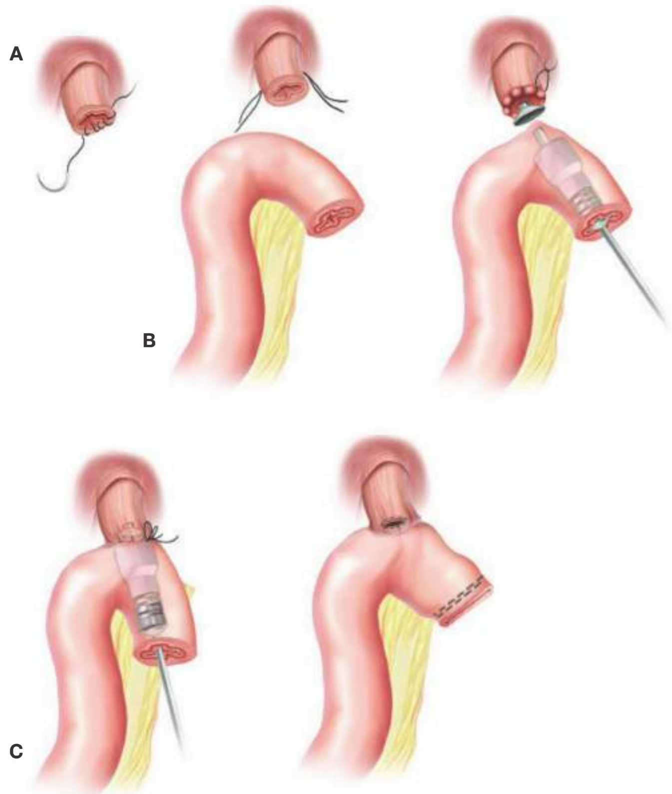

FIG 14 ● Stapled esophagojejunal anastomosis. **A.** Purse string is placed at the end of esophagus with a 2-0 Prolene. **B.** The anvil of the EEA stapler is introduced into the esophagus and the purse string is tied. **C.** The EEA stapler is introduced into the Roux limb through the end of the jejunum and directed toward the antimesenteric border of the Roux limb. The pin of the EEA stapler is now opened with anticlockwise rotation of the knob and brought out through the point on the antimesenteric border of the Roux limb where the anastomosis is planned. This pin is attached to the anvil, stapler closed, and fired. The doughnuts are checked for completeness and integrity.

CLOSURE

- After the restoration of gastrointestinal continuity, a feeding jejunostomy is placed distal to the jejunojejunal anastomosis. The patient may already have a feeding jejunostomy if one was placed during staging laparoscopy before neoadjuvant therapy.
- Prior to abdominal wall closure, we typically ensure absence of kinks, twists, or tension in the reconstructed intestinal continuity.

PEARLS AND PITFALLS

Mobilization of the greater curvature	■ Short gastric vessels should be carefully divided to avoid troublesome bleeding or iatrogenic splenic injury leading to inadvertent splenectomy.
Dissection of the infrapyloric region	■ The origin of the right gastroepiploic artery from the gastroduodenal artery should be carefully dissected, especially in the obese patients, due to difficulty in identifying this vessel.
Dissection of the GE junction	■ Adequate length of the esophagus should be dissected to yield a tension-free esophagojejunal anastomosis.
Construction of esophagojejunal anastomosis	■ The esophagojejunal sutures should be full thickness to ensure a robust anastomosis.
Feeding jejunostomy tube	■ If the feeding jejunostomy tube is placed during the staging laparoscopy, the surgeon should be cognizant of the need of constructing a Roux limb for the restoration of gastrointestinal continuity at the time of definitive surgery. Thus, the loop of jejunum just distal to the ligament of Treitz, which would be used for fashioning the Roux limb, should not be used for the placement of jejunostomy tube.

POSTOPERATIVE CARE

- Similar to other major abdominal operations, patients who undergo total gastrectomy require close attention to hemodynamics, optimization of fluid and electrolyte status, pain management, and pulmonary toilet.
- We increasingly use pain blocks (epidural, paravertebral blocks) in the care of these patients.
- NG tube is typically left to suction and is removed on postoperative days 3 to 4. If NG tube accidentally comes out, it should not be replaced due to the concern for anastomotic disruption. If NG tube needs to be replaced, it should be done under fluoroscopic guidance.
- If patient does not demonstrate any symptoms and signs of anastomotic leak by days 5 to 7, then they can be started on a clear liquid diet and then advanced to a postgastrectomy diet based on return of bowel function. Postgastrectomy diet consists of six small meals instead of three large meals. Most patients with time are able to liberalize the food choices as well as portion size.

OUTCOMES

- Although older data from gastric cancer trials quote an 8% in-hospital mortality for patients with total gastrectomy,[2] in recent series, in-hospital mortality of 1% to 2%, anastomotic leak rate of 1% to 3%, and duodenal stump leakage of less than 1% have been reported.[10,11] The cancer-specific outcomes depend on the stage of gastric cancer. Stage-specific 5-year survival of 57% to 71% for stage I, 33% to 45% for stage II, 14% to 20% for stage III, and 4% for stage IV M0 (AJCC 1988) has been reported[12] in the era prior to widespread acceptance of adjuvant or perioperative therapies. In a landmark study evaluating the role of adjuvant therapy in the treatment of stage Ib to IV resectable gastric cancer, addition of chemoradiation to surgery alone improved the 3-year overall and relapse-free survival from 41% to 50% and 31% to 48%, respectively. Similarly, perioperative chemotherapy without radiation for gastric cancer leads to improvement of overall 5-year survival from 23% to 36%.[13,14]

COMPLICATIONS

- **Early surgical complications:** Given the magnitude of surgery, total gastrectomy is associated with multiple systemic complications such as pulmonary embolism, pneumonia, atelectasis, myocardial infarction, and deep venous thrombosis. The diagnosis and management of these complications is no different from that after other major operations. Complications related to technical, physiologic, and anatomic aspect of total gastrectomy are described below.
  - **Anastomotic leak**
    - Presentation: Leak rates of 2% to 8% have been reported for esophagojejunal anastomosis. The type of reconstruction (stapled vs. hand sewn) has not been shown to influence this complication. This complication presents around postoperative days 6 to 9 and is heralded by unexplained fevers, tachycardia, and systemic inflammatory response.
    - Investigation: When suspected, a gastrografin swallow (followed by use of barium if needed) is used to evaluate for a leak. A CT scan with oral and IV contrast to evaluate for intraabdominal collections should be obtained.
    - Management: Initial management consists of NPO, IV antibiotics, nutrition, either enteral through feeding jejunostomy or parenteral, and drainage of any intraabdominal collection. Surgeons are increasingly using placement of a stent to help seal operative anastomotic leaks. Presence of feeding jejunostomy, which can help support the patient through enteral feeding, is very helpful in this situation. The resolution of the leak can be monitored by weekly gastrografin study. Operative exploration and repair is rarely required.
  - **Postoperative intraluminal bleeding**
    - Presentation: Bleeding from the anastomosis may present as sanguineous drainage from NG tube, melena, and/or drop in hematocrit or hemodynamic alteration.
    - Management: Most bleeding episodes resolve in response to conservative management with limited transfusion and correction of coagulopathy. Rarely, upper endoscopy with identification of bleeding site and its control with electrocautery or clips is required. We typically use endoscopic intervention as a last resort because of the fear of potential perforation.
  - **Postoperative extraluminal bleeding**
    - Presentation: Extraluminal bleeding presents in the early postoperative period as hemodynamic instability and falling hemoglobin. Although many etiologies are likely, unrecognized injury to the spleen, in the form of capsular tears or unligated short gastric arteries, is the most common reason for significant extraluminal bleed.
    - Management: If splenic injury is recognized during the gastrectomy, then splenic capsular tears can be managed by topical hemostatic preparation. Bleeding short gastric vessels can be managed with the use of surgical clip placement or use of energy devices. Uncontrolled bleeding may warrant a splenectomy. Postoperative bleeding that was not recognized during the procedure and is unresponsive to hemodynamic support with correction of coagulation parameters mandates return to the operating room with correction of underlying cause.
  - **Duodenal stump breakdown**
    - Presentation: Duodenal stump leak presents as signs and symptoms suggestive of intraabdominal sepsis such as fever, tachycardia, increasing abdominal pain, and leukocytosis.[15] An abdominal and pelvic CT scan with oral and IV contrast reveals an intraabdominal collection in the vicinity of duodenum requiring a percutaneous drain placement. If the drain output is bilious, it heightens the suspicion of duodenal fistula, which is confirmed by performing a drain study once the drain output does not decrease with time. Duodenal suture line failure can also present much more acutely in form of duodenal stump blowout if there is a downstream obstruction. The fistula may be an end fistula when it forms at the duodenal staple line or a lateral fistula when duodenum perforates laterally.
    - Management: Duodenal fistula is a difficult problem due to high volume loss of biliary and pancreatic secretions. Management involves supportive treatment with parenteral nutrition, correction of electrolyte abnormalities, antibiotics in early phase, and control of drainage with

special attention to skin care. Supportive treatment for as long as 6 weeks may be attempted. If resolution of duodenal fistula is not achieved, a percutaneous transhepatic tube can be advanced through the bile duct and into the duodenum to allow for retrograde drainage and control. Surgical management includes the take down of fistula, and duodenal reconstruction with Roux-en-Y end-to-side duodenojejunostomy. If the duodenal blowout presents as acute abdomen, then exploratory laparotomy, placement of a lateral tube duodenostomy, and wide drainage of right upper quadrant is required.

- **Delayed complications**
  - **Nutritional deficiencies**
    - Postgastrectomy diet: Patients postgastrectomy need to be started on postgastrectomy diet, which involves taking six small meals a day due to the loss of storage capacity of the stomach. With time, most patients can liberalize the volume and type of foods they consume. Some patients might be able to tolerate a diet similar to what they consumed preoperatively.
    - Iron supplementation: Postgastrectomy patients need to be on iron supplementation as the duodenum is the primary site of iron absorption and is bypassed. Also, the loss of gastric acidity impairs the conversion of ferric iron to the more absorbable ferrous form; 150 mg to 300 mg per day of elemental iron in three divided doses is recommended.
    - Vitamin B_{12} supplementation: Patients with total gastrectomy will develop vitamin B_{12} deficiency if not supplemented. Reduction in intrinsic factor and loss of gastric acidity impairs its absorption. Oral vitamin B_{12} (up to 100 μg per day) or monthly intramuscular vitamin B_{12} is recommended.
    - Supplementation of folate, calcium, and vitamin D is also recommended.
  - **Anastomotic stricture**
    - Presentation: Patients may present with dysphagia either early in postoperative period or many years after the initial operation.
    - Management: The differential diagnosis for anastomotic stricture includes postoperative edema, fibrosis/scarring, and local cancer recurrence. The diagnostic workup starts with contrast study followed by endoscopy with biopsy. Dysphagia secondary to edema will resolve with no interventions. Benign strictures can be managed by endoscopic or fluoroscopic balloon dilation. There is an increasing role of self-expanding metal stent for this condition. If the stricture is due to recurrent cancer, then the patient should be restaged and managed accordingly.

Chapter 16 Gastrostomy

John Daniel Hunter, III John Roland Porterfield, Jr.

DEFINITION

- A gastrostomy tube (G-tube) is a transcutaneous tube that is positioned in the lumen of the stomach. The primary functions of the G-tube are enteral access for nutrition and gastric decompression. They can be temporary or permanent depending on the patient's underlying pathology and clinical needs.
- A G-tube can be placed with an open, laparoscopic, endoscopic, or image-guided percutaneous approach.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history and physical exam should focus on the indication for enteral access, hemodynamic stability of the patient, current functional status of the gastrointestinal (GI) tract, and previous GI or upper abdominal surgeries.
- Indications for G-tube include feeding access and gastric decompression. They also play a role as an additional method of gastropexy following antireflux procedures or to prevent gastric torsion.
- Patients who are hemodynamically unstable should not undergo elective G-tube placement. In these scenarios, gastric access can be maintained through a nasogastric route.
- Assessing the status of the GI tract is essential for operative planning and patient benefit.
  - If the G-tube is to be used for feeding, the patient should have a functional GI tract distal to the stomach and without evidence of mechanical bowel obstruction, adynamic ileus, GI ischemia, or peritonitis.
  - Safe access to the stomach via the oropharynx and esophagus needs to be verified prior to proceeding with percutaneous endoscopic gastrostomy (PEG) tube placement. If this route is obstructed or otherwise unsafe, an open, laparoscopic, or image-guided percutaneous technique should be used.
  - In patients with esophageal pathology that may necessitate an esophagectomy, a G-tube should be avoided because the stomach may be used as a conduit for reconstruction following esophagectomy. In this scenario, a feeding jejunostomy is our preferred route of enteral nutrition.
- A thorough surgical history is imperative prior to G-tube placement. Patients with a history of previous upper abdominal or gastric surgery will be at higher risk for inadvertent colon or small bowel injury during PEG tube placement. An extensive abdominal surgical history may prohibit safe laparoscopic or endoscopic G-tube placement and thus an open technique may be the safest route.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Specific imaging or other diagnostic studies are generally unnecessary for G-tube placement. However, it is often the case that patients have had a plethora of upper abdominal imaging for other reasons that may provide valuable information or clues to previous unknown surgical procedures or unexpected anatomic findings.
- For PEG tube placement, it is important to look for structures, particularly the liver and transverse colon, which may be resting anterior to the stomach along the line of the proposed G-tube tract. In patients with increased risk of abdominal adhesions (i.e., previous operations, history of peritonitis) and radiographic evidence of abdominal structures lying between the abdominal wall and stomach, PEG placement should be avoided in favor of a laparoscopic or an open approach.

SURGICAL MANAGEMENT

Preoperative Planning

- The patient should be NPO for a minimum of 6 hours prior to the procedure.
- Antibiotics should be given within 30 minutes of incision to reduce the incidence of abdominal wall infection around the tube site. First-generation cephalosporins are our preference when not contraindicated by a patient's known allergies.
- For patients undergoing a PEG tube placement, the patients should be provided an antiseptic mouth rinse to reduce oral flora being carried into the abdominal wall soft tissues.

Positioning

- For endoscopic or surgical G-tube placement, the patient should be positioned supine.
- For laparoscopic placement, the patient should be supine with the right arm tucked to allow adequate room for the surgeon and assistant to both work comfortably on the right side.

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY TUBE PLACEMENT

Equipment

- There are several PEG kits available. These vary depending on technique (push or pull) and tube size (20 French [Fr] or 28 Fr). Most of these kits come with everything needed for placement, including prep and sterile drapes. We use the Bard Ponsky PEG kit, 20 Fr.
- A standard adult or pediatric endoscope is required, preferably with an external display so that both operating surgeons can see the endoscopic view.

Endoscopy and Tube Site Selection by Transillumination

- With an endoscopist at the patient's head and surgeon scrubbed at the patient's abdomen, the room lights are dimmed and the endoscopist introduces the endoscope into the stomach.

- A quick look around the entire stomach is performed to rule out occult gastric pathology.
- The endoscopist should fully insufflate the stomach.
- The endoscopist should advance the polypectomy snare to the end of the scope then withdraw 2 cm so that it is ready for the ensuing steps.
- Transillumination will allow the surgeon to locate the appropriate place on the abdominal wall for the G-tube to be placed. This is done by retracting the scope into the body of the stomach several centimeters distal to the gastroesophageal junction and then directing it toward the anterior stomach.
  - Some endoscopic light sources offer a transilluminate feature that temporarily increases the light intensity to enhance visualization through the abdominal wall by the surgeon.
  - Palpation is sometimes required to compress the tissue between the stomach and skin to better reveal the light.
  - It is often necessary to darken the room to visualize the light.
- Carefully palpate multiple areas and choose the spot with the brightest area of transillumination (**FIG 1**).
- Ensure that the sight is at least 2 to 3 cm from the left costal margin for patient comfort.
- Mark the spot with a marking pen or press the needleless tip of a Luer lock syringe into the skin to leave an indentation mark.
- Insertion of a fine 25-gauge or 27-gauge needle, as used for infusion of local anesthesia, may be used to best identify the perfect placement position and tube track.

Optional Technique for Site Selection

- For additional assurance that there is no intervening bowel between the tube site chosen by transillumination and the stomach, the following technique can be used.[1]
  - Using a 10-mL syringe with several milliliters of saline and a small-gauge needle, advance the needle perpendicularly through the abdominal wall at the spot previously chosen, keeping the plunger drawn back.

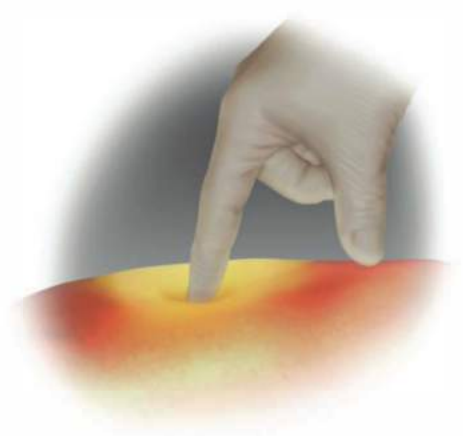

FIG 1 ● Transillumination of the abdominal wall.

- Watch the saline in the syringe for air bubbles. If the initial presentation of bubbles is seen at the same time the endoscopist sees the needle from inside the stomach, you can safely assume you have not passed through any bowel before entering the stomach.
- If you see bubbles before the endoscopist sees the needle from inside the stomach, you may be passing through bowel and thus should choose another point of entry and repeat (**FIG 2**).
- During this process, it is important to limit the force applied to the abdominal wall as this may compress a portion of an unexpected piece of bowel lying along the proposed track.

Tube Placement

- Infiltrate the site chosen with local anesthetic and make an approximately 0.5-cm skin incision with a no. 11 blade.
- The endoscopist should advance the previously positioned polypectomy snare and center the loop over the area of the mucosa that was identified during abdominal wall site selection. This type of synchronization and planning not only facilitates a timely procedure but also avoids visceral movement once the best site is selected (**FIG 3**).
- The needle with the angiocath is then placed through the abdominal wall at the designated site and advanced into the stomach under direct visualization into the loop created by the polypectomy snare. The needle is then removed while the angiocath is left in place (**FIG 4A**).
- The snare is left loose.
- The looped wire or the stiffer guidewire (see "Push Technique") is advanced through the angiocath.
- After several centimeters are passed through the snare, the snare loop is tightened around the wire (**FIG 4B**).
- The scope is then completely withdrawn while the polypectomy snare is held snug around the wire, pulling the wire through the abdominal wall. This leaves the wire passing through the abdominal wall via the angiocath, into the stomach, through the esophagus, and out of the mouth.
- At this point, there are two techniques available—"push" and "pull"—that can be chosen based on available supplies and surgeon's preference.

Pull Technique

- The looped wire that was pulled through the stomach to the mouth is connected to the looped wire at the tapered external end of the PEG tube (**FIG 5**).
- The surgeon then pulls the suture from the abdominal wall end, advancing the PEG tube through the esophagus into the stomach. The endoscopist should follow the tube down to visualize from within the stomach. To save time, the polypectomy snare can be cinched around half of the button of the PEG tube to allow the scope to easily follow the tube while it is being pulled by the surgeon (**FIG 6**).

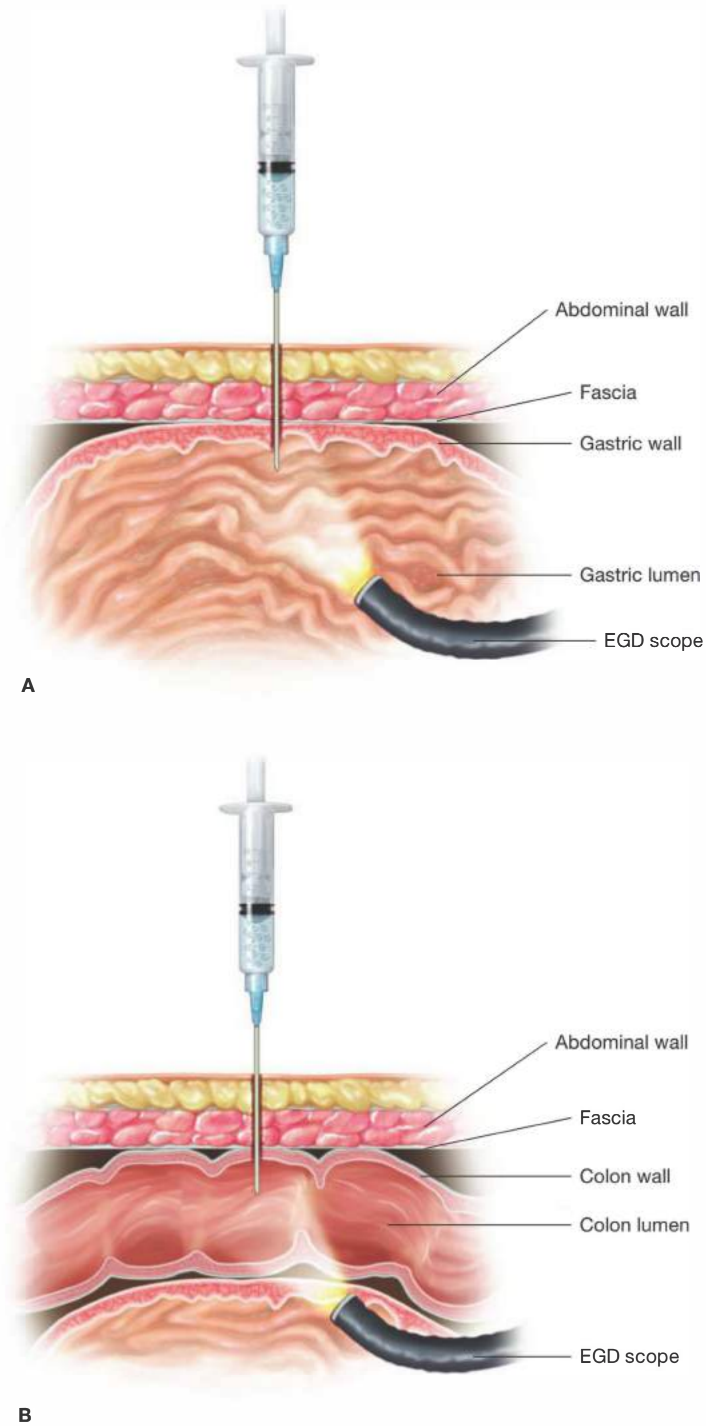

FIG 2 ● **A.** Bubbles are seen at the same time as the endoscopist sees the needle, confirming intragastric positioning without intervening bowel. **B.** Bubbles are seen *before* the needle is seen by the endoscopist, suggesting bowel between the stomach and abdominal wall.

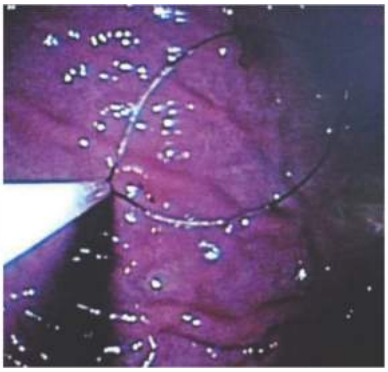

FIG 3 ● The snare is positioned against the mucosa where the needle is intended to pass.

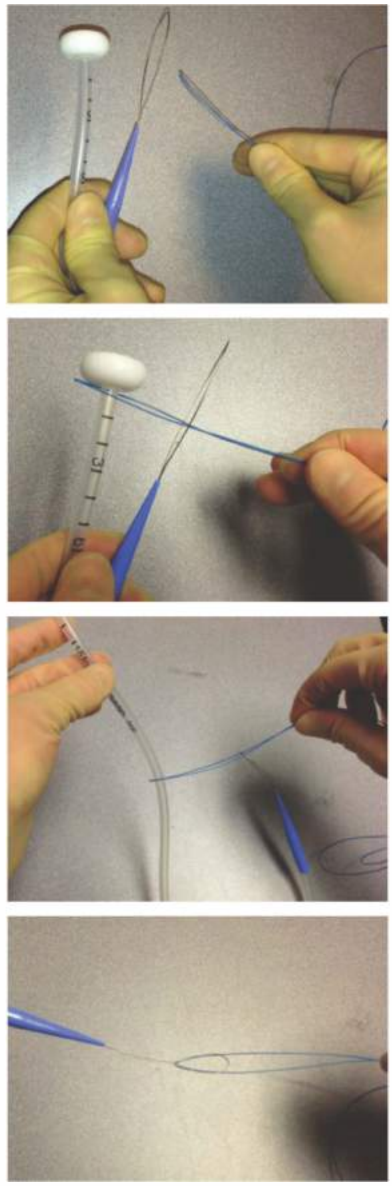
- When the tapered end of the PEG tube begins to come through the abdominal wall, additional force directed perpendicular to the abdominal wall is required to pull the tube through (**FIG 7**).
- The tube should be pulled until the button is resting loosely against the gastric mucosa.

A

B

FIG 4 ● **A.** The needle and angiocath are advanced into the stomach in the center of the snare by the surgeon. The needle is removed. **B.** The wire is passed through the angiocath into the stomach and through the center of the snare. The snare is then tightened around the wire.



A

B

C

D

FIG 5 ● With the looped wire exiting the patient's mouth, the tapered end of the PEG tube is secured to the wire. There is often a wire loop on the PEG to facilitate this attachment. Pass the wire through the loop **(A)** and around the button end of the tube **(B)**. Pull the rest of the tube through the wire **(C)** so that they are now secured together **(D)**.

- The endoscopist should confirm position of the button to rule out bleeding while the surgeon notes the thickness of the abdominal wall when securing the bolster.

Push Technique

- This technique requires a stiffer guidewire to be used.
- The G-tube is inserted over the wire by the endoscopist and advanced while tension is held on the wire by both the surgeon and endoscopist.

FIG 6 ● The snare can be tightened around half of the PEG flange to facilitate prompt scope reentry into the stomach.

- The tube is then pushed until the surgeon is able to grasp the tapered end as it emerges through the skin.
- The surgeon then pulls the tube until the button rests loosely against the gastric mucosa, as described earlier.

Securing the Tube

- The outer bolster included in the kit is then applied to the external portion of the tube and directed toward the skin.

FIG 7 ● Once the tapered end of the PEG is seen exiting through the abdominal wall, a steady pull directed toward the ceiling by the surgeon is required to advance the PEG tube to its final position.

- The bolster should rest about 2 to 3 mm above the skin.
- Avoid compressing the abdominal and gastric wall between the bolster and button (FIG 8). This can cause ischemic necrosis to these tissues, potentially leading to abdominal wall infection, tube extrusion, or the stomach falling away from the abdominal wall.
- The kit manufacturers often recommend and provide antibiotic ointment to be applied to the interface of the tube as it enters the skin to decrease the formation of an abdominal wall infection.
- The tube is then cut to the appropriate length and an adapter is secured to the end to allow a sealed connection for feeding, drainage, or to secure the cap to prevent leakage.
- We connect a collection bag during the immediate postoperative period to allow the GI tract to be decompressed of any gas that was insufflated during the procedure and to decrease the risk of reflux during emergence from sedation.

FIG 8 ● The bolster is advanced so that it is just touching and depressing the skin.

OPEN GASTROSTOMY TUBE

Equipment

- A standard laparotomy setup should be used.
- For the G-tube, a 22-Fr Foley catheter or the G-tube from a laparoscopic G-tube kit can be used. There are commercially available G-tubes that allow simultaneous gastric decompression and jejunal feeding, which may be beneficial in some scenarios.

Incision

- When done as a single procedure, a 4-cm upper midline incision to expose the stomach should be used (FIG 9).
- Just beneath the linea alba, the extraperitoneal fat and the falciform ligament should be retracted to the right to assist with visualization of the left upper quadrant.
- A small wound protector functions well as a retractor and limits the subcutaneous tissues exposure to contamination from the gastric flora.

Gastrotomy and Tube Placement

- The location of the gastrotomy should be on the anterior surface of the midportion of the stomach, close to the greater curve (FIG 10). Mark this point with the cautery or a surgical marking pen.
- Using a 3-0 absorbable monofilament suture on a taper needle, sew a circular purse string around the gastrotomy site with a diameter of about 1 cm. Place a second purse string around the first one concentrically taking care to create a purse string diameter of approximately 2 cm. This allows the gastric wall to partially intussuscept, creating nice track for the tube (FIG 11).

FIG 9 ● Open G-tube incision.

- Next, grasp the left linea alba at the exposed incision with an atraumatic clamp and elevate the left abdominal wall. Pick a point through the middle of the left rectus muscle where the tube will exit the abdominal wall. Make sure that this is at least two fingerbreadths below the left costal margin and at the approximate level of the gastrotomy. Make a 5-mm incision in the overlying skin and pass a fine clamp through the rectus from the peritoneum through the 5-mm incision in the skin. Grasp the end of the catheter and bring it through the abdominal wall (**FIG 12**). Care should be taken during this process to avoid injury to the balloon on the tip of the catheter and its integrity should be checked at this point by infusing sterile water (*not* saline) into the balloon.

FIG 10 ● Preferred location of gastrostomy on anterior surface of the stomach.

FIG 11 ● Using nonabsorbable suture, a double purse-string stitch is placed around the enterotomy site. The inner circle should be about 1 cm in diameter and the outer should be about 2 cm in diameter.

- Using the point of a cautery device, make a small gastrotomy in the center of the purse string and confirm entry into the stomach. Do not dilate the gastrotomy (**FIG 13**).
- Place the catheter through the gastrotomy into the stomach. Starting with the inner stitch, tie the two purse-string sutures down around the catheter. Inflate the balloon with 10 mL of water. Do not secure too tight as to close off the catheter or cause ischemia to the gastric wall (**FIG 14**).

Fixation (Optional)

- In some scenarios, the stomach or gastric remnant in patients with a history of a gastric bypass may not reach the abdominal wall; in this case, fixation should be avoided. When this is the case, it is advantageous to pass the tube through a small portion of omentum prior to insertion through the gastrotomy so that the omentum is readily able to begin forming a healthy track between the abdominal wall and the gastric lumen.

FIG 12 ● The left linea alba is grasped and retracted medially. A skin incision is made at the G-tube site and a Kelly clamp is passed through the abdominal wall and out through the skin incision. The enteral end of the G-tube is then pulled through the abdominal wall.

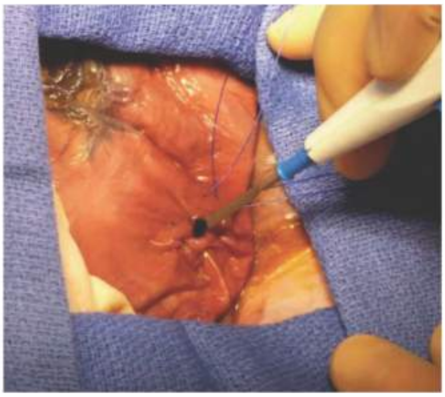


FIG 13 ● Cautery is used to create a gastrotomy at the center of the purse string.

- When fixation is desired, the goal is to secure the stomach to the abdominal wall at the point where the tube passes through the rectus. This seals the tract made by the tube and helps to prevent gastric content spillage into the peritoneal cavity.
- Using a 3-0 absorbable suture on a taper needle, place four separate stitches through the seromuscular layer of the stomach and peritoneum of the abdominal wall. This should be done four times around the point where the tube enters the abdominal wall. Start with the lateral (furthest) stitch first, then superior, inferior, and finally medial. Secure each suture after it is placed and do not tie them until the end. Once all four sutures have been placed, tie them down in the order they were placed while relaxing on the retraction of the left abdominal wall.
- Before tying, ensure that the stomach is not on too much tension or twisted in any way.

Closure

- Close the abdomen in standard fashion.
- Secure the tube to the skin with a 3-0 nylon suture to prevent the tube from being dislodged.
- If a manufactured G-tube was used, the supplied bolster may be used to secure the tube along with a nylon suture. Make sure that the bolster is not too tight to prevent abdominal wall or gastric wall ischemia. The bolster should rest without tension 2 to 3 mm above the skin (**FIG 8**).
- We connect a collection bag during the immediate postoperative period to allow the GI tract to be decompressed of any gas that was insufflated during the procedure and to decrease the risk of reflux during emergence from sedation.

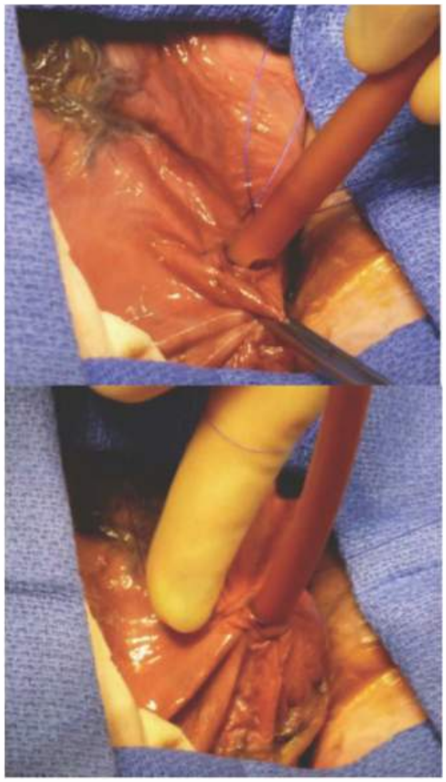

FIG 14 ● The tube is inserted into the stomach through the gastrotomy and the purse strings are tied, starting with the inner circle.

LAPAROSCOPIC GASTROSTOMY TUBE

Equipment and Port Placement

- Several commercial laparoscopic G-tube kits are available. We use the Flexiflo Lap G™ by Abbot Nutrition. This section will describe G-tube placement using this kit. The steps described can be modified for other kits and the package inserts for each kit should be read as they often pertain pertinent pearls for success.
- A standard laparoscopic setup including a 5-mm 0-degree or 30-degree laparoscope and a single 5-mm port is used.
- The procedure can be accomplished with only one periumbilical port for the camera so long as there are no adhesions that need to be taken down and the stomach can be insufflated by anesthesia via an orogastric tube. If these conditions cannot be met, additional ports may be needed to lyse adhesions and/or manipulate the stomach. The ports should triangulate toward the stomach in the left upper quadrant (**FIG 15**).
- The T-fasteners used in this procedure aid in providing traction for the stomach while the tract is being dilated and the G-tube is being placed. This is very helpful when only a single laparoscopic port is used for the

FIG 15 ● Port placement for laparoscopic G-tube.

camera and no additional laparoscopic instruments are used. However, if an additional instrument port has to be placed for adhesions or stomach manipulation as mentioned earlier, the T-fasteners can be eliminated from the procedure and the extra instrument port can provide the traction on the stomach during the dilation and tube placement steps.

Tube Placement

- Once laparoscopic access has been gained and all necessary adhesions have been cleared, anesthesia should insufflate the stomach via an orogastric tube. Pick a site in the left upper quadrant where the G-tube should enter the abdomen. The entry point should be at least two fingerbreadths below the left costal margin. The surgeon should palpate in this general area while watching the laparoscopic screen to find the place where the depressed abdominal wall lines up with the stomach. Avoid placing the tube too close to the gastroesophageal junction or antrum to avoid obstruction. The anterior surface of the midbody closer to the great curvature is the preferred location (**FIG 10**).
- Mark the tube site on the skin and then mark points 2 cm in four directions around the tube site for the T-fasteners.
- Starting with the most superior mark, insert the needle with the loaded T-fastener through the abdominal wall angled slightly toward the center mark. Once the needle is seen in the peritoneal cavity, direct it to point around the proposed gastrostomy site that corresponds to the skin location. Advance the needle with the loaded T-fastener into the stomach up the double-line marking. Press the plunger on the needle to deploy the T-fastener (**FIG 16**). Place a clamp on the T-fastener tail approximately 1 to 2 cm from the skin.
- Repeat the step to deploy the remaining three T-fasteners. Ask anesthesia to remove some air from the stomach so that the stomach begins to fall away from the abdominal wall. The anterior wall of the stomach should be visible with the four T-fasteners entering in

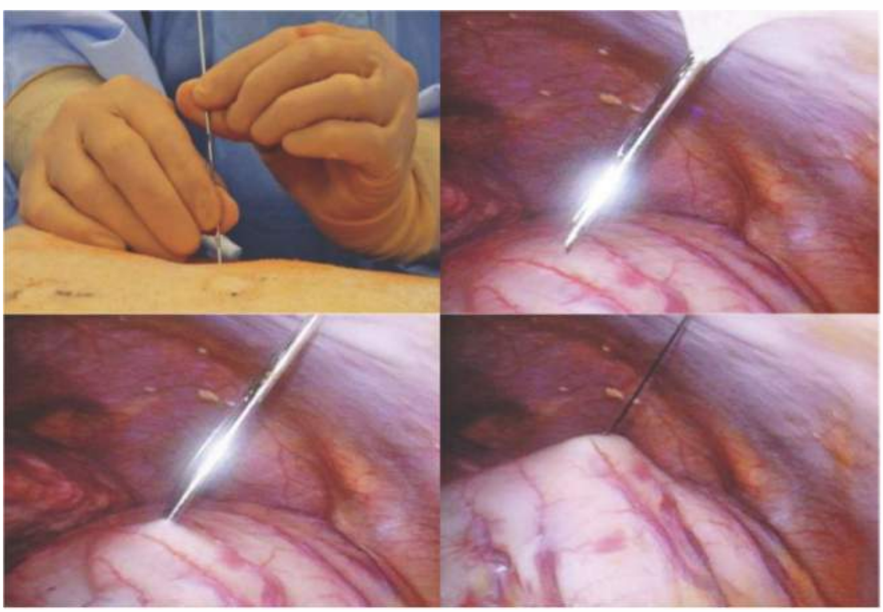

FIG 16 ● The sequence of steps for T-fastener placement is shown here. Note the insertion of the needle to the double black bar marking before deployment of the T-fastener.

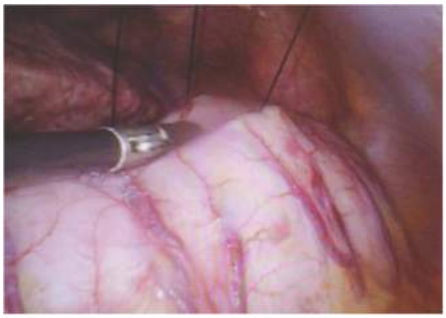

FIG 17 ● Final view after all T-fasteners have been placed.

an approximate diamond shape (**FIG 17**). The center of diamond will be the tube insertion site.

- Make a 5-mm skin incision at the chosen tube site and direct the 18-gauge needle with a 40-mL slip-tipped syringe through the abdominal wall and into the peritoneal cavity. Under direct visualization with the laparoscope, direct the needle into the stomach through the point at the center of the diamond created by the T-fasteners (**FIG 18**). The T-fasteners can be used to manipulate the stomach to guide entry of the needle. Insufflate air to be absolutely certain that the tip of the needle is intraluminal.
- Pass the supplied wire into the stomach and remove the needle.
- Using the supplied serial dilators, dilate the tract through the abdominal and gastric wall. The stomach should be just off the abdominal wall during this step so that the dilators can be seen exiting the abdominal wall and passing into the stomach. A back-and-forth twisting motion can help when advancing the dilators through the tissue (**FIG 19**).
- Once the track is sufficiently dilated, insert the smallest dilator through the tube and guide the tube over the wire into the stomach (**FIG 20**).

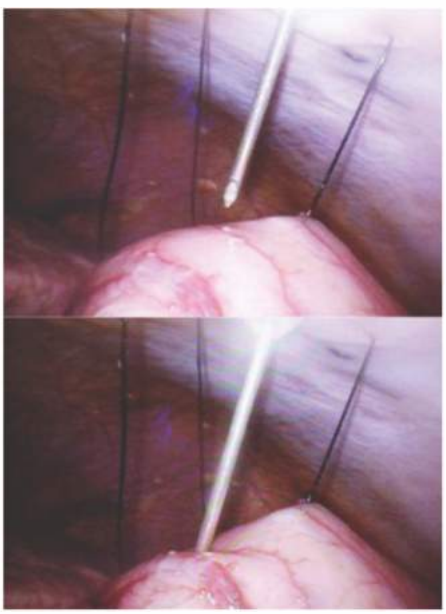

FIG 18 ● The large-bore needle is directed into the stomach through the center of the T-fasteners.

FIG 19 ● The dilator is passed over the wire though the abdominal wall and into the stomach.

FIG 20 ● The smallest dilator is inserted into the G-tube and two are guided over the wire through the tract and into the stomach. The wire and dilator are removed together leaving the tube in place.

- Remove the wire and dilator together. Inflate the balloon port with 18 to 20 mL of water and pull back the tube back so the stomach rests against the abdominal wall. The outer flange should be advanced so that it rests just on the skin. Too much squeeze between the outer flange and intraluminal balloon can result in gastric and/or abdominal wall necrosis (**FIG 8**).
- In a similar manner, gently pull the T-fasteners individually so that the stomach rests just on the abdominal wall and crimp them into position using a needle driver. This will leave small cotton bolsters against the skin that may be removed by cutting the sutures below the bolsters 2 weeks after the procedure (**FIG 21**).

FIG 21 ● The T-fasteners are gently retracted so that the stomach is secured against the abdominal wall and crimped into place.

PEARLS AND PITFALLS

Indications	▪ Be certain that a G-tube best fits the needs of the patient. Frequently, physicians may request a G-tube when in reality the patient needs a jejunostomy tube (J-tube) or vice versa.
Preprocedure planning	▪ Review previous upper abdominal procedures or history of peritonitis that may have scarred another piece of bowel along the proposed track of the G-tube. ▪ Be prepared to sufficiently darken the room for transillumination.
Patient position	▪ Position the patient supine with the entire abdomen exposed to be prepped once a suitable site is identified for tube placement.
Tube site selection	▪ The skin incision should be at least 2 cm inferior to the costal margin. ▪ The gastrotomy site should nicely line up without tension with the site for the tube to course through the abdominal wall.
PEG	▪ Enter slowly with the needle watching for any bubbles in the syringe before the tip of the needle is seen by the endoscopist, which would indicate the traverse of another hollow viscus.
Laparoscopic G-tube	▪ Position the patient supine with the right arm tucked to allow a comfortable working space for the surgeon and the laparoscopic assistant on the right side of the patient.
Open G-tube	▪ Place the second purse-string suture at least 1 cm outside the first so that the gastric wall will intussuscept into the gastric lumen thereby creating a secure track around the tube.
Securing the tube	▪ Do not secure the bolster on the tube too tightly against the skin as it may result in necrosis of the skin or the gastric wall.
Postprocedure care	▪ Leave the tube to gravity drainage initially to decompress any excess gas within the proximal GI tract and to reduce the risk of reflux upon emergence of sedation. ▪ An abdominal binder is helpful for securing the tube and preventing premature or inadvertent removal during patient movement or in a patient with impaired mental status.

POSTOPERATIVE CARE

- For gastric decompression, the tube should be left to gravity drainage via a collection bag. The gastric tube should never be hooked up to low wall suction. The tube does not have a sump port and if suction is applied, it will adhere to the posterior gastric wall and cause suction necrosis, bleeding, and/or perforation.
- Tube feedings may be started the evening of the procedure at a low rate, usually about 10 mL per hour. If the patient tolerates this, he or she can advance by 10 mL per hour every 4 hours until the nutritional goal is reached.
- Care should be taken to avoid the tube catching or pulling while the patient is moving or if the patient's neurologic status is such that he or she can grasp and pull the tube. An abdominal binder or gauze dressing can be used to cover the tube. Hand mittens can be used in the high-risk patient.
- The patient and their caregiver should receive education regarding proper tube care and simple troubleshooting.
- For patients going home with a G-tube for gastric decompression, they should be taught how and when to intermittently vent the tube. This will allow them to not have to keep the tube attached to a drainage bag at all times.

OUTCOMES

- Not applicable

COMPLICATIONS

- Clogged tube
  - A clogged tube can be flushed clear in essentially every case with a small syringe. Due to the laws of hydraulics, the smaller the diameter of the syringe the more pressure that can be generated. We recommend the smallest syringe that will tightly fit into the opening in the tube. When a Foley catheter is used as the G-tube, the entire end of a 3-mL syringe will fit snugly and will often clear the obstruction when flushed with water. Carbonated acidic beverages such as Coke™ may also aid in clearing an obstruction and should be allowed to stay in the tube for an hour or more before attempting to flush the tube.
- Dislodged tube
  - It is imperative that patients and caregivers are taught to reinsert the tube immediately if they become dislodged so that the tract does not close. If they are unable to reinsert, then they should immediately go to an emergency department where a smaller catheter could be temporarily advanced into place preserving the tract, which could be later dilated and the proper tube placed.
  - If a tube is reinserted easily without resistance and flushing with water causes no discomfort, the tube may be used per the patient's routine without a confirmational radiologic study.
  - However, if the replacement is complicated or if there is discomfort with flushing, the tube position should be checked to ensure proper positioning.
- Fractured tube
  - If a tube is fractured with or without leakage, it may be temporarily patched with waterproof occlusive tape such as electrical tape or Duct® tape. The tube should be electively exchanged for a new tube during a regular clinic appointment. If the tube is new or in complex scenarios, it may need to be exchanged over a glide wire by a gastroenterologist, interventional radiologist, or a surgeon.
- Abdominal wall abscess
  - Tube site infections rarely lead to significant abscess formation, but if this occurs, it should be treated with incision and drainage leaving the wound open as with any infected open wound. The tube may need to be removed to allow the infection to heal.
- Tube placed through another piece of bowel
  - If the tube has penetrated the colon or small bowel, a surgical consult is indicated.
    - If the tube remains essential to the patient's care, then proceed to operating room (OR) for laparoscopic or open abdominal exploration with repair of the injury and placement of an open G-tube.
    - If the tube has been in place and functional for months but is no longer necessary, the tube may be removed realizing there is a potential need for repair of the gastric to colon or small bowel fistula. It has been our experience that most of these gastroenteric fistulas will close on their own or prove to be asymptomatic and inconsequential.
- Gastric outlet obstruction
  - Gastric outlet obstruction is most frequently associated with an overinflated balloon. When this is suspected, decreasing the amount of fluid in the balloon and being certain that the balloon is up against the gastric wall instead of free floating within the gastric lumen where it could be passed through the pylorus are important aspects to consider.

Chapter 17 Feeding Jejunostomy

John Daniel Hunter, III John Roland Porterfield, Jr.

DEFINITION

- A jejunostomy tube (J-tube) is a flexible soft tube that connects the intraluminal jejunum with the outside world through the abdominal wall. The main function is to provide long-term access to the proximal gastrointestinal (GI) tract for enteral nutrition when oral intake is not possible or inadequate.
- A J-tube can be placed through an open or a laparoscopic approach. Often, they are placed in conjunction with a larger operation when it is anticipated that the patient will not progress to adequate oral intake in a timely fashion during the early postoperative course. The J-tube affords the advantage of early enteral nutrition even when the upper GI tract cannot be used.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history and physical exam should focus on the indication for enteral access J-tube, hemodynamic stability of the patient, current functional status of the GI tract, and previous surgeries.
- Patients who are hemodynamically unstable generally should not undergo elective J-tube placement.
- The patient should be assessed for a functional GI tract distal to the ligament of Treitz (LOT) and should not have evidence of mechanical bowel obstruction, adynamic ileus, GI ischemia, or peritonitis.
- A thorough surgical history is imperative prior to J-tube placement. Preexisting tubes, drains, mesh from previous hernia repairs, or stomas may require alternative planning. An extensive abdominal surgical history may prohibit safe laparoscopic J-tube placement and an open technique may be employed.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiologic workup is generally not necessary for J-tube placement. However, it is often the case that patients have had a plethora of upper abdominal imaging for other reasons that may provide valuable information or clues to previous unknown surgical procedures or unexpected anatomic findings.

SURGICAL MANAGEMENT

Preoperative Planning

- The patient should be NPO for a minimum of 6 hours prior to the procedure.
- Antibiotics should be given within 30 minutes of incision to reduce the incidence of abdominal wall infection around the tube site. First-generation cephalosporins are our preference when not contraindicated by the patient's known allergies.
- Generally, the jejunostomy feeding tube will exit the patient's abdomen in the left upper quadrant (LUQ). As mentioned previously, preexisting tubes, drains, implanted mesh, and stomas may require tube site adjustment.

Positioning

- For an open J-tube, the patient should be placed in the supine position. Usually, this procedure is done in addition to a larger procedure and thus the patient is already positioned accordingly.
- For a laparoscopic J-tube, the patient should be positioned supine with the right arm tucked to allow for adequate room for the surgeon and assistant to both work comfortably on the right side.
- It is important to be certain the patient is secured to the bed for intraoperative bed tilting, which may assist with exposure of the proximal jejunum.

OPEN JEJUNOSTOMY TUBE PLACEMENT

Equipment

- The type of tube used for the feeding jejunostomy is decided upon by the surgeon to optimize the longevity, comfort, and function for the patient. There are many commercially available tubes that vary widely in features, availability, and cost.
- If a tube is being placed as part of a larger procedure and will likely be removed within 6 to 8 weeks, a standard 14-French (Fr) "red rubber Robinson" catheter is economical, time tested, and very functional.
- The most important tube characteristics are that it should be soft, pliable, and preferentially not containing a balloon unless it is a small balloon, less than 5 mL, and specifically designed to be placed within the jejunum. Balloon catheters within the small bowel are a frequent cause of recurrent bowel obstructions and should be avoided.
- The enteral end should be free of sharp edges that could damage the mucosa or promote migration or perforation. The holes should be of adequate size to allow feedings to pass through with minimal risk of clogging. The external portion should be tapered up to allow standard feeding pump tubing to be attached.
- At our institution, a 12- to 18-Fr "red rubber Robinson" catheter is often used. Extra holes can be cut into the distal portion to allow tube feeds to flow with less resistance. These holes may be created by folding the tube over and cutting the corner of the fold (**FIG 1**). Alternatively, the tube from a laparoscopic jejunostomy kit can be used (Flexiflo Lap J™ laparoscopic jejunostomy kit by Abbott Nutrition).

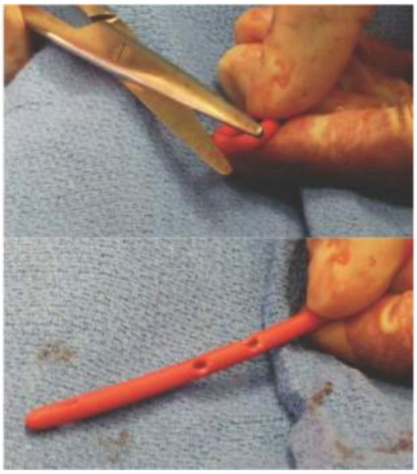

FIG 1 ● Cutting extra holes in a red Robinson tube will reduce resistance of flow to the tube feeds.

Incision

- If the open J-tube placement is being done as a stand-alone operation, the incision should be centered in the midline at the level of the LOT.
- The supraumbilical vertical midline incision should be carried through the linea alba with enough length to locate the LOT, mobilize 20 to 30 cm of jejunum, and allow for fixation of the jejunal segment to the peritoneum of the abdominal wall around the tube exit site. If there are minimal adhesions, this incision may be kept relatively small, 5 to 7 cm, and the majority of the operation can be done on eviscerated jejunum (FIG 2).
- A limitation of an incision that is too small is that it may prove difficult to fix the bowel to the abdominal wall through the small incision. Exposure of this step should not be compromised in anyway to avoid lengthening the incision.

Mobilization of Jejunum

- Once the peritoneal cavity has been entered, the omentum and transverse colon are retracted cephalad to expose the small bowel. A segment of small bowel is chosen in the LUQ and traced proximally until the LOT is identified.
- Once the LOT is identified, the small bowel is examined all the way to the ileocecal valve to ensure no occult pathology, obstruction, or torsion is present.
- The tube insertion site is chosen where the tube will pass through the abdominal wall. This will generally be in the LUQ. The surgeon must ensure the chosen segment of jejunum will reach the parietal surface of the abdominal wall without any tension or torsion. Lysis of adhesions may be needed to make sure the jejunum can reach the abdominal wall without tension.
- Placement of atraumatic clamps on the left side of the fascia allows the abdominal wall to be retracted anteriorly for exposure of tube placement. While keeping retraction, a strong fine clamp is passed from inside the abdomen through the point chosen in the abdominal wall. A 3-mm skin incision, at the clamp exit site, is created and the tube is grasped and the distal end is pulled through the abdominal wall into the peritoneal cavity. Both ends of the tube are clamped together and positioned out of the way (FIG 3).

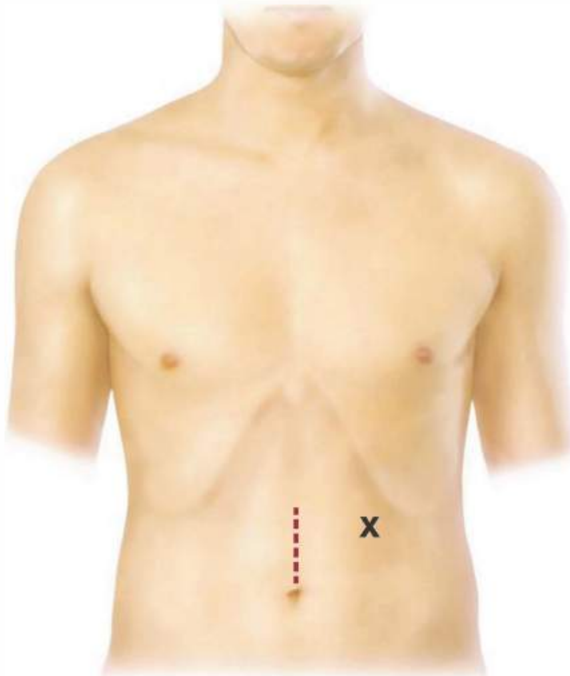

FIG 2 ● Open incision diagram with tube exit site marked.

Enterotomy and Placement of the Jejunostomy Tube

- A segment of jejunum approximately 30 cm from the LOT is chosen as the site for the J-tube placement. This portion of jejunum can be eviscerated for the next steps if a smaller incision has been used. Using a 3-0 nonabsorbable or absorbable suture, place an approximately 4-mm purse-string suture in a box formation on the antimesenteric side of the small bowel (FIG 4). A double purse-string stitch may be used for additional security (FIG 5).
- At this point, it is essential to note the proximal and distal ends of the jejunum and to ensure the orientation is maintained through the entire procedure.
- Using cautery, create a small enterotomy in the center of the purse-string suture. It is helpful to grasp the bowel by the mesentery during this step. Inadvertent cautery injury to the opposite side of the small bowel can be avoided by cutting the serosa and muscularis with the cautery but "popping" into the lumen with a fine clamp (FIG 5).
- Place the distal end of the feeding tube through the enterotomy into the lumen and direct it distally. The catheter is advanced until at least 10 cm is intraluminal. It can be advanced further if there is an excessive amount of tubing left externally (FIG 6).
- Tie down the purse-string suture, taking care not to overtighten and occlude the tube (FIG 7).

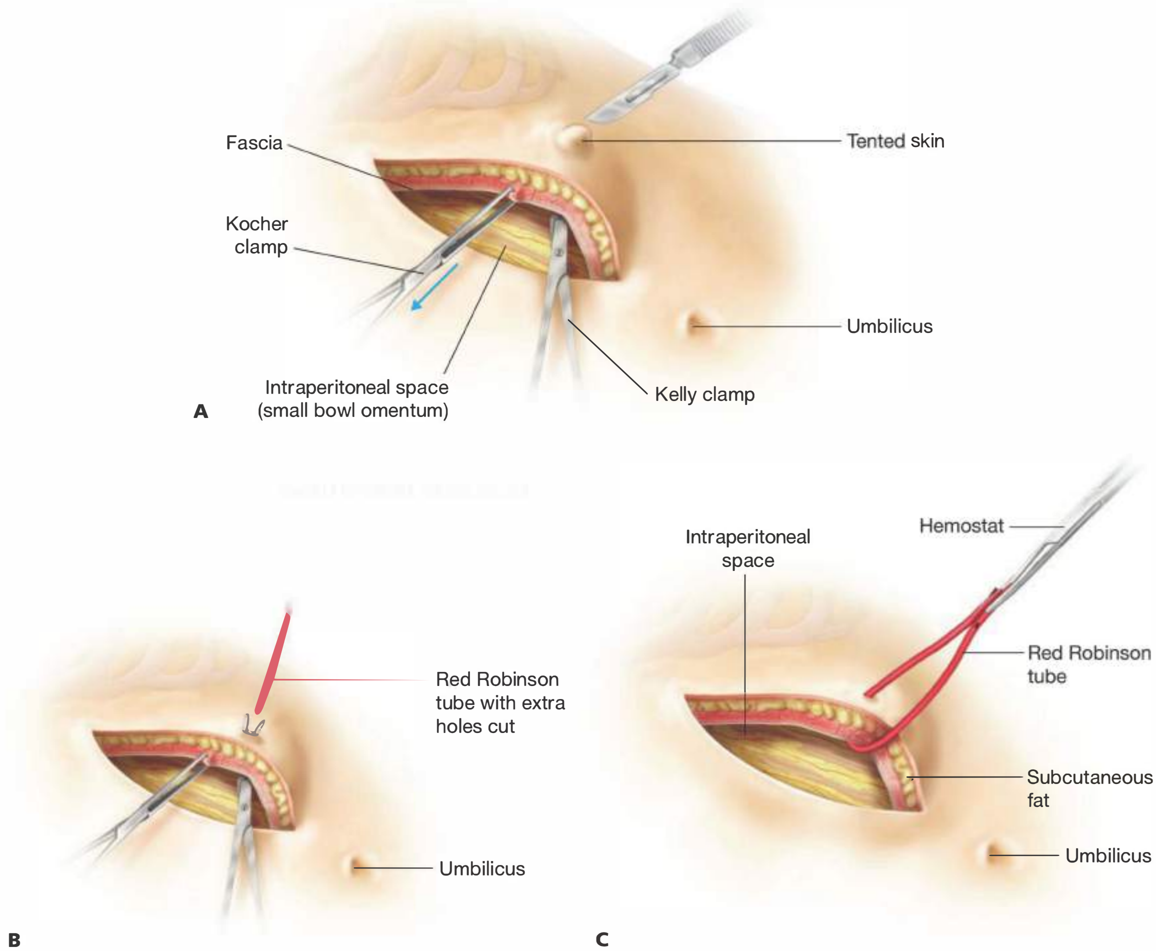

FIG 3 ● Facial retraction anterior and midline with stab incision being made for the feeding tube.

FIG 4 ● Placement of purse-string stitch on antimesenteric jejunum.

FIG 5 ● The enterotomy is made with a cautery and then a hemostat is used to "pop" into the lumen. Note the double purse-string stitch used.

- The tube entry sight is then imbricated using a three-point triangular technique (**FIG 8**).
- Next, a Witzel tunnel is created. Starting at the enterotomy, the small bowel is imbricated over the feeding tube using interrupted 3-0 absorbable suture on a taper needle (**FIG 9**) for a distance of about 5 cm. These are seromuscular bites spaced approximately 5 to 10 mm apart, ensuring the tube is not exposed. Care should be taken not to place the bites too far from the tube, as this will draw more bowel into the Witzel tunnel and narrow the jejunal lumen (**FIG 10**).
- The jejunal segment must now be secured to the parietal peritoneum. This will allow the formation of a tract so that if the tube is inadvertently removed, it can be replaced without reentering the abdomen. This should be done in a way that the bowel is flush with the abdominal wall. Four "tacking" sutures of absorbable 3-0 suture can be placed around the tube exit site. The first is placed lateral to the tube, away from the operating surgeon. A seromuscular bite is taken and then a bite of peritoneum is taken at the corresponding location in the abdominal wall (**FIG 11**). Start with the lateral (furthest) suture first, then superior, inferior, and finally medial. Secure each suture with a clamp after it is placed and do not tie until they are all appropriately placed.
- Once all four sutures have been placed, it is best to tie them in the order they were placed (**FIG 12**). An additional tacking suture may be placed 5 to 10 cm distally to secure a longer segment of bowel to the abdominal wall. This may help prevent torsion on the bowel around a single fixed point. The small bowel should now be adherent to the LUQ abdominal wall (**FIG 13**).
- The external portion of the tube should be secured to the skin using a 2-0 nonabsorbable monofilament suture (**FIG 14**).
- The abdomen is then closed in layers.
- The tube may be capped or placed to gravity drainage via a bag. Covering the tube with a dressing and tape or abdominal binder will help prevent it from being inadvertently dislodged during patient movement.

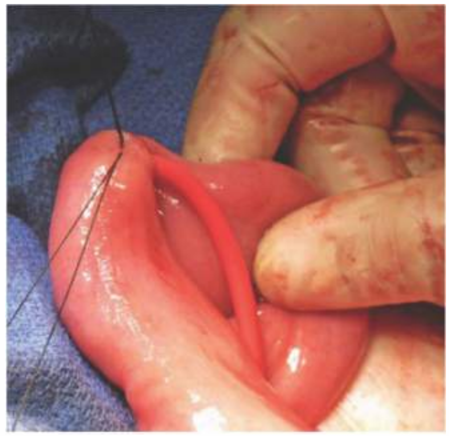

FIG 7 ● Tying down purse string to secure the feeding tube.

FIG 6 ● Directing end of feeding tube into distal jejunum.

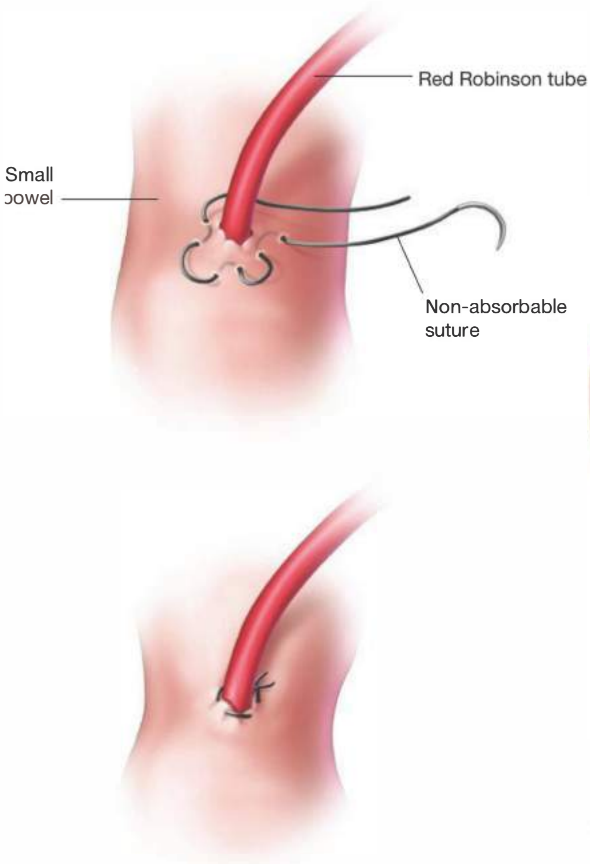

FIG 8 ● Triangle stitch to imbricate the tube entry site.

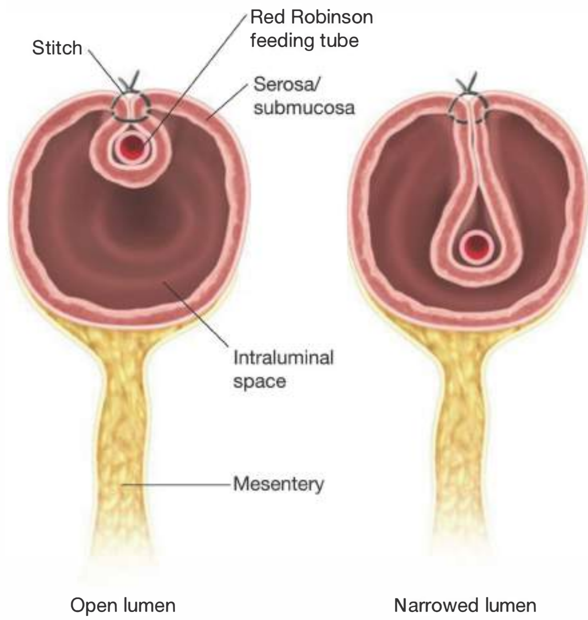

FIG 10 ● Cross section of Witzel tunnel. The **left** shows the correct placement of sutures with adequate lumen diameter. The **right** shows a narrowed lumen from suture bites placed too far from the tube.

FIG 9 ● Creation of the Witzel tunnel.

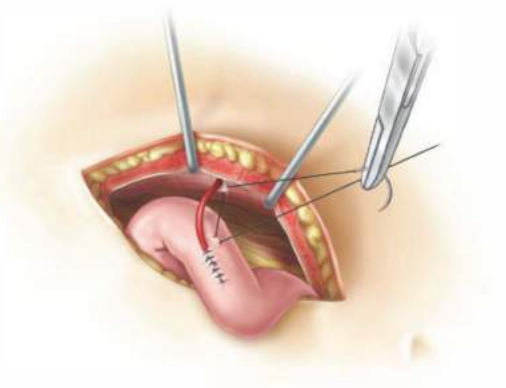

FIG 11 ● Placement of first tacking suture.

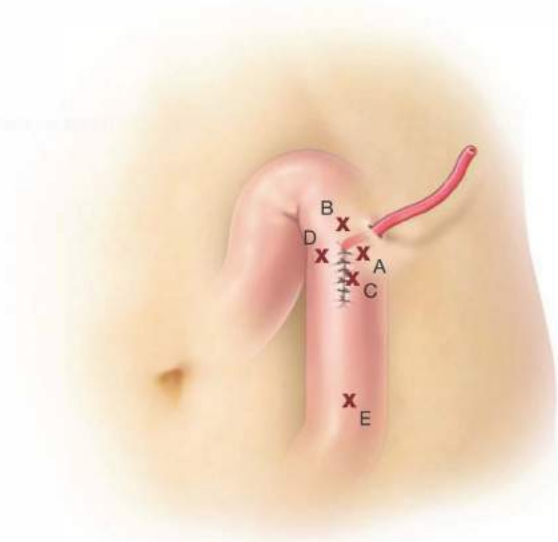

FIG 12 ● Final appearance of bowel attached to the abdominal wall. The sutures should be placed in order from *A* to *E*.

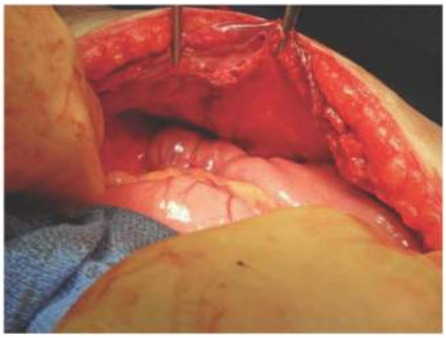

FIG 13 ● Final view of small bowel fixed to abdominal wall after the four tacking sutures have been placed. Note the feeding tube is not visible.

FIG 14 ● Securing the external portion of the tube to the abdominal wall.

LAPAROSCOPIC JEJUNOSTOMY

Equipment and Port Placement

- Several commercially available laparoscopic jejunostomy kits are available. We use the Flexiflo Lap J™ laparoscopic jejunostomy kit by Abbott Nutrition. This section will describe J-tube placement using this kit. The steps described can be modified for other kits, and the package inserts for each kit should be read as they often contain pertinent pearls for success.
- A standard laparoscopic setup including a 5-mm 0-degree or 30-degree laparoscope and two to three 5-mm ports is used.
- Port placement should triangulate toward the proposed tube exit site in the LUQ (FIG 15). The J-tube site should be at least two fingerbreadths below the left costal margin at approximately the midclavicular line.

Jejunal Mobilization and Tube Placement

- Once the ports are placed, the abdomen should be inspected to rule out occult pathology or evidence of a distal obstruction.
- The upper port should be used to retract the colon and omentum cephalad. The middle port is used for the camera. The lower port should be used to expose the small bowel.

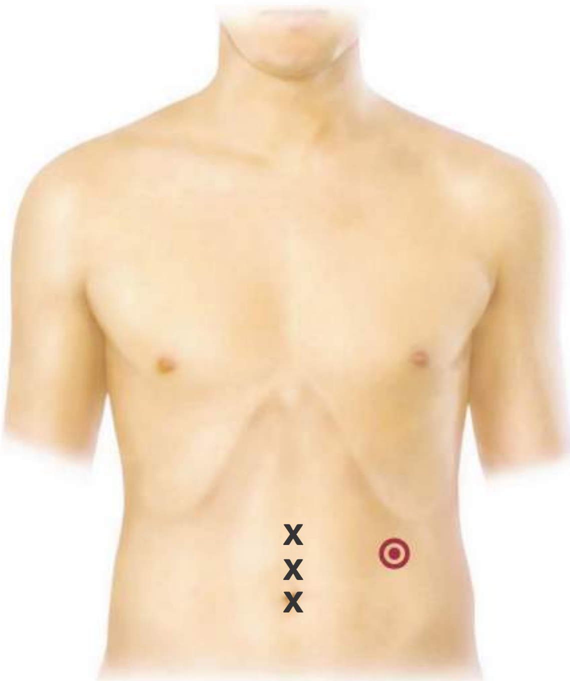

FIG 15 ● Port placement diagram for laparoscopic J-tube. The tube site is represented by the target.

- To identify the LOT, the transverse colon is retracted anteriorly as the patient is placed in Trendelenburg position and the mesentery of the transverse colon is followed toward its origin. The proximal most portion of the jejunum can be seen exiting the retroperitoneum at the LOT. Alternatively, if this exposure is unable to be obtained, the small bowel may be followed in the LUQ until the LOT is reached (FIG 16).
- Once the proximal jejunum is convincingly identified, it should be traced distally 20 to 30 cm to identify the tube site. Once the tube site is identified, it is essential to keep the proper orientation of the bowel throughout the completion of the procedure.
- The tube site on the abdominal wall should be chosen by identifying the area on the inner abdominal wall where the selected jejunal segment most easily reaches. The bowel should be free of tension at this point. The point on the abdominal wall should also be at least 2 cm below the costal margin. Placement of a fine needle through the abdominal wall into the peritoneal cavity often facilitates identifying and maintaining the best placement (FIG 17).
- The T-fasteners supplied in the kit are placed next. They are placed in a diamond configuration around the tube entry site, marked with the fine needle. They should be placed 2 cm from the needle at the skin level, pass through the fascia, and exit approximately 1 cm from the needle in the peritoneal cavity (FIG 18).
- To start, the assistant grasps the chosen segment of jejunum and pulls it to the tube site, holding it in proper orientation. The first T-fastener is passed through the superior point of the diamond. Once intraabdominal, the needle/T-fastener is advanced through the bowel wall. It is easy to inadvertently pass the needle through the "back wall" of the bowel at this point. The assistant should orient the bowel so that the mesenteric side is as far from the needle as possible during placement.
- The needle should be advanced to the 2-cm (double) mark and then deployed (FIG 19). Pull back on the fastener to ensure the bowel catches, retract it to the abdominal wall, and then apply a clamp to the external portion of the suture to keep the bowel in position.
- The next three T-fasteners are placed in a similar manner. The far lateral one should be deployed after the superior one, followed by the inferior, and then finally the medial fastener.

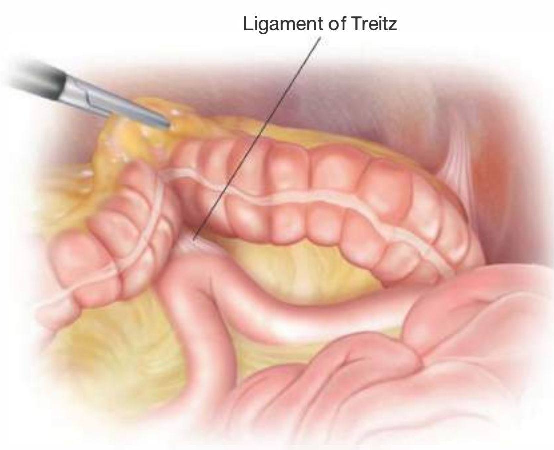

FIG 16 ● The small bowel is followed in the LUQ to the LOT.

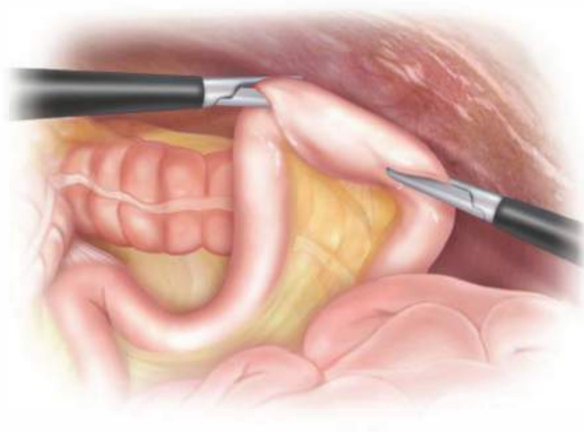

FIG 17 ● There should be no tension when the small bowel is retracted toward the chosen area on the abdominal wall. A needle can be placed through the abdominal wall to easily mark the area from the peritoneal cavity.

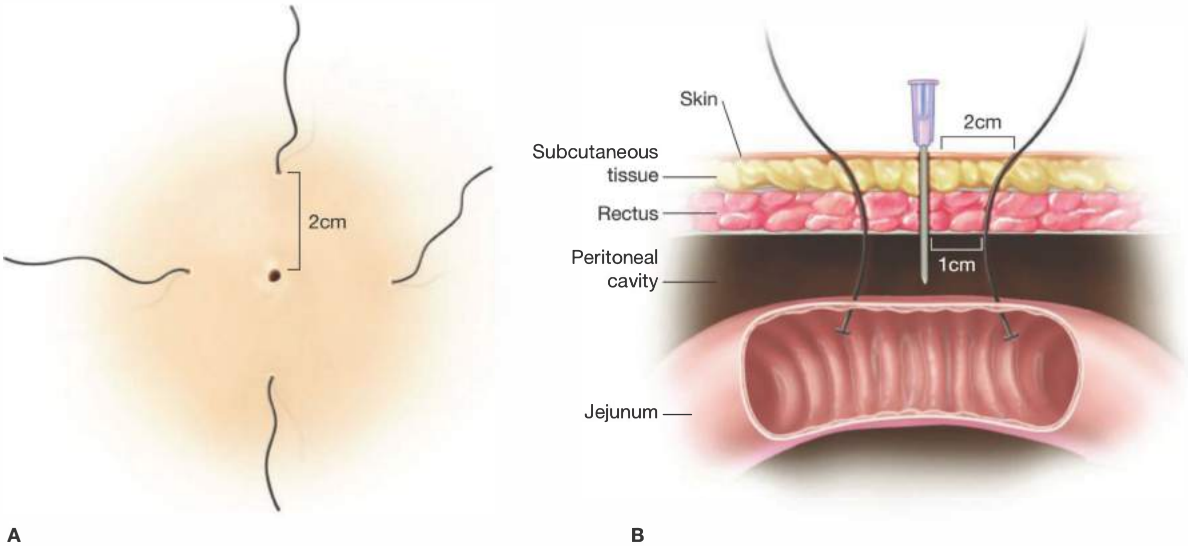

FIG 18 ● **A.** Diamond configuration of T-fasteners around the tube entry site as seen on the abdominal wall. **B.** Cross-sectional view of trajectory of T-fasteners as they pass through the abdominal wall. Note they enter 2 cm from the tube site at the skin and exit 1 cm from the tube site at the peritoneum.

- At this point, the antimesenteric side of the bowel should be almost flush with abdominal wall in four places (**FIG 20**). A small gap should be left for the next step.
- The 18-gauge needle is then advanced into the small bowel in the center of the four T-fasteners. Saline, air, or a brief insufflation with carbon dioxide from the laparoscopic insufflator will ensure that the needle is intraluminal. A fluid wave should be seen passing though the bowel. If the needle is submucosal, a local infiltration of saline in the bowel wall will be seen, but it will not pass as a fluid wave within the bowel.
- The wire is then advanced through the needle into the bowel while the assistant uses a blunt grasper to direct the wire into the distal limb of the jejunum. The wire can coil in the bowel easily during this step. This may be avoided if the assistant stretches the distal limb as the wire is passed (**FIG 21**).

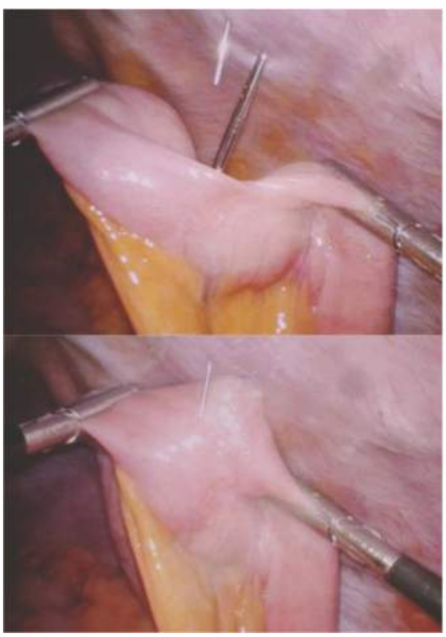

FIG 19 ● The needle is advanced into the small bowel up to the double marking and the T-fastener is then deployed. Gentle traction after deployment will ensure the T-fastener has engaged the bowel properly.

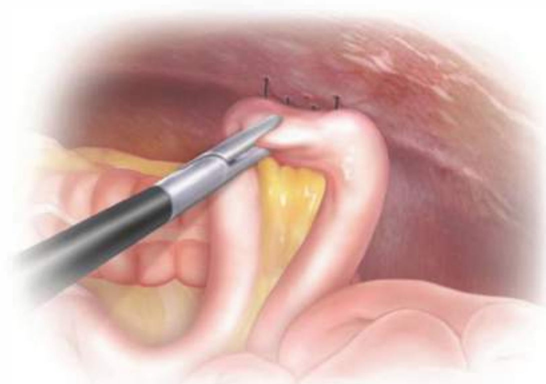

FIG 20 ● A view of the bowel after all four T-fasteners have been placed. Note the small gap to allow visualization during placement of the J-tube.

FIG 21 ● As the wire is being advanced, the assistant can provide gentle traction on the distal bowel to allow the wire to pass easily.

- The needle is then removed.
- Pull up on the fasteners gently so that the jejunal segment is anchored to the abdominal wall. Pull just enough that the bowel makes contact with the wall. The wire should not be visible at this point.
- A skin nick is made at the wire entry site, and the dilator along with the peel-away sheath is passed over the wire, through the abdominal wall, and into the distal limb of the small bowel (FIG 22).
- Care must be taken during this step so that the opposite side of the small bowel is not perforated and that the dilator and sheath should easily follow the path of a gently curved wire.
- The wire and dilator are then removed.
- The J-tube is passed in to the distal limb through the peel-away sheath. The tube should be at least 10 cm into the jejunum. Avoid leaving too much of the tube externally to reduce the risk of it being inadvertently pulled out.
- While an assistant holds the tube in place at the skin, the sheath is cracked and removed by peeling it apart slowly, making certain that the J-tube remains in proper position (FIG 23).
- Inject 10 mL of saline or air through the small port to ensure the tube is patent. This also again allows for conformation that the tube is in fact intraluminal. A fluoroscopy study could be used with similar contrast to that used for a cholangiogram if there is any question regarding the intraluminal nature of the tube.

FIG 22 ● The dilator and sheath are passed over the wire, through the abdominal wall, and into the jejunal lumen.

- At this point, the fasteners, which were pulled up and held gently to anchor the jejunal segment to the abdominal wall, may be secured. Crimping the fasteners on the suture just above the skin bolsters secures them in place (FIG 24). Care must be taken to avoid these fasteners being pulled too tight as this could lead to erosion through the bowel. The tube should not be visible at this point from inside the abdominal cavity.

FIG 23 ● After the dilator and wire are removed, the J-tube is passed through the sheath and into the jejunum. The sheath is then peeled away while the tube is held in place.

- With the T-fasteners entering the skin 2 cm from the tube, there is plenty of room to slide the flange down to the skin and secure it with one or multiple sutures. Be careful not to inadvertently pull the tube out at this step.
- A final evaluation with the laparoscope should reveal no tension or torsion on the bowel as it rests on the anterior abdominal wall.
- The trochar sites are closed in standard fashion and the procedure is complete.
- An abdominal dressing with tape or abdominal binder is placed over the tube to avoid it snagging during patient transport.

FIG 24 ● The T-fasteners are crimped into place at the skin level.

PEARLS AND PITFALLS

Indications	■ Be certain that a J-tube best fits the needs of the patient. Frequently, physicians may request a J-tube when in reality the patient needs a gastrostomy tube (G-tube) or vice versa.
Preprocedure planning	■ Review previous upper abdominal procedures or history of peritonitis that may have scarred another piece of bowel along the proposed track of the J-tube.
Patient position	■ Position the patient supine with the entire abdomen exposed and prepped and draped.
Open G-tube	■ Place the triangle suture and the imbricating sutures carefully to avoid excessively narrowing the lumen of the bowel.
Tube site selection	■ The tube site should be at least 2 cm inferior to the costal margin. ■ Keeping midline retraction on the fascia with clamps while making the incision through the abdominal wall will ensure that the tube does not get kinked as it traverses the abdominal wall once the fascia is closed.
Laparoscopic J-tube	■ Position the patient supine with the right arm tucked to allow a comfortable working space for the surgeon and the laparoscopic assistant on the right side of the patient. ■ Take special care to avoid penetration of the back wall of the jejunum with the needle. ■ Ensure, without question, that the wire and the tube pass intraluminally.
Securing the tube	■ Do not slide the bolster on the tube down tightly against the skin as it may necrose the skin or lead to pulling of the base of the tube through the jejunal wall and into the peritoneum.
Postprocedure care	■ An abdominal binder is helpful for securing the tube and preventing premature or inadvertent removal during patient movement or in a patient with impaired mental status.

POSTOPERATIVE CARE

- Tube feedings can be started the evening of the procedure at a "trophic" or low rate, usually about 10 mL per hour. If the patient tolerates this, they can be advanced by 10 mL per hour every 4 hours until the nutritional goal is reached.
- Care should be taken to avoid the tube catching or pulling while the patient is moving or if the patient's neurologic status is such that they can grab and pull the tube. An abdominal binder or gauze dressing can be used to cover the tube. Hand mittens can be used in the high-risk neurologic patient.
- The patient and his or her caregiver should receive education regarding proper tube care and simple troubleshooting.

OUTCOMES

- Not applicable

COMPLICATIONS

- Clogged tube
  - A clogged tube can be flushed in essentially every case with a small syringe. Due to the laws of hydraulics, the smaller the diameter of the syringe the more pressure. We recommend the smallest syringe that will tightly fit into the opening in the tube. Carbonated acidic beverages such as Coke™ may also aid in clearing an obstruction when they are allowed to sit within the tube for an hour or more.
- Dislodged tube
  - It is imperative that patients and caregivers are taught to reinsert the tube immediately if it becomes dislodged so that the tract does not close. If they are unable to reinsert, then they should immediately go to an emergency department where a smaller catheter could be temporarily advanced into place, preserving the tract that could be later dilated, and the proper tube placed.

- If a tube is reinserted easily without resistance and flushing with water causes no discomfort, the tube may be used per the patient's routine without a conformational radiologic study.
- However, if the replacement is complicated or if there is discomfort with flushing, the tube position should be checked to ensure proper positioning.
- For tubes that have been in place for more than 1 month, it is exceptionally unlikely that the tube would not reenter the same bowel and rest in the same functional position where it was dislodged from.

- Fractured tube
  - If a tube is fractured with or without leakage, it may be temporarily patched with a waterproof occlusive tape such as electrical tape or Duct® tape. This tube should be electively exchanged for a new tube during a regular clinic appointment. If the tube is new or in complex scenarios, it may need to be exchanged over a glidewire by a gastroenterologist, interventional radiologist, or a surgeon.
- Abdominal wall abscess
  - Tube site infections rarely lead to significant abscess formation, but if this occurs, it should be treated with incision and drainage, leaving the wound open as with any infected open wound.
- Small bowel obstruction
  - Small bowel obstruction is most frequently caused by a balloon on the J-tube or from torsion at the tube insertion site.
  - When an obstruction is evident, any fluid in a balloon should be removed and the bowel obstruction treated with nasogastric decompression as with any bowel obstruction.
  - If this does not resolve the obstruction, a computed tomography (CT) scan with oral contrast administered 2 hours prior to the study may be of assistance in assessing torsion of the bowel around the tube insertion site.
  - If torsion is confirmed, an operative exploration either in a laparoscopic or open approach is required to relieve the obstruction.

Chapter 18 Laparoscopic Gastric Bypass

Elizabeth A. Dovec Ronald H. Clements

DEFINITION

- Obesity is a medical condition in which excess body fat has accumulated to the extent that it may have an adverse effect on health, leading to reduced life expectancy and/or increased health problems.[1]
- The body mass index (BMI) is a measurement obtained by dividing a person's weight in kilograms by the square of the person's height in meters.[2]
  - BMI greater than or equal to 30 kg/m^2 is *obesity*.
  - BMI greater than or equal to 35 to 39.9 kg/m^2 is *severe obesity*.
  - BMI greater than or equal to 40 to 49.9 kg/m^2 is *morbid obesity*.
  - BMI greater than or equal to 50 kg/m^2 is *super obesity*.
- Obesity is a leading preventable cause of death worldwide, with increasing prevalence in adults and children. Obesity is one of the most serious public health problems of the 21st century.[3]
- The World Health Organization (WHO) predicts that overweight and obesity may soon replace more traditional public health concerns such as malnutrition and infectious diseases as the most significant cause of poor health.[4] Before the 20th century, obesity was rare[5]; however, in 1997, the WHO formally recognized obesity as a global epidemic.[6] As of 2008, the WHO estimates that at least 500 million adults (>10%) are obese.[7]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients should undergo comprehensive preoperative evaluation and have multidisciplinary support, with attention to psychological issues and dietary intake, for optimum outcome.
- A thorough history should be performed prior to treatment, including a detailed past medical and surgical history, present medications and allergies, family history, social history, and discussions at previous attempts at weight loss.
- Obesity-related comorbidities include, but are not limited to, hypertension, dyslipidemia/hyperlipidemia, diabetes mellitus, obstructive sleep apnea, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), coronary artery disease (CAD), vascular disease, renal failure, urinary stress incontinence, polycystic ovarian syndrome (PCOS), back pain, joint pain, pseudotumor cerebri, and anxiety/depression.

SURGICAL MANAGEMENT

- The goals of the surgical treatment of obesity include
  - Improving health
  - Improving quality of life
  - Increasing the life span
- The American Society of Metabolic and Bariatric Surgery (ASMBS) and National Institutes of Health (NIH) have reached several conclusions about bariatric surgery and formulated a consensus statement. These organizations agree that bariatric surgery is the most effective treatment for morbid obesity.
- Gastric bypass has been the gold standard in the treatment of the morbidly obese (BMI of ≥40 kg/m^2) and severely obese (≥35 to 39.9 kg/m^2) patients with obesity-associated comorbidities. It is the most frequently performed bariatric procedure in the United States.
- A Roux-en-Y gastric bypass is a restrictive and malabsorptive procedure.

Preoperative Planning

- Preoperative education is a vital part to the success of the patient. Patients must be instructed on what to expect both preoperatively and postoperatively.
- All patients at our program undergo a surgical evaluation, medical clearances, insurance requirements, psychological evaluation, nutrition education, online information seminars, and attend a support group prior to their surgery.
- A detailed bariatric diet guideline packet is provided to all patients describing each diet phase. Documented understanding of the dietary expectations is imperative.
- All medications are reviewed and anticoagulation discontinuation is discussed, as applicable.
- Instruction on early ambulation beginning the afternoon of surgery and continuing every 1 or 2 hours while awake thereafter
- Sequential compression devices (SCDs) are on and verified to be functioning prior to the induction of anesthesia. Routine prophylactic subcutaneous anticoagulation administration is not done unless the patient has a known prior thromboembolic event or the procedure is expected to take longer than 2 hours.

Positioning

- The patient is placed on the table in supine position. After satisfactory anesthesia had been administered, the patient is first secured to the bed. A thick, wide strap is placed tightly above the knees and padded well. Two pads are placed under the patient's heels. A footboard is pushed firmly to the patient's feet allowing the feet to turn out slightly but being cognizant not to bow the knees (**FIG 1**).
- The left arm is left out at a 75-degree angle and secured to the arm board with a gauze wrap. If the patient's body habitus allows, the right arm is ideally tucked at the side. The bed is positioned down as low as possible.
- A standing stage is placed on the patient's right side to be used by the operating surgeon. The assisting surgeon stands on the patient's left side.
- A 34-Fr gastric lavage tube is placed in the patient's stomach and allowed to drain. A glove may be placed at the end of the lavage tube to prevent spillage of gastric contents. No other devices except the gastric lavage tube and endotracheal tube should be in the patient's mouth.

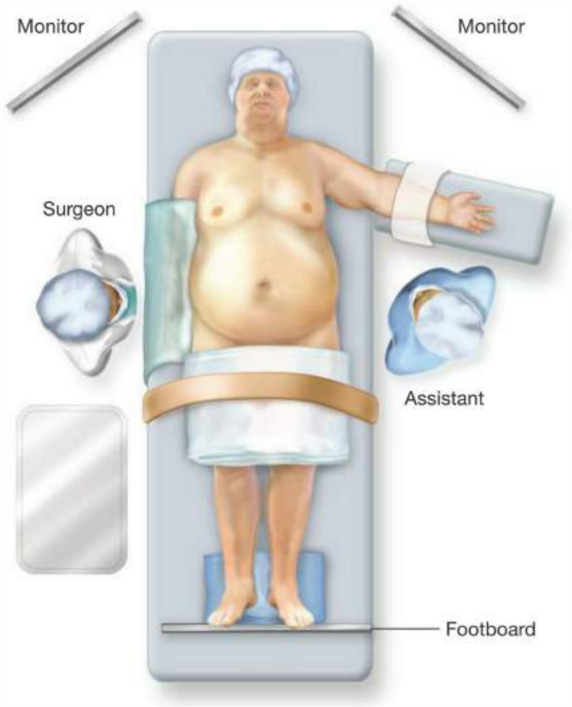

FIG 1 ● Patient positioning.

PLACEMENT OF INCISIONS

- Sixteen centimeters is measured down in the left paramedian position. The skin and underlying fascia is injected with local anesthetic, and a 10-mm visual port is inserted through the left rectus sheath, identifying all layers of the abdominal wall. Pneumoperitoneum is then established. An inspection of the abdomen and pelvis is then performed ensuring there was no injury from the initial trocar placement.
- The remaining five ports are then placed. The first 5-mm trocar is placed just inferior to the xiphoid process and to the left of the falciform for liver retraction. A second 5-mm trocar is placed approximately 2 cm to the right and inferior to the first 5-mm trocar placement. This 5-mm right paramedian port is also placed to the left of the falciform. A 12-mm right paramedian trocar is placed to the left of the falciform approximately one handbreadth from the second 5-mm trocar. A 5-mm left subcostal trocar is placed 2 cm below the costal margin. A final 5-mm trocar is placed 1 or 2 cm below the level of the initial port, as far lateral as possible (FIG 2).

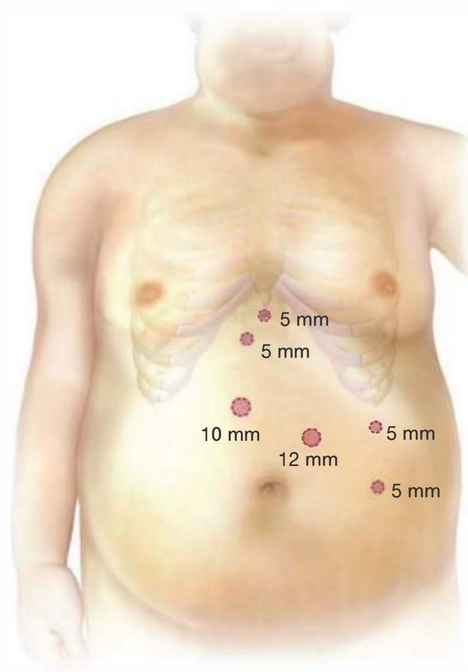

FIG 2 ● Port placement.

LIVER BIOPSY

- A needle biopsy of the liver is obtained because blood tests do not accurately predict the presence, absence, or degree of histologic changes due to fatty liver disease. The liver is elevated by two bowel graspers placed through the left lateral ports to ensure the biopsy needle does not go through the liver and cause injury to underlying structures. Two core biopsies are obtained from the left lateral segment of the liver for pathologic examination for the diagnosis and staging of nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH).

LIVER RETRACTION

- The patient is placed in full reversed Trendelenburg position. The liver is retracted with a locking Allis grasper clamp placed through the subxiphoid 5-mm port and secured to the diaphragm just anterior to the gastroesophageal (GE) junction (**FIG 3**).

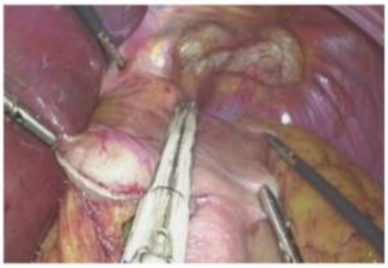

FIG 3 ● Liver retraction and vertical 60-mm stapler.

GASTRIC POUCH CREATION

- With the gastric lavage tube retracted into the esophagus by the anesthetist, the angle of His is exposed and dissected with an ultrasonic dissector.
- Identification, dissection, and primary posterior repair of a hiatal hernia is done at this time, if necessary. Five centimeters is measured down from the GE junction along the lesser curve where the lesser sac is entered immediately adjacent to the lesser curve of the stomach using the ultrasonic dissector to divide branches of the left gastric artery.
- A 45-mm laparoscopic stapling device with appropriate-sized staples is oriented transversely to the lesser curve and fired.
- The 34-Fr gastric lavage tube is advanced to abut this newly placed horizontal staple line. Additional firings of laparoscopic stapling devices are placed parallel to the lavage tube. Complete transaction of the stomach and hemostasis are ensured by inspecting the entire staple line. Once divided, the gastric lavage tube is retracted back into the esophagus.
- The retrogastric and pancreatic adhesions are freed using the ultrasonic dissector to increase pouch mobility (**FIG 4**).

FIG 4 ● Completed pouch.

IDENTIFICATION OF THE LIGAMENT OF TREITZ

- The table is taken out of reversed Trendelenburg and placed in the supine position. The omentum is retracted cephalad, exposing the transverse mesocolon, which is also elevated and retracted cephalad. The proximal jejunum is retracted to expose the ligament of Treitz and the inferior mesenteric vein (**FIG 5**).

FIG 5 ● Identification of the ligament of Treitz.

CREATION OF THE BILIOPANCREATIC LIMB

- Starting at the ligament of Treitz, a marked grasper in the surgeon's right hand is used to measure 40 cm distally (FIG 6).
- The jejunum is divided with a white 60-mm laparoscopic stapling device, with care being taken not to undercut the biliopancreatic or Roux limb mesentery.
- If necessary, further mesenteric division can be accomplished with an ultrasonic dissector.

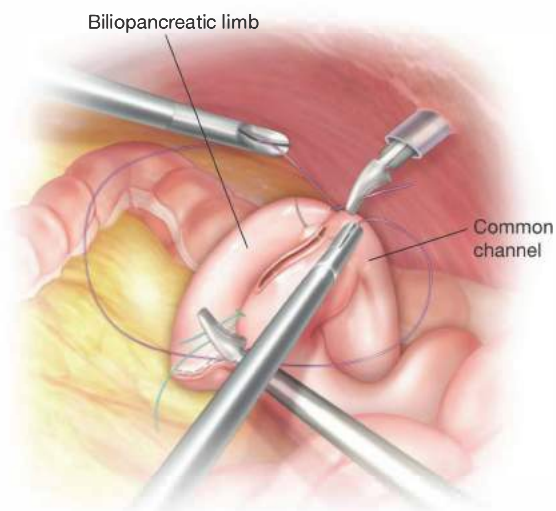
FIG 6 ● Measurement of the biliopancreatic limb.

JEJUNOJEJUNOSTOMY CREATION

- A 2-0 undyed absorbable suture is placed on the tip of the distal jejunum to later identify the Roux limb (FIG 7). The Roux limb is measured using the previous technique with a marked grasper in the surgeon's right hand. A 95-cm Roux limb is created if the patient's BMI is less than 50. A 150-cm Roux limb is created if the patient's BMI is greater than 50.
- The site chosen for the anastomosis is brought into apposition to the proximal jejunum with the cut end of the biliopancreatic limb oriented toward the patient's right side and cephalad to the distal Roux limb.
- A pretied, 24-cm long, 2-0 absorbable suture is placed through the Roux limb and biliopancreatic limb approximately 3 cm from the biliopancreatic tip. This suture will later be used for enterotomy closure.
- A pretied, 26-cm long, 2-0 nonabsorbable suture is placed through the Roux limb and biliopancreatic limb approximately 1 cm from the biliopancreatic tip. This suture will later be used for mesenteric closure.
- An ultrasonic dissector is used to make enterotomies in the biliopancreatic and Roux limbs.

FIG 7 ● Roux limb identification suture.

- A white 60-mm laparoscopic stapling device is placed into the enterotomies to construct a side-to-side jejunojejunostomy. Hemostasis of the staple line is assured.
- The assistant distracts the absorbable and nonabsorbable sutures to orient the enterotomy into a slit rather than a circle. The enterotomy is closed by running the absorbable suture in two layers (FIG 8).



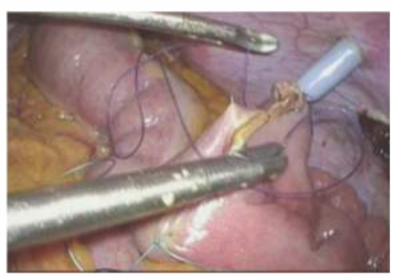


FIG 8 ● Closure of enterotomy defect before starting to sew.

CLOSURE OF MESENTERIC DEFECT

- The mesenteric defect is closed in a running, locking fashion with the previously placed 2-0 nonabsorbable suture (**FIG 9**).

FIG 9 ● Closure of mesenteric defect.

DIVISION OF GREATER OMENTUM

- The omentum is divided vertically, toward the direction of the liver retractor, with the ultrasonic dissector to facilitate bringing the Roux limb up to the gastric pouch. This step can be omitted if the omentum is thin or if the Roux limb is placed in the retrocolic retrogastric position.

CREATION OF GASTROJEJUNOSTOMY

- With the Roux limb in the left upper quadrant, a pretied, 26-cm long, 2-0 absorbable suture is placed between the antimesenteric side of jejunum and posterior wall of the gastric pouch approximately 2 cm from the tip of the Roux limb. The patient is placed in full reversed Trendelenburg position.
- An interrupted, undyed, 2-0 absorbable suture is placed 1.5 cm from the running suture on the antimesenteric side of the Roux limb and posterior wall of the gastric pouch.
- An adequate gastrotomy is created just posterior to the transverse staple line of the gastric pouch using an ultrasonic device.
- An adequate enterotomy is created by entering the Roux limb. Care should be taken not to injure the posterior wall of the jejunum.
- A side-to-side gastrojejunostomy is created by placing the cassette side of the stapler into the stomach and the anvil side into the jejunum. The assistant orients the tip of Roux limb so that it is in line with the stapler as it is inserted to the 20-mm mark. The stapler is closed and fired (**FIG 10**).
- While the assistant continues to hold the tip of the Roux limb in approximation with the gastric pouch, the surgeon places a 2-0 absorbable stitch between the Roux limb and the gastric pouch just beyond the apex of the gastrojejunostomy staple line to suspend the jejunum to the pouch.
- The assistant distracts the absorbable and nonabsorbable sutures to orient the gastrojejunostomy into a slit

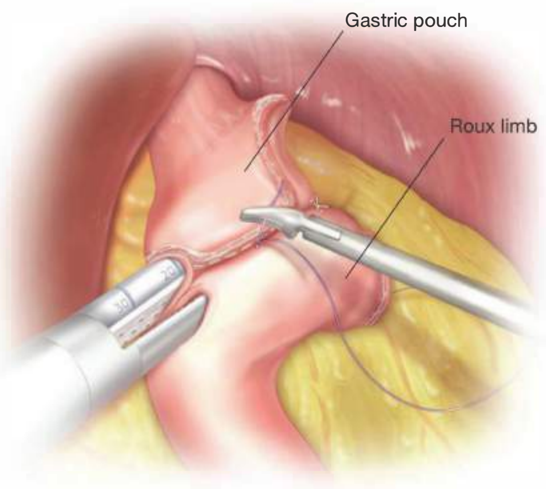

FIG 10 ● Stapling the gastrojejunostomy.

rather than a circle. The first layer of the gastrojejunostomy is closed using the previously placed, pretied 2-0 absorbable suture in a running fashion. The 34-Fr gastric lavage tube is then passed across the gastrojejunostomy to prevent suturing the back wall and to calibrate the opening. After locking the final suture on the first row, the same suture is used to place a second layer running back toward the knot. The anesthetist periodically moves the lavage tube to prevent sewing it into place. The gastric lavage tube is completely removed upon completion of the second layer, and the suture is tied to its tail (FIG 11).

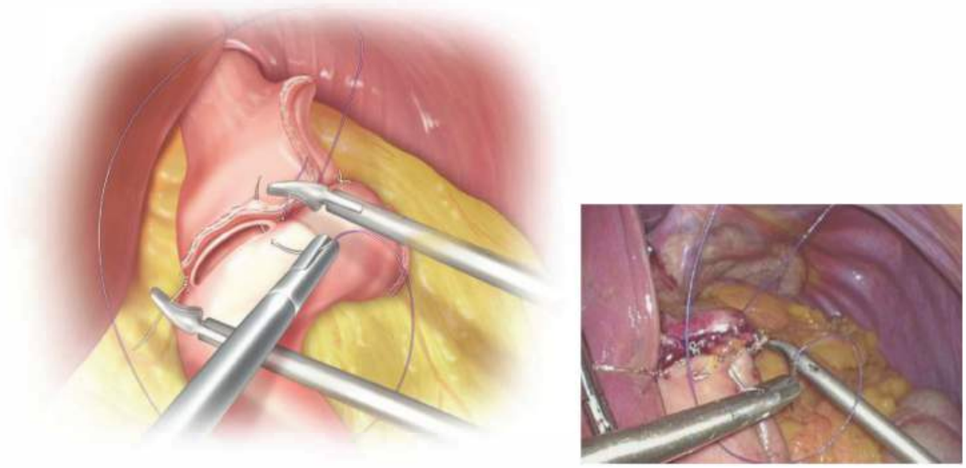

FIG 11 ● Closure of gastrojejunostomy.

CLOSURE OF PETERSEN DEFECT

- The mesenteries of the biliopancreatic, Roux limb, and transverse mesocolon are all secured with a 2-0 nonabsorbable suture to obliterate a potential hernia site at Petersen defect.

UPPER ENDOSCOPY LEAK TEST

- The Roux limb is occluded with a bowel clamp approximately 2 cm distal to the gastrojejunostomy. The assistant retracts the distal gastric remnant and omentum to keep the gastrojejunostomy in view. With the patient placed in Trendelenburg position, the gastric pouch, gastrojejunostomy, and tip of the Roux limb are submerged under saline (FIG 12).
- An endoscope is passed across the gastrojejunostomy to ensure its integrity, hemostasis, and patency. The scope is withdrawn into the pouch, which is inflated

FIG 12 ● Placement of bowel clamp. Submerged anastomosis with light transilluminating the jejunum.

with air from the endoscope. The submerged areas are inspected for bubbling, which, if present, are identified and repaired with 2-0 absorbable suture. The test is then repeated until there is no further leaking observed. The length of the gastric pouch is confirmed by measuring the distance between the gastrojejunostomy and the Z line. The endoscope is removed, saline is aspirated from the abdominal cavity, all instruments are removed, and the trocars are removed under direct visualization to ensure hemostasis.

SKIN CLOSURE

- No fascial sutures are placed in the 10- and 12-mm trocar sites, because radially dilating trocars are used and they are both placed off the midline.
- The skin is closed with 4-0 absorbable monofilament suture in a subcuticular fashion. A waterproof sterile adhesive is placed to close the epidermis.

PEARLS AND PITFALLS

Pearls:
- The use of sterile adhesive allows the patient to shower and have no dressings to change.
- Patients are maintained on proton pump inhibitor therapy for 30 days to reduce the risk of early marginal ulceration.
- Initially, all medications should be administered in the crushed or elixir form.
- Extended-release medications (XR, XL, ER, or EC) often cannot be crushed, broken, or opened and will need to be changed by their prescribing provider to an immediate release or alternate form that can be crushed or opened.
- Daily supplements with an adult strength chewable or liquid multivitamin and at least 1,200 mg of calcium citrate with vitamin D are recommended.
- Long-term dietary goals should include 50 to 80 g of protein per day.

Pitfalls:
- Liquid calories and sweets can cause late dumping syndrome.
- Snacking should be avoided to prevent developing a pattern of eating called "grazing."
- Pregnancy is not recommended in the first 18 months after surgery.
- Birth control pills alone may not be effective for birth control after surgery. Patients are instructed to speak with their gynecologist regarding other methods of birth control.
- Patient's fertility may increase after surgery and weight loss.

POSTOPERATIVE CARE

- Diet
  - Patients remain NPO the night of surgery and are advanced to noncarbonated, low caloric, bariatric clear liquid diet on postoperative day (POD) 1 if they are not tachycardic, tachypneic, or experiencing excessive pain. If the patient tolerates this step, they are advanced to a pureed diet upon discharge home.
- Activity
  - It is imperative that the patient walk on the evening of the operation, because we only use SCDs for deep venous thrombosis (DVT) prophylaxis.

OUTCOMES

- The long-term average weight loss after a Roux-en-Y gastric bypass is 60% to 70% excess body weight (EBW).
- There is usually rapid resolution of comorbidities such as diabetes mellitus, sleep apnea, hyperlipidemia, and GE reflux disease.

COMPLICATIONS

- Early serious complications (<30 days) include gastrointestinal bleeding, bowel obstruction, anastomotic leak, intraabdominal abscess, DVT, pulmonary embolism (PE), wound infection, and mortality; all of which should be less than 1% in experienced centers.
- Late complications (>30 days) include bowel obstruction, anastomotic stenosis, marginal ulceration, gastrointestinal bleeding, cholelithiasis, internal herniation, gastro–gastro fistula, vitamin deficiencies, and mortality.

Chapter 19

Laparoscopic Sleeve Gastrectomy

Ozanan R. Meireles Eric G. Sheu Matthew M. Hutter

DEFINITION

- Sleeve gastrectomy or partial vertical gastrectomy is defined as the creation of tubular, sleeve-shaped, lesser curve–based stomach by resection of the greater curvature of the gastric body and fundus.
- Laparoscopic sleeve gastrectomy (LSG) has been an increasingly popular procedure due to its relative technical simplicity and excellent safety and efficacy profile. With an increased number of insurers now covering the sleeve gastrectomy, the number of LSG performed in the United States has grown rapidly in the last several years.
- LSG was initially performed as the first stage of the biliopancreatic diversion–duodenal switch procedure. However, beginning in 2008, LSG has been performed as a stand-alone bariatric operation, and short- and medium-term follow-up have documented its safety and efficacy.
- In 2010, a Current Procedural Terminology (CPT) code was assigned to the procedure and, more recently, the American Society for Metabolic and Bariatric Surgery has issued a statement with 3- and 5-year data and robust experience acknowledging LSG as an approved primary bariatric procedure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete history and physical examination should be obtained, with particular attention given to history or identification of metabolic disorders such as diabetes, dyslipidemia, and fatty liver disease; cardiovascular disease; obstructive sleep apnea; venous thromboembolism as well as a history of previous abdominal operations.
- Per National Institutes of Health (NIH) consensus guidelines, bariatric surgery is indicated for patients with a body mass index (BMI) greater than 40 or a BMI greater than 35 with obesity-associated comorbidities. Insurers and payers, though, may have other stipulations.
- A detailed nutritional history, including prior attempts at weight loss through dietary, exercise, and medical programs, and psychologic/psychiatric history should be obtained.
- Multidisciplinary evaluation with registered dietitians, psychologists, and medical physicians is critical prior to consideration for any bariatric surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- In the absence of history or physical findings suggestive of upper gastrointestinal (GI) pathology, preprocedural imaging is not mandatory.
- However, symptoms such as dysphagia, early satiety, or odynophagia should prompt further radiologic or endoscopic evaluation.
- In our practice, some find a preoperative barium swallow helpful to rule out gross esophageal motility disorder; assess for hiatal hernias; and exclude mass lesions, stricture, diverticula, and other anatomic abnormalities. Others get a swallow study only if the history and symptoms raise any concerns.
- Subsequent upper endoscopy can then be selectively used to follow up any concerning findings from the swallow study.
- When esophageal dysmotility is suspected based on history or swallow study, preoperative esophageal manometry is obtained.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative laboratory, pulmonary, and cardiac evaluation are performed as indicated by patient history, age, and comorbidities as with other major abdominal surgery.
- Patients should be encouraged to lose as much weight as possible leading up to surgery. We place our patients on a low caloric diet 2 to 3 weeks before surgery in order to decrease the volume and rigidity of the left lobe of the liver, facilitate laparoscopic exposure, and allow for a less technically demanding and safer operation.
- Appropriate antibiotic and venous thromboembolism prophylaxis should be administered in a timely fashion.

Positioning

- The patient is positioned supine or in the split-leg position according to the surgeon's preference. Specialized bariatric beds are available to accommodate the super obese and allow for ergonomic positioning of the patient. The arms and legs should be well secured along with a footboard to allow steep reverse Trendelenburg to facilitate visualization of the left upper quadrant intraoperatively. An orogastric tube should be placed to decompress the stomach after endotracheal intubation.

PORT PLACEMENT

- Initial peritoneal access is obtained using the surgeon's preferred method. Pneumoperitoneum is created, and subsequent ports are placed under direct visualization. Many geometric arrangements for port placement will allow adequate exposure for the operation. In general, five ports in the upper abdomen will allow adequate access and visualization for the operation. These will usually include two working ports for the operating surgeon and ports for the camera, liver retractor, and assistant. At least one 12- or 15-mm trocar is required to allow introduction of a stapler. Two example diagrams of port placement are shown in **FIG 1**.

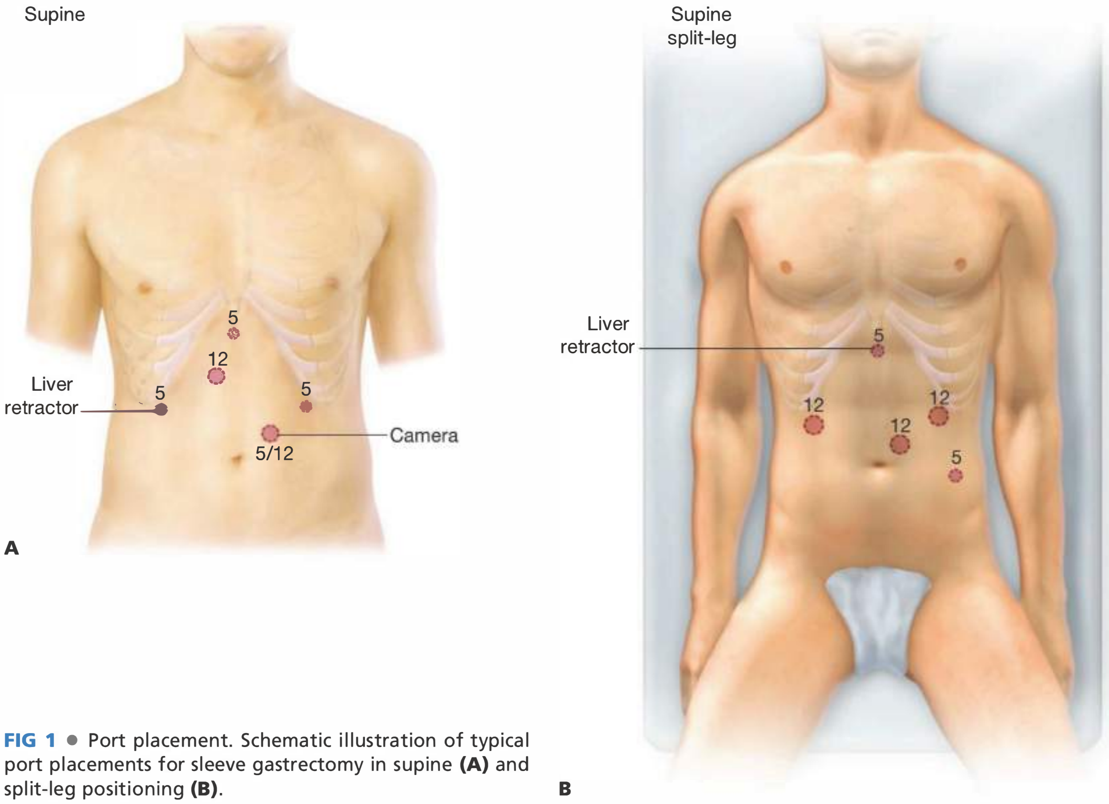

FIG 1 ● Port placement. Schematic illustration of typical port placements for sleeve gastrectomy in supine **(A)** and split-leg positioning **(B)**.

MOBILIZATION OF THE STOMACH

- After exploration of the peritoneal cavity, the patient is placed into steep reverse Trendelenburg position to drop away the intestines and omentum, and a liver retractor is placed to expose the stomach and hiatus.
- The pylorus is identified and the distal margin of the sleeve is measured within 2 to 6 cm proximal to the pylorus (**FIG 2A,B**). The greater curvature of the stomach is mobilized by transecting the gastrocolic ligament and short gastric vessels. An ultrasonic or bipolar vessel-sealing device speeds this dissection (**FIG 3**). Proximally, the vessels are divided up to the highest short gastric, a reliable landmark which often dives posteriorly toward the pancreas (**FIG 4**). We find that complete mobilization of the angle of His from the left crus of the diaphragm and freeing of any lesser sac adhesions to the pancreas or posterior gastric space facilitates subsequent formation of the gastric sleeve. These adhesions are often avascular and can be taken sharply. Complete mobilization to allow adequate resection of the fundus is believed to be a critical step of sleeve gastrectomy.[1]
- The surgeon should look for a hiatal hernia and fix it should it be readily evident. We do not promote the routine dissection of the hiatus to identify a "hiatal hernia" that is not readily apparent.

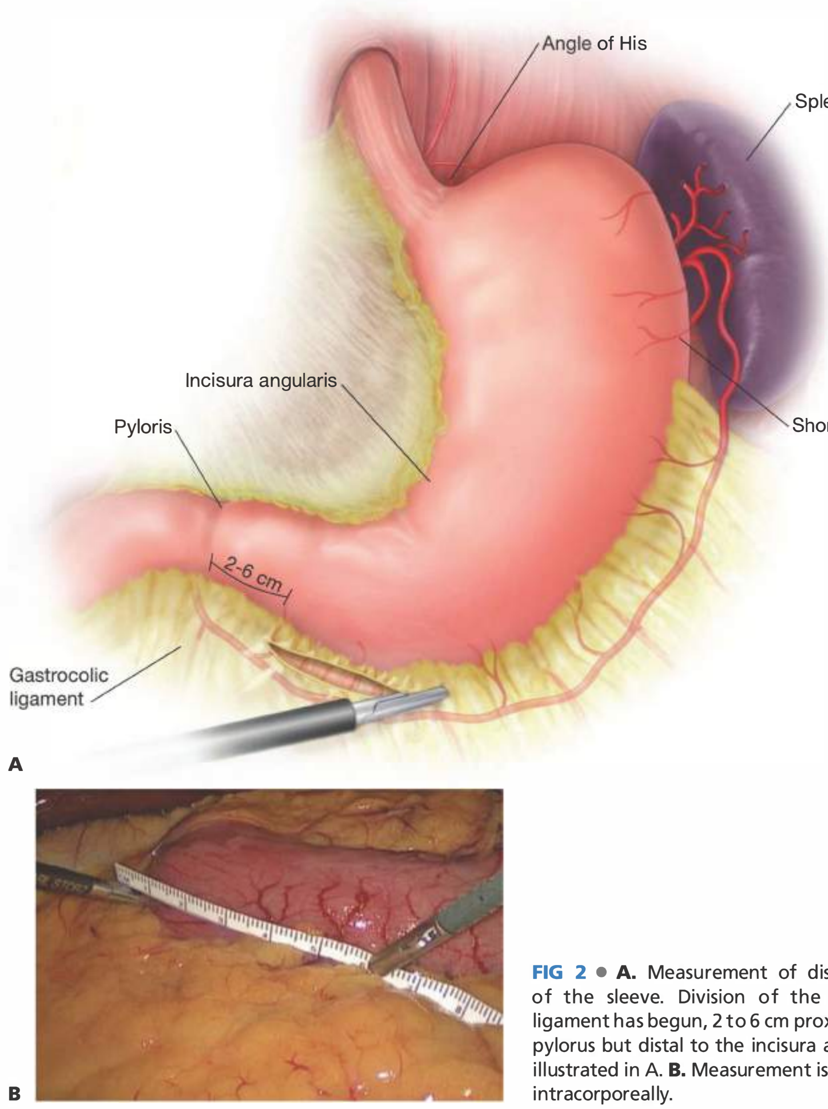

FIG 2 ● **A.** Measurement of distal margin of the sleeve. Division of the gastrocolic ligament has begun, 2 to 6 cm proximal to the pylorus but distal to the incisura angularis as illustrated in A. **B.** Measurement is performed intracorporeally.

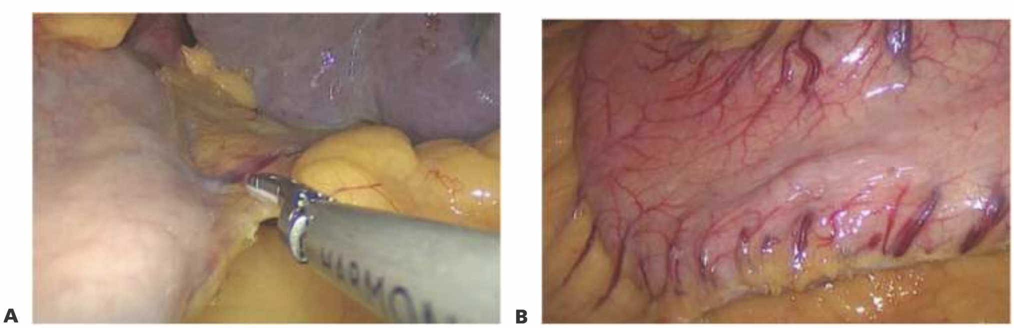

FIG 3 ● Division of short gastrics and gastrocolic ligament. **A.** The gastrocolic ligament and short gastric vessels are divided using an ultrasonic dissector. **B.** Final view of the distal margin of the dissection as previously measured from the pylorus is shown.

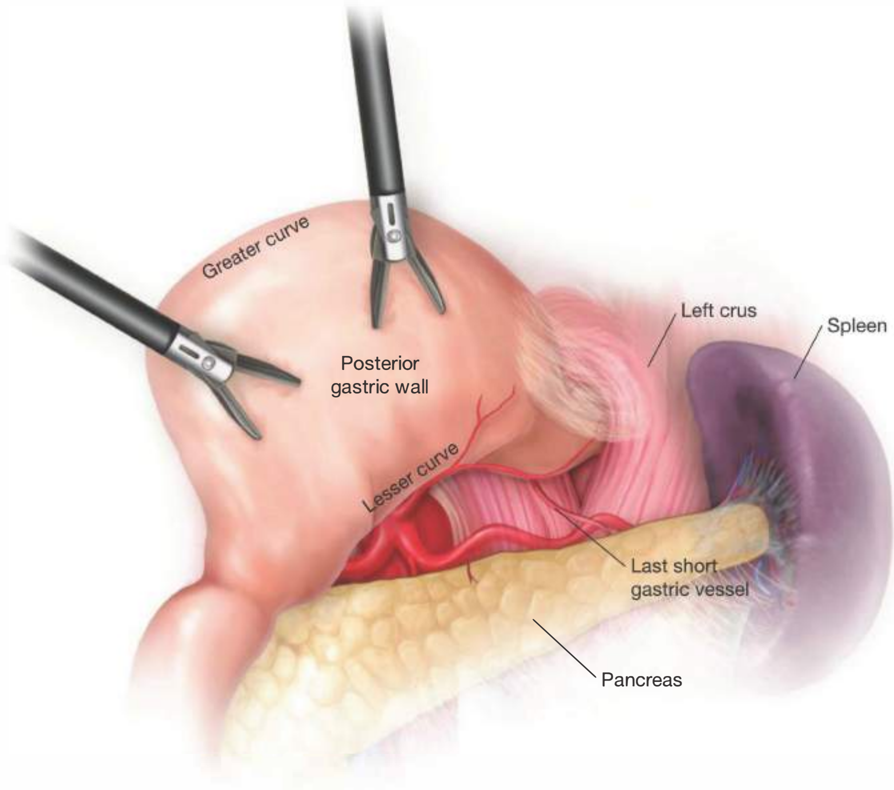
A



B

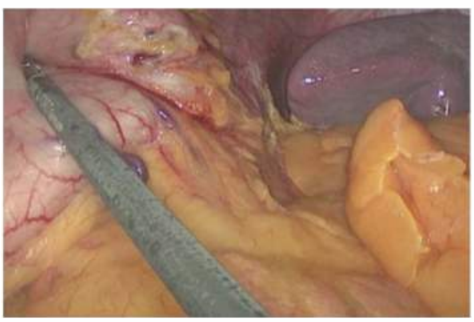


FIG 4 ● **A.** Complete mobilization of gastric fundus from the diaphragm and lesser sac. The last short gastric vessel often dives posterior and into the pancreas and is a reliable anatomic landmark. **B.** The gastric fundus is fully mobilized up to the left crus of the diaphragm, and lesser sac adhesions are dissected to facilitate subsequent stapling.

CREATION OF THE GASTRIC SLEEVE

- Accurate and safe formation of the gastric sleeve is performed using a bougie introduced into the oropharynx, down the lesser curvature, and into the gastric antrum as a guide (FIG 5). Choice of size and type of bougie remains a surgeon's preference. The recent sleeve consensus statement recommended use of a 32- to 36-Fr bougie.[1] Various Maloney dilators or flexible endoscopes may be used as a bougie. Our practice is to use the therapeutic endoscope (36 Fr in caliber) to size the sleeve, which we find helpful to later perform a provocative leak test and examine our staple line endoluminally.
- With the chosen bougie in place, and after confirmation that no other intragastric tubes (e.g., orogastric tubes, temperature probes) remain in place, transection of the greater curvature of the stomach begins 2 to 6 cm proximal to the pylorus using a linear cutting stapler. It is critical to avoid narrowing of the sleeve, particularly at the incisura angularis, and to take equal portions of

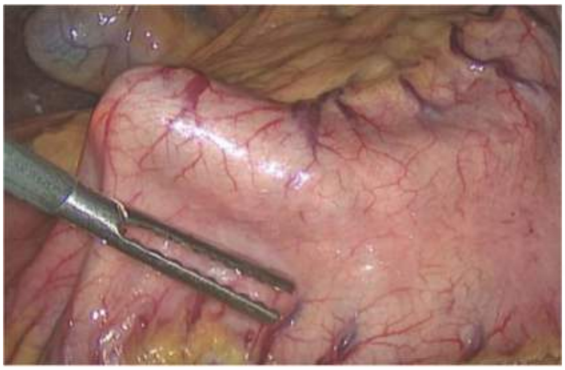

FIG 5 ● Placement of intragastric bougie. A bougie is placed along the lesser curvature into the antrum to guide formation of the sleeve. This illustration shows the use of an endoscope, which is easily manipulated to match the contour of the lesser curvature.

the anterior and posterior walls of the stomach to avoid "spiraling" the sleeve (**FIG 6**).

- The gastric sleeve formation is completed with subsequent fires of the linear stapler along the bougie, thus resecting the greater curvature of the stomach. With each staple fire, continued care is made to assure that equal amounts of anterior and posterior gastric wall are resected (**FIG 7**). It is often helpful to have the assistant maintain lateral traction on the lateral aspect of the stomach and, at times, toward the posterior aspect. The final staple line should veer off the gastroesophageal junction as this area is particularly susceptible to leaks.[1] In **FIG 8**, a laparoscopic and endoscopic view of the completed sleeve is shown.
- Staple loads should be chosen as appropriate for the thickness of the tissue. The gastric wall is generally thickest on the initial distal staple line at the antrum. The use of staple line reinforcement is controversial. There is some evidence that staple line reinforcement may decrease the incidence of bleeding complications; however, any impact on leak rates is less clear. Several absorbable and permanent staple line buttressing materials are available. Some oversew an unreinforced staple line routinely, which should be performed with the bougie in place to prevent narrowing of the gastric conduit if it is done. Others prefer not to use reinforcements, or to routinely oversew, due to concerns of excessive material where staple lines cross, the added expense, and unclear benefit or potential harms from those practices.

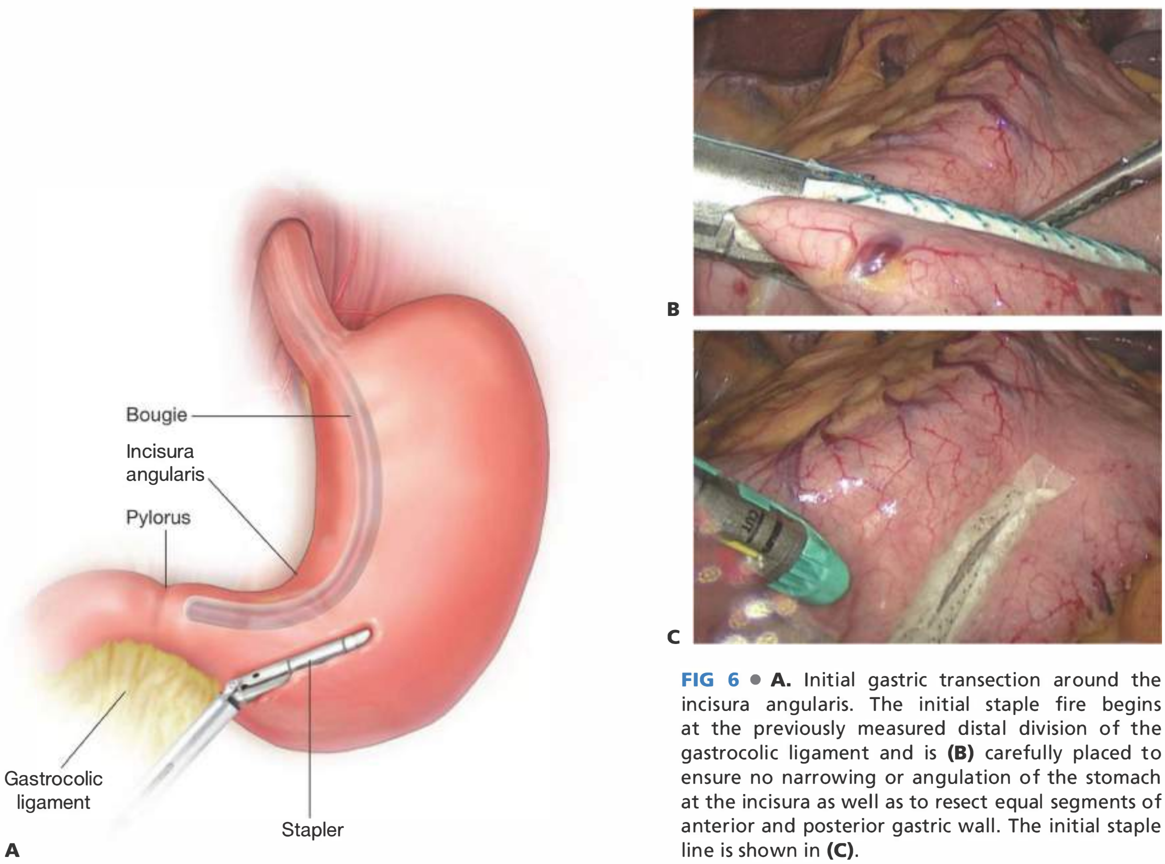

FIG 6 ● **A.** Initial gastric transection around the incisura angularis. The initial staple fire begins at the previously measured distal division of the gastrocolic ligament and is **(B)** carefully placed to ensure no narrowing or angulation of the stomach at the incisura as well as to resect equal segments of anterior and posterior gastric wall. The initial staple line is shown in **(C)**.

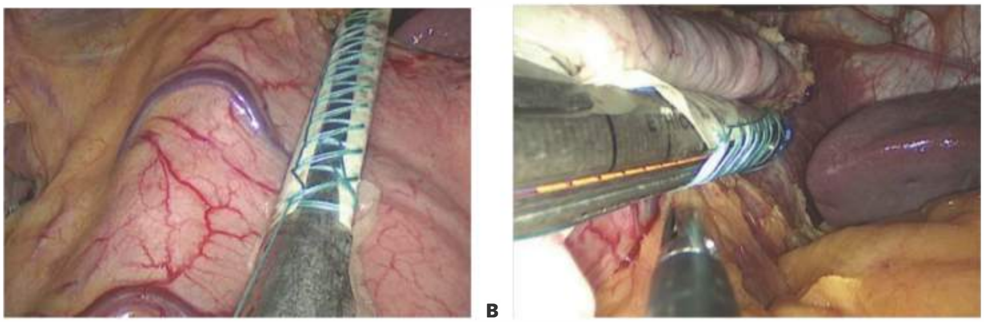
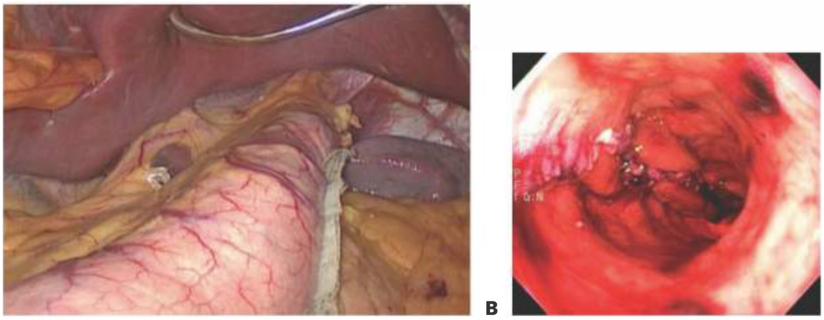


A B

FIG 7 ● Transection of greater curvature of stomach. Subsequent gastric transection is performed parallel to the lesser curvature, along the bougie, and aimed toward the angle of His. In these photographs, staple line buttressing material is used. The placement of the stapler is examined anteriorly **(A)** and posteriorly **(B)** to ensure equal alignment of the gastric walls.



A B

FIG 8 ● Laparoscopic **(A)** and endoscopic **(B)** view of completed sleeve gastrectomy.

PROVOCATIVE LEAK TEST

- A provocative leak test can be performed after the sleeve is created, either with gas or liquid dye. Our practice is to submerge the staple line in saline irrigation while insufflating the sleeve with carbon dioxide (CO_2) via the indwelling endoscope and clamping the distal stomach. A laparoscopic assessment for evidence of leaks or bubbles is done, and simultaneously, an endoluminal examination is performed to exclude intraluminal bleeding and to assess the gastric conduit for any narrowing or kinking. Alternatively, insufflation or instillation with distention via a nasogastric or other device can be done with CO_2, air, or colored liquid; however, oxygen alone should not be used.
- Hemostasis of the staple line and divided greater curvature vessels is ensured. Although some surgeons choose to recreate the gastrocolic ligament by suturing the omentum to the staple line in an effort to prevent torsion of the sleeve, we do not routinely do that. The gastrectomy specimen is removed, which can usually be accomplished using a protective bag without enlarging any incisions. The bougie, liver retractor, and trocars are removed under direct vision; pneumoperitoneum is released; and closure is performed of the extraction site with a fascial closure device.

PEARLS AND PITFALLS

- Secure positioning of the patients extremities with a footboard is imperative to allow steep reverse Trendelenburg to optimize laparoscopic visualization.
- During division of the gastrocolic ligament and short gastrics, care should be taken to avoid injury to the gastroepiploic vessels and spleen.
- It is important to assure that the proximal fundus is completely mobilized by dissecting up to the left crus and taking the highest short gastric vessel.
- Freeing of lesser sac adhesions to the pancreas and posterior gastric stomach and release of the angle of His from the left crus give additional mobility of the greater curve to allow precise placement of the stapler for greater curvature resection.
- A 32- to 40-Fr bougie should be placed along the lesser curvature of the stomach to aid in sizing of the gastric sleeve.
- Care should be taken to avoid narrowing the gastric conduit, particularly at the incisura angularis.
- Accurate placement of each stapler ensuring equal resection of the anterior and posterior gastric walls is critical to avoid spiraling of the sleeve, which could result in postoperative obstruction.

POSTOPERATIVE CARE

- Postoperative care is similar to other bariatric patients. Early postoperative ambulation, adequate postoperative analgesia, and frequent pulmonary toilet are important to help avoid pulmonary and thrombotic complications. Appropriate perioperative antibiotics and venous thromboembolic prophylaxis are continued. We keep our patients NPO on the first postoperative evening, but allow oral intake of important medications.
- The use of routine postoperative upper GI series is of debatable value. It is our practice to routinely obtain a Gastrografin and barium swallow examination on postoperative day 1 (**FIG 9**). We find this study helpful not only to exclude leak or obstruction but also to obtain a baseline study of each patient's anatomy for future reference.
- Following the swallow study, the patient is started on a clear liquid diet and oral analgesics. We discharge our patients on either postoperative day 1 or 2. We maintain our patients on a liquid diet for 9 to 14 days and then introduce soft foods. Multivitamin supplementation is started on discharge, and we keep our patients on acid suppression in the perioperative period.

FIG 9 ● Postoperative barium study of a sleeve gastrectomy.

OUTCOMES

- Early data shows that the LSG is a safe and effective bariatric and metabolic operation, with outcomes positioned between the adjustable gastric band and Roux-en-Y gastric bypass (GBP).[2] Weight loss and improvements in comorbid conditions such as diabetes, sleep apnea, hyperlipidemia, and hypertension with LSG are significantly better than the gastric band, but do not quite reach the levels seen after GBP.
- Similarly, rates of perioperative complications for the sleeve gastrectomy lie between the band and the bypass. Overall, the incidence of death, serious complication, readmission, and reoperation in the early postoperative period are equivalent for the LSG and the bypass and higher than for the gastric band. Most studies have also shown a trend toward decreased rates of specific complications for the LSG compared to the bypass—for example, obstruction, stricture, and anastomotic ulcer.[2,3] Although promising, good quality data are still lacking on the long-term effectiveness and safety of the LSG.

COMPLICATIONS

- The most frequent complications after LSG are bleeding, urinary tract infections, superficial site infections, and deep venous thromboses (DVTs). They are similar to other bariatric operations in their incidence, diagnosis, and treatment.
- A few LSG-specific complications merit further discussion. Leaks occur overall at a similar incidence as the GBP. Sleeve leaks can occur both early and late and are most often found at the proximal staple line near the angle of His. Principles and treatment of LSG leaks are similar to other abdominal leaks, including control of sepsis with wide drainage and antibiotics and nutritional optimization. Treatment of leaks after sleeve gastrectomy can be particularly challenging, as the intact pylorus and gastric conduit itself often create a relative distal obstruction and enteral access for nutritional supplementation is more problematic. However, unique to management of LSG leaks is the use of covered stents, which can be placed endoscopically and can be useful to control leaks in combination with intraabdominal drainage.

- Although extremely infrequent, obstruction after sleeve gastrectomy can occur, and unlike the GBP, they are not due to internal hernia, as the intestinal spaces are not disturbed, but more commonly due to narrowing or twisting of the gastric conduit. Again, upper endoscopy can be particularly helpful for diagnosing this problem and treatment with endoscopic dilation.
- Severe gastroesophageal reflux has also been described following LSG. Management should include fluoroscopic and endoscopic imaging of the sleeve to assess and treat any defined obstruction. Recalcitrant reflux may even require reoperation with sleeve conversion to Roux-en-Y GBP.

Chapter **20** Laparoscopic Gastric Band

Darren S. Tishler Pavlos K. Papasavas

DEFINITION

- The laparoscopic adjustable gastric band (LAGB) is a Food and Drug Administration (FDA)–approved, implantable medical device for the treatment of morbid obesity and obesity-related medical comorbidities. The adjustable gastric band (AGB) consists of an adjustable saline-filled annular balloon, a segment of tubing, and a subcutaneous access port (**FIG 1**). This simple hydraulic system is placed around the upper portion of the stomach, just distal to the gastroesophageal (GE) junction, to create a small (approximately 30 mL) stomach pouch. The subcutaneous port is placed on the abdominal wall fascia and allows for the band stoma area to be adjusted by the addition or removal of saline solution using a noncoring needle. The AGB restricts the amount the stomach can accommodate to varying degrees, depending on the fluid volume in the band. The AGB helps to slow the progression of food from the small upper pouch to the distal stomach as well as possibly stimulating the production of gastric peptides and neuronal pathway signals related to satiety.
- The AGB differs from other bariatric procedures in three main ways: It is adjustable, reversible, and involves no cutting or stapling of the stomach.
- The AGB is an exclusively restrictive procedure, unlike other malabsorptive procedures such as the Roux-en-Y gastric bypass (RYGB) (see Part 2, Chapter 18) and the duodenal switch.
- Patients who undergo AGB are at a low risk for developing major nutritional and vitamin deficiencies. Although medication pill size can be a factor, the AGB does not have any effect on the absorption of medications and other nutritional supplements.

FIG 1 ● AGB system.

PATIENT HISTORY AND PHYSICAL FINDINGS

- No validated algorithm exists to prescribe the most appropriate bariatric procedure.
- Although the AGB is indicated for patients with body mass index (BMI) of 30 to 40 kg/m^2 with medical comorbidities or BMI greater than 40 kg/m^2 with or without medical comorbidities, best results are often obtained in patients with lower BMI.
- AGB typically produces best results in patients who are ambulatory and capable of performing regular aerobic activity.
- In patients who fail to achieve adequate weight loss with AGB, the two most common factors are lack of exercise and depression. These issues, when present, need to be addressed both prior to surgery and during the requisite aftercare.
- Ideal patients for AGB have an understanding of the importance of regular follow-up visits for band adjustments. Several studies have demonstrated an association between number of aftercare visits and weight loss. Patients require, on average, six to eight visits in the first year to achieve optimal results with the AGB procedure.[1]
- Although patients with long-standing severe gastroesophageal reflux disease (GERD) symptoms may improve immediately after the placement of an AGB, long-term tolerance of restrictive procedures can be a problem in this subset of patients.
- Allergies must be assessed, as some patients could rarely experience adverse reactions to the materials in the band.
- In patients with a history of autoimmune disease, gastric banding procedures are contraindicated at this time by the FDA.[2] However, several studies have demonstrated both safety and efficacy of gastric banding in this patient population.[3] Contraindications to adjustable gastric banding are listed in Table 1.

Table 1: Contraindications to Adjustable Gastric Band Placement

Absolute Contraindications	Relative Contraindications
• Uncontrolled psychiatric disease • Current substance or alcohol abuse • Current history of anorexia or bulimia • Achalasia • Prior GE junction surgery (fundoplication, Heller myotomy)	• Cigarette smoking • Severe GERD • Gastroparesis • Esophageal dysmotility • Autoimmune disease • Prior bariatric surgery

GE, gastroesophageal; GERD, gastroesophageal reflux disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- **Barium upper gastrointestinal (UGI) fluoroscopic evaluation** is obtained in all of our patients prior to restrictive procedures to rule out the possibility of a hiatal hernia and as a screening tool for functional and structural esophageal disorders.
- **Routine diagnostic endoscopy** is not required in all patients prior to placement of the AGB. However, it can be of use in patients with an abnormal UGI study to confirm findings of esophageal or upper gastric abnormalities or other unusual anatomy (i.e., diverticulum, paraesophageal hernia, Schatzki's ring).
- **Esophageal function testing** is a useful adjunct in patients with a suspected esophageal motility disorder. Patients with significant esophageal dysmotility or conditions such as achalasia and diffuse esophageal spasm should not be considered for adjustable gastric banding due to the high risk of long-term band intolerance.

SURGICAL MANAGEMENT

Preoperative Planning

- LAGB should be performed at a multidisciplinary bariatric surgery program or center.
- The surgeon must be comfortable with laparoscopic intracorporal suturing and procedures of the GE junction. Familiarity and preferably comfort with other bariatric surgical procedures is required.
- Informed consent for the procedure should include a comprehensive discussion of alternative bariatric surgical procedures, need for long-term follow-up and adjustments, and discussion of risks (Table 2).
- A preoperative very low calorie diet (VLCD) is used to deplete hepatic glycogen stores and reduce liver volume to facilitate UGI exposure. Surgery is postponed for patients with rapid weight gain just prior to the scheduled procedure.

Positioning

- The patient is positioned supine with both arms extended. A footboard and thigh straps are used to secure the patient to the operating table.
- Reverse Trendelenburg position helps to expose the upper abdomen, and steep positioning is often needed for patients with a large amount of omentum and upper abdominal fat.
- The stomach is decompressed immediately after intubation with an orogastric tube. Deep muscle relaxation aids the exposure of the GE junction.
- The surgeon stands to the patient's right with an assistant to the left.
- During the setup for the procedure, the scrub assistant will prepare the band per the manufacturer recommendations to flush any air from the system.
- Prophylactic antibiotics are given immediately prior to incision. In addition, mechanical and pharmacologic deep vein thrombosis (DVT) prophylaxis is used.

Table 2: Risks of Adjustable Gastric Banding

General/systemic	Infection, bleeding, venous thromboembolism, death Dehydration, inadequate weight loss, weight regain, nutritional deficiencies
Device related	Device intolerance Prolapse Erosion Dysphagia/reflux/vomiting/regurgitation Port leakage/tubing disconnection

ENTRY TO ABDOMEN AND EXPOSURE

- Laparoscopic exposure to the abdomen is obtained using an optically guided trocar in the left paramedian position approximately 3 to 5 cm below the costal margin. Either a 30-degree, 45-degree, or deflectable-tip camera is used.
- Additional trocars are placed with a 12- or 15-mm trocar to accommodate the AGB insertion into the abdomen. Precise positioning of trocars ensures appropriate angle for the placement of the AGB around the upper stomach (**FIG 2**).
- A Nathanson or similar liver retractor is placed just above the GE junction to retract the left lobe of the liver. Upward (anterior) traction on the liver retractor helps to visualize the phrenoesophageal ligament and proximal gastric anatomy. A solid and strong mounting clamp for the retractor greatly enhances the exposure. In some cases, an assistant pulling anteriorly on the retractor can facilitate exposure on a patient with both hepatomegaly and a large amount of fat around the GE junction.

TECHNIQUES

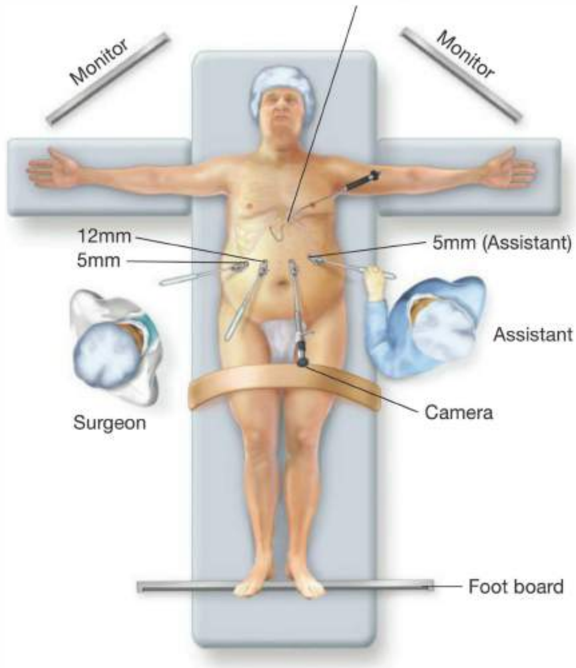

FIG 2 ● Positioning and trocar placement. Careful placement of the trocars facilitates proper placement and orientation of the AGB.

DISSECTION

- The hepatogastric ligament (pars flaccida) is opened using hook electrocautery or ultrasonic shears. Care must be taken to not injure a replaced or accessory hepatic artery.
- The anterior GE (Belsey's) fat pad is either lifted from the proximal stomach or removed altogether. There are often small branch vessels arising from the left gastric artery within this fat.
- The angle of His (junction of greater curvature of stomach and esophagus) is minimally dissected to free the stomach from the diaphragm. This can be performed either bluntly or with hook electrocautery. Inferior traction on the fundus by the assistant facilitates this exposure (**FIG 3**).
- If a small hiatal hernia is seen, it should be repaired anteriorly after reduction and gentle mediastinal dissection. Larger hiatal hernias may require a traditional posterior repair.
- A small incision is made with electrocautery low down on the right crux of the diaphragm, at the point where a small band of fat crosses the crux (**FIG 4**). Care must be taken to identify the vena cava prior to this dissection. Exposure of this region is facilitated by the assistant providing gentle lateral (leftward) retraction of the lesser curvature of the stomach.

FIG 3 ● Dissection of angle of His.

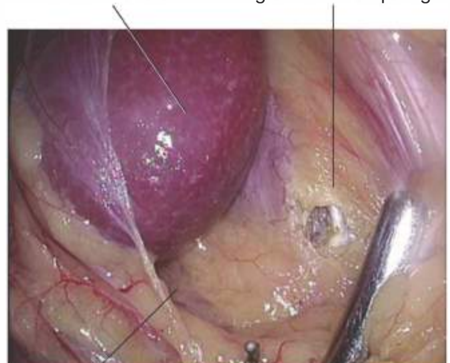

FIG 4 ● Exposure of right crux of diaphragm. Note lateral retraction of lesser curvature of stomach.

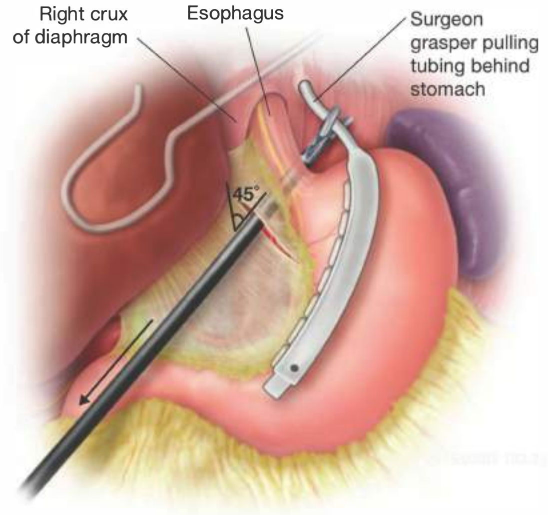
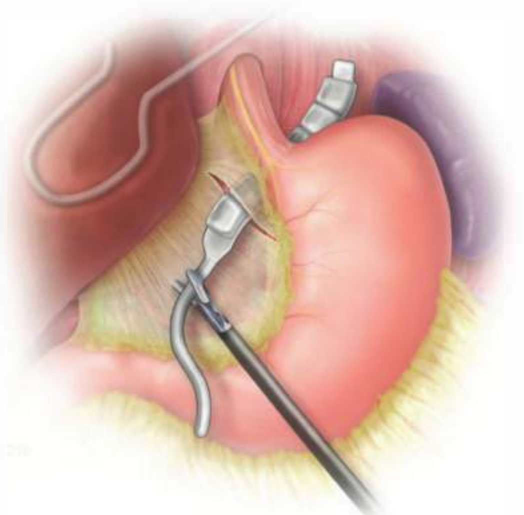
PLACEMENT OF ADJUSTABLE GASTRIC BAND

- Either a long blunt grasper or specialized curved instrument is passed behind the upper portion of the stomach from right to left at a 45-degree angle to the long axis of the body (**FIG 5**). There should be no resistance to the passage of this instrument and it should be observed exiting exactly at the point where the angle of His dissection was made. Care must be taken to not perforate the stomach or esophagus posteriorly during this step of the procedure.
- The band is grasped and brought behind the stomach using the grasper just placed behind the stomach. The orientation of the band for placement (band first or tubing first) is determined based on which brand of band is selected.
- The AGB is buckled per manufacturer instructions (**FIG 6**). The band should sit loosely on the stomach when buckled and be able to rotate easily. If a gastric tube was used to help identify the GE junction, it should be removed at this time.

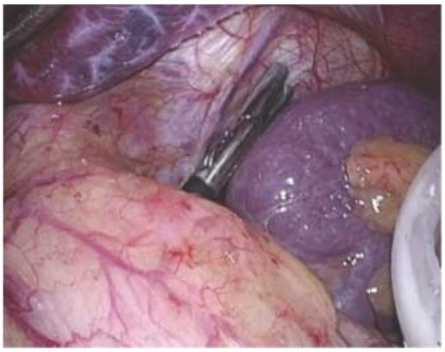
FIG 6 ● Band is buckled after placement around upper stomach.



A



B



C

FIG 5 ● **A,B.** Grasper placed behind upper stomach at 45-degree angle to grasp tubing and bring unbuckled band behind stomach. **C.** Intraoperative view.

TECHNIQUES

GASTROGASTRIC PLICATION

- A series of gastrogastric sutures are then placed from lateral (left) to medial (right) (**FIG 7**). Nonabsorbable sutures can either be placed in an interrupted or running fashion. The entire lateral and anterior portions of the band should be covered stopping at the buckle. Anywhere from two to four sutures may be needed to complete this step of the procedure.
- Recently, some surgeons have begun to place additional anterior gastric plication sutures below the level of the AGB to possibly (1) improve restriction and weight loss and (2) reduce the incidence of band prolapse.

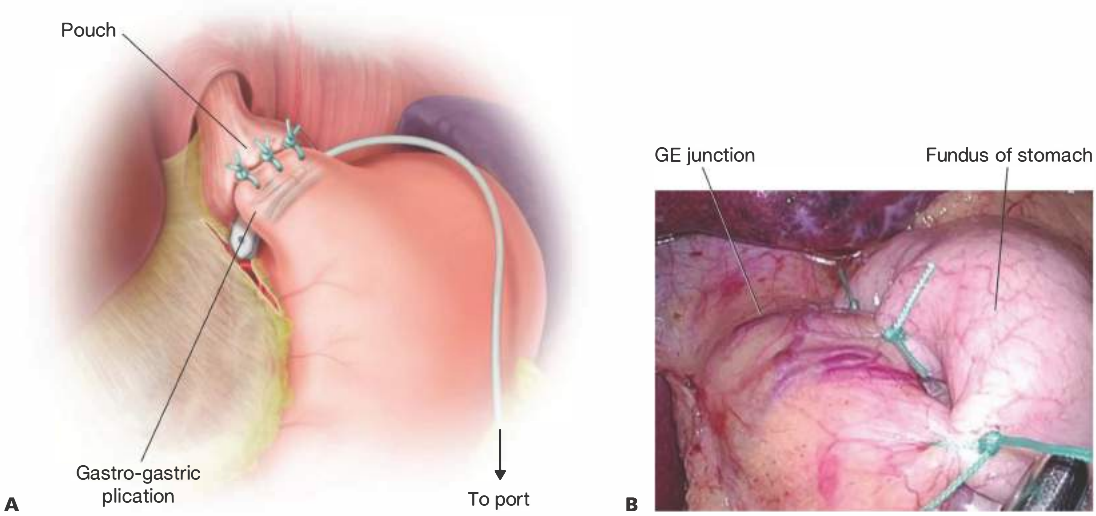


FIG 7 ● **A,B.** Gastrogastric plication sutures. Stomach folded over and laterally and anteriorly. GE, gastroesophageal.

PLACEMENT OF SUBCUTANEOUS ACCESS PORT

- Prior to removal of the trocars, the tubing from the band is exteriorized, trimmed, and connected to the access port. Excessive tubing length should not be left in the patient's abdomen to prevent the possibility of the tubing causing a bowel obstruction. The port is affixed to the abdominal wall on the rectus muscle with care that the port is not placed directly under the costal margin or in a position where it will be aggravated by the patient's clothing. Most surgeons place the port in either the right or left upper quadrant.
- The port can be affixed to the fascia using one of three techniques.
  - The port can be attached to a small disc of mesh and then placed in a small, tight subcutaneous pocket directly on the fascia without any suturing.
  - The port can be attached using interrupted nonabsorbable sutures placed directly into the anterior fascia.
  - A proprietary port applier can be used to affix the port directly to the fascia.
- Care needs to be taken to ensure that the fascia is clear of fat for proper port adherence.
- Scarpa's fascia is closed over the port prior to subcuticular closure of the skin.
- Band adjustment or "prefilling" is generally not required, as the band tends to be tight during the first few postoperative days due to gastric edema.

ALTERNATIVE BAND PLACEMENT TECHNIQUES

- Both single-incision and dual-incision techniques have been described for the placement of AGBs. The authors of this chapter do not perform the procedure using these techniques. However, if such a technique is desired, it requires the ability to
  - Place the band in the same position as in a multiport operation
  - Not jeopardize the exposure of the critical landmarks for the procedure
  - Allow for uncompromised suturing of the gastrogastric plication sutures.

PEARLS AND PITFALLS

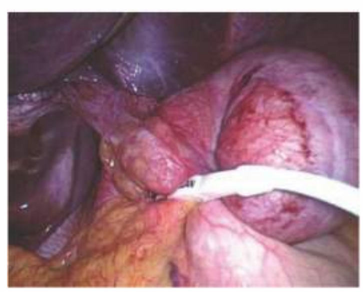
Vitamin supplementation	■ Daily multivitamins, calcium; vitamin B_{12} generally not required
Hiatal hernia repair	■ Always look for and repair at time of surgery.[4] A "dimple" at the hiatus warrants further investigation.
Port mesh fixation	■ Port can be affixed to abdominal wall by sewing a small disc of polypropylene mesh to the port and placing the port on anterior abdominal wall fascia with minimal dissection
Follow-up and adjustments	■ Optimal adjustment critical for success ■ Frequent aftercare visits are needed for best results.
Upper GI contrast swallow study	■ Perform annually and when patient is having difficulty achieving optimal band fill volume
Foods to avoid	■ Dry crumbly foods: chips, crackers, cookies, cakes, pretzels ■ Liquid calories: ice cream, alcoholic drinks, milk, soft drinks

POSTOPERATIVE CARE

- Patients are typically discharged within 24 hours. Patients with low BMI, uncomplicated procedures, and no evidence of obstructive sleep apnea can be safely discharged the day of surgery.
- Venous thromboembolism (VTE) prophylaxis is continued until discharge in all patients and postdischarge in high-risk patients.
- A baseline water-soluble UGI swallow study is selectively obtained on postoperative day 1. This study should demonstrate flow of contrast through the band with minimal restriction. The band itself should lie at approximately 45 degrees to the vertical axis of the body (**FIG 8**). Failure of contrast to pass through the band is usually due to postoperative edema and will resolve within 24 to 72 hours in most cases. Alternatively, a plain upper abdominal x-ray can be obtained in patients already able to tolerate liquids. This baseline image is important as a comparison at a later date if a prolapse is suspected (change in band orientation) (**FIG 9**).
- Sips of water are started on the day of surgery. Sugar-free clear liquids are started on postoperative day 1. Sugar-free full liquid diet is progressed to soft diet over the first 2 weeks after the procedure, and a general bariatric diet is begun 3 to 4 weeks after surgery. Bread, rice, pasta, and fibrous meats are avoided initially.
- Patients are cautioned about the signs and symptoms of dehydration prior to discharge from the hospital. Intravenous (IV) fluid is continued until just prior to discharge to help minimize early dehydration.
- Like other bariatric surgery procedures, good outcomes with adjustable gastric banding require adherence to a regimented diet, daily aerobic exercise, and long-term support and follow-up. However, the AGB also requires regular adjustments for optimal weight loss and comorbidity resolution.
- Patients are seen for a postoperative check 2 weeks after surgery. Wounds are inspected and diet progression is reviewed.
- Patients are evaluated for the following on each visit:
  - Presence of hunger between meals
  - Ability to feel satisfied after eating a small meal
  - Meal size
  - Weight loss since last visit

FIG 8 ● Abdominal radiograph demonstrating normal band orientation.

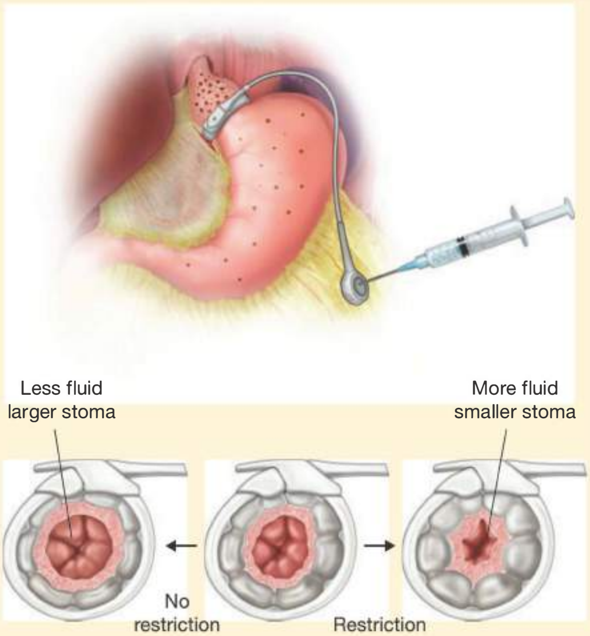
A



B

FIG 9 ● **A,B.** Large prolapse of AGB. Note flattening of band orientation.

Table 3: Band Adjustments



Remove fluid (too tight)	Optimal fluid	Filled (too tight)
Hunger	Small meals	Poor food choices
Large meals	Optimal weight loss	Regurgitation
Poor weight loss	Satiety	Discomfort while eating
	Patient satisfaction	Poor weight loss
		Night cough or GERD

GERD, gastroesophageal reflux disease.

- Patients should lose between 0.5 and 2 lb per week with an optimally adjusted band. Large meals, hunger, and poor weight loss are indications to tighten the band. Small meals, satiety, and optimal weight loss indicate a well-adjusted band. Finally, maladaptive eating behaviors (cravings for dry crumbly foods, sweets, ice cream, and soups), GERD, and nighttime coughing are signs that the band is too tight. See Table 3 for guidelines.

Band Adjustments

- Once determined that an adjustment is needed, the patient is placed in the supine position. Arms crossed behind the head or across the chest can help tense the abdominal musculature to facilitate port access. The port is located, and the area is cleaned with an alcohol swab. The patient is asked to perform an abdominal "crunch" or partial sit-up to elevate the port.
- A noncoring 20-gauge (Huber) needle is used for port access. The needle is placed on a syringe containing sterile saline to prevent air from being introduced into the system.
- The port is stabilized between the thumb and index finger with the nondominant hand (**FIG 10**). Care is taken to not redirect the needle once placed under the skin, as this leads to a bending of the needle. Local anesthetic is generally not necessary.
- Once the port is accessed, a small amount of fluid is drawn back into the syringe to confirm entry into the port. Although some surgeons remove all fluid from the port prior to an adjustment, this step is not routinely necessary, as fluid can simply be either added or removed.
- By quickly removing the needle, leakage from the self-sealing port is prevented.
- Adjustments can be performed under fluoroscopy. Proponents of this technique note that optimal adjustment can be obtained faster and overtightening of the band can be prevented.
- Patients need to be able to swallow water with minimal or no restriction prior to leaving the office after adjustment. A liquid diet for 1 to 3 days after the adjustment minimizes need for early readjustment. Patients should return to the office if progressive dysphagia, pain, cough, or frequent vomiting occurs.
- Each band type and size has its own filling protocol and capacity. It is unusual, however, for patients to reach maximal capacity of the band.
- Patient visits should be scheduled for every 4 to 6 weeks for the first year after surgery, with band adjustments being performed as needed during these visits. Patients are instructed to return to the office immediately if there are any signs or symptoms of a tight band (water brash, dysphagia, vomiting, maladaptive eating behaviors, or dehydration).
- Frequent visits for adjustment are continued long as the patient is losing weight. Once a desired and stable weight is obtained, the frequency of visits can be decreased but should remain at a minimum of one to two visits per year.
- UGI fluoroscopic swallow is performed annually or any time a patient develops any symptoms suggestive of a band prolapse such as progressive dysphagia, frequent vomiting, and/or requirements for frequent removal of fluid with worsening symptoms.

OUTCOMES

- Based on a meta-analysis, laparoscopic gastric banding results in an average percentage of excess weight loss (%EWL) of 47.4% (40.7% to 54.2%) during the first 2 postoperative years.[5]
- A long-term follow-up study has shown that %EWL is preserved at 47.1% 15 years following LAGB, with a revision rate of 50.1% (79% during the perigastric era and 38.4% during the pars flaccida era) and an explant rate of 5.6%.[6]
- In a meta-analysis of 32,908 patients undergoing LAGB, type 2 diabetes mellitus resolved in 56.7% of patients.[7]
- In a prospective randomized study, 60 patients newly diagnosed with type 2 diabetes mellitus, aged between 20 and 60 years and with a BMI between 30 and 40 kg/m^2 were

FIG 10 ● Technique for accessing subcutaneous port. Port is stabilized by nondominant hand.

randomized to either follow a conventional diabetes management program or follow the same program and also undergo LAGB. The conventional program included lifestyle modification and open access to a general physician, dietitian, nurse, and diabetes educator. Remission of type 2 diabetes was achieved by 13% in the conventional-therapy group and by 73% in the surgical group.[8]

- Hypertension, hyperlipidemia, and sleep apnea improve or resolve in 70.8%, 71%, and 68%, respectively.[5]
- There is controversy on the effect of LAGB on GERD. In one study, LAGB led to resolution of GERD in 80% and improvement in 11% of patients at 2 years postoperative.[9] In another study, GERD symptoms decreased postoperatively from 32.9% to 7.7%, but newly developed GERD symptoms were found in 15% of the patients and esophageal dysmotility increased from 3.5% to 12.6%.[10]
- Significant improvement in health-related quality of life (HRQOL) is observed in the first year after LAGB.[11] Food tolerance and gastrointestinal quality of life 2 to 4 years postoperatively appears to be lower with LAGB compared to RYGB or laparoscopic sleeve gastrectomy (LSG).[12]

COMPLICATIONS

- Early device-related complications are rare.
- Port infection in the first few weeks is usually related to the wound itself. However, an unrecognized gastric perforation must be considered in the event the infection does not quickly resolve with antibiotics.
- AGB patients must have long-term surveillance for prolapse (slippage). Prolapse may be a result of the band being too tight, repeated vomiting, or frequent overeating. A patient with a prolapse presents with progressive reflux, dysphagia, and poor weight loss, as well as usually requiring fluid to be removed from the band over time to maintain ability to tolerate solid foods. Confirmation of prolapse is made with a barium swallow. A flattening of the angle of the band toward the horizontal, vertical orientation of the band, or en-face rotation of the band is highly suggestive of AGB prolapse. Early identification of prolapse increases the chances that the band position can be revised.
- Band erosions into the stomach are rare with the pars flaccida (hepatogastric ligament technique). One should suspect erosion anytime there are signs and symptoms of a chronic port infection. Late port infections, in our experience, are usually a sign of a more significant underlying problem with the band.
- Tubing and/or port malfunction are usually a result of incorrect positioning of the port. The nonarmored portion of the tubing can be punctured during band adjustments and is probably the most common cause of a system leak. System leaks of saline and or inability to maintain volume early on after surgery are most likely due to the band being punctured by a needle during initial placement. Rarely, the tubing may become fractured from frequent repetitive motion. Tubing dislodgement has also been described. One should suspect a system leak in a patient who suddenly reports the ability to eat much larger meals due to a lack of restriction.
- Some patients will develop AGB intolerance months to years after placement. Despite a normal positioned band on UGI fluoroscopy, some patients are not able to tolerate even a small amount of restriction from the band. GE reflux and regurgitation can be severe and prevent any meaningful long-term weight loss.

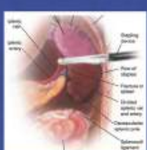
Operative Techniques in Hepato-Pancreato-Biliary Surgery



Chapter 1

Laparoscopic Cholecystectomy

Georgios Rossidis

DEFINITION

- Laparoscopic cholecystectomy describes a procedure involving the removal of the gallbladder using a laparoscope, a fiberoptic instrument inserted into the abdomen.[1]

DIFFERENTIAL DIAGNOSIS

- There are a number of indications for a laparoscopic cholecystectomy. The widespread use of ultrasonography has led to an increasing detection of patients with asymptomatic gallstones and the management of these patients is controversial because only 2% to 3% of these patients become symptomatic per year.
- The indications in asymptomatic patients are the following:
  - Patients who are immunocompromised or awaiting organ allotransplantation or have sickle cell disease
  - Presence of gallbladder polyps that are bigger than 10 mm or are increasing in size rapidly
  - Porcelain gallbladder
  - Gallstones bigger than 3 cm in diameter in areas with high prevalence of gallbladder cancer
- The indications in symptomatic patients are the following:
  - Episodes of biliary colic in patients with identified gallstones
  - Acute cholecystitis
  - Patients with biliary dyskinesia diagnosed with cholecystokinin-HIDA cholescintigraphy
  - Patients with gallstone pancreatitis with no choledocholithiasis based on imaging and laboratory values
  - Patients with choledocholithiasis. In most situations, cholecystectomy follows ERCP for extraction of the common bile duct stones.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A good medical history is necessary to provide information about associated comorbidities that may affect the patient's tolerance to pneumoperitoneum or operative treatment in general.
- Patients with cardiorespiratory disease may not tolerate the impact of CO_2 pneumoperitoneum on cardiac output or CO_2 elimination.
- Coagulopathic disorders or anticoagulants should be identified and managed.
- Medical history can identify the patients who have a higher risk for choledocholithiasis (patients with jaundice, gallstone pancreatitis, or cholangitis).
- Physical examination of the abdomen reveals any surgical scars, hernias, or stomas that may alter the port placement. Previous abdominal surgery does not preclude attempt at laparoscopic cholecystectomy. Adhesive disease is a rare indication for conversion to an open procedure.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Ultrasonography is now the gold standard for the noninvasive diagnosis of cholelithiasis. This imaging test is highly accurate (>96%), can be performed at the patient's bedside, and does not require the use of ionizing radiation. Gallstones must fulfill three major sonographic criteria. They must (1) show an echogenic focus, (2) cast an acoustic shadow, and (3) seek gravitational dependence (**FIG 1**). Presence of a dilated common bile duct during ultrasonography is suggestive of choledocholithiasis. In the case of acute cholecystitis, ultrasound can demonstrate pericholecystic fluid, gallbladder wall thickening, and even a sonographic Murphy's sign, documenting tenderness specifically over the gallbladder.
- In atypical cases, a hepatobiliary iminodiacetic acid (HIDA) cholescintigraphy scan may be used to demonstrate obstruction of the cystic duct, which definitively diagnoses cholecystitis. Filling of the gallbladder during a HIDA scan essentially eliminates the diagnosis of cholecystitis (**FIG 2**).
- HIDA scan is the diagnostic tool of choice in biliary dyskinesia and is performed with the concurrent administration of cholecystokinin. An ejection fraction of less than 20% is suggestive of the disease.
- If there is suspicion of choledocholithiasis, as in patients with jaundice, pancreatitis, cholangitis, or dilated common bile duct on ultrasonography, the biliary tree can be delineated and inspected for presence of gallstones with the use of magnetic resonance cholangiopancreatography (MRCP) (**FIG 3**). MRCP is highly sensitive (>90%) and almost has a 100% specificity. As a noninvasive test, MRCP provides accurate imaging of the biliary tree, but in the setting of choledocholithiasis, it does not provide a therapeutic solution.
- Endoscopic retrograde cholangiopancreatography (ERCP) can be used as a diagnostic and therapeutic modality (**FIG 4**). In the presence of stones in the common bile duct during ERCP, a sphincterotomy is performed to allow enlargement of the papilla and subsequent extraction of stones with a balloon or basket (**FIGS 5** and **6**). With this approach, more than 80% of all stones can be removed successfully. Larger stones may

FIG 1 ● Ultrasound of the abdomen showing multiple gallstones in the lumen of the gallbladder. There is no gallbladder thickening or pericholecystic fluid, thus acute cholecystitis is ruled out.

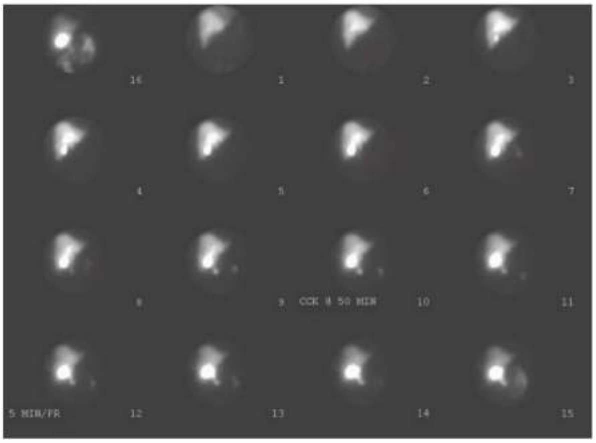


FIG 2 ● HIDA cholescintigraphy scan. Filling of the gallbladder during a HIDA scan, as in this study, essentially eliminates the diagnosis of cholecystitis.

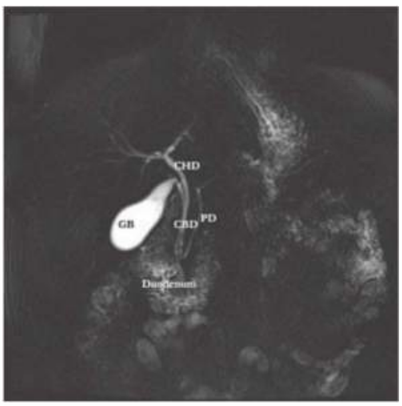

FIG 3 ● Magnetic resonance cholangiopancreatography (MRCP). Note the filling defect in the distal common bile duct suggestive of choledocholithiasis. *CBD*, common bile duct; *CHD*, common hepatic duct; *GB*, gallbladder; *PD*, pancreatic duct.

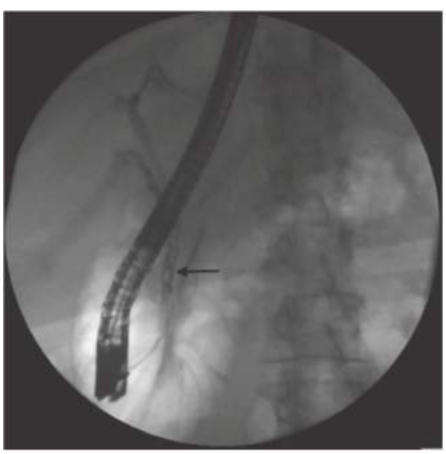

FIG 4 ● Endoscopic retrograde cholangiopancreatography (ERCP). The *solid arrow* shows filling defect in the distal common bile duct, suggestive of choledocholithiasis.

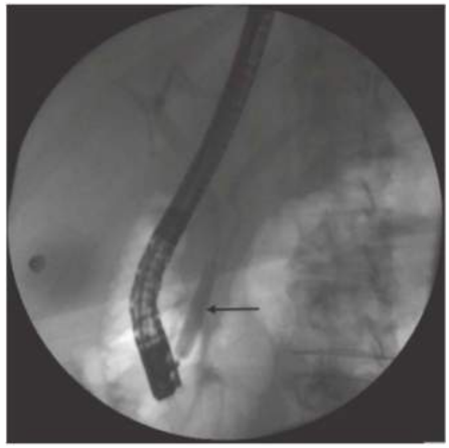

FIG 5 ● ERCP on the same patient with sphincterotomy and balloon sweeping of all common bile duct stones. The *solid arrow* shows the endoscopic balloon.

require additional removal techniques such as mechanical or intraductal lithotripsy. ERCP has a complication rate of around 8%; complications are sedation-related, pancreatitis, bleeding, perforation, and infection.

- Preoperative laboratory studies should include liver function, renal function, electrolyte, and coagulation studies. Abnormal liver function studies may reflect choledocholithiasis or primary hepatic dysfunction.

SURGICAL MANAGEMENT

Preoperative Planning

- In the preoperative area, the patient is asked if any conditions exist that were not present during the last clinic visit and would factor in the operative decision making; for example, a recent myocardial infarction or other cerebrovascular event.
- The patient is asked to void just prior to transfer to the operating room so as to avoid placement of a Foley catheter that is not indicated for an elective laparoscopic cholecystectomy.
- The operative consent, imaging, and laboratory values are reviewed.

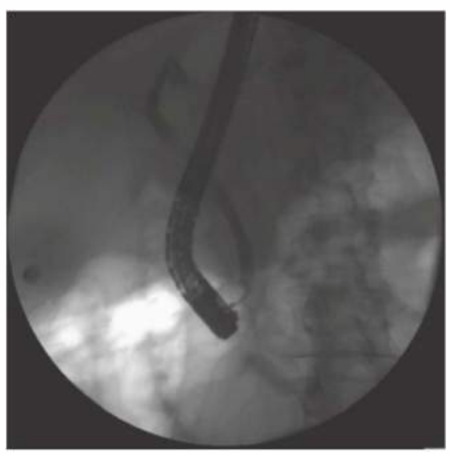

FIG 6 ● Completed ERCP showing a patent common bile duct and absence of filling defects.

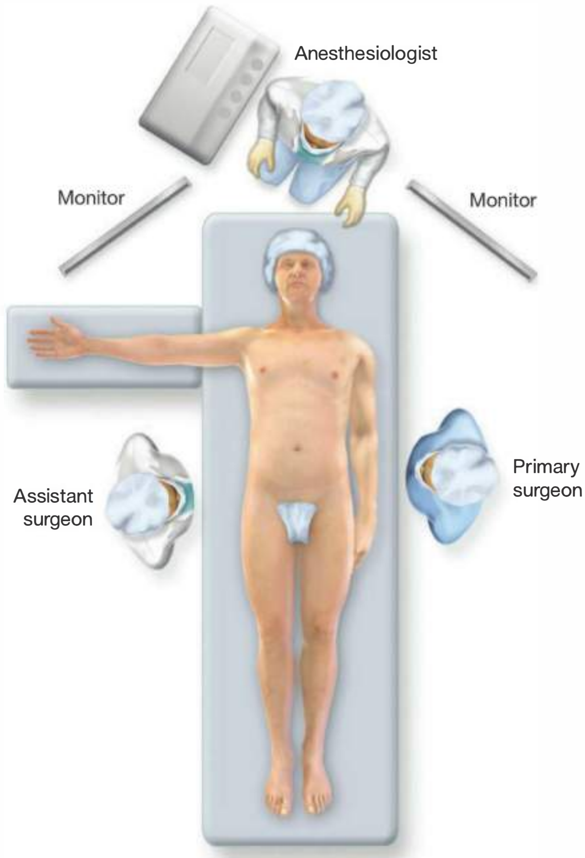

FIG 7 ● The patient is placed in a supine position with the left arm tagged and the right arm extended. The primary surgeon stands to the left of the patient and the assistant to the right of the patient.

Positioning

- The patient is placed in a supine position with the right arm extended and the left arm is secured along the patient's torso (**FIG 7**).
- A footboard is placed at the patient's feet, and the patient is strapped at the thighs and the legs to avoid a fall from the bed during steep reverse Trendelenburg position (**FIG 8**).
- Heel pads, sequential compression devices for deep venous thrombosis prophylaxis, and warming devices are also placed.
- An orogastric tube is inserted to decompress the stomach.
- The primary surgeon stands at the patient's left and the assistant surgeon at the patient's right (**FIG 7**).
- Two monitors are placed at the head of the bed, one on the right and one on the left, facing the surgeon and the assistant.
- The laparoscopic camera, light source, insufflation tubing, suction, and electrocautery are passed to a tower at the feet of the patient.

FIG 8 ● The patient is strapped at the thighs and legs and a footboard is placed to support the patient during reverse Trendelenburg.

ENTRY INTO THE PERITONEAL CAVITY AND ACHIEVING PNEUMOPERITONEUM

- The base of the umbilicus is grasped with two penetrating towel clips and is elevated for easier access. A 5-mm incision is created at the base of the umbilicus with the use of a no. 11 blade. The base of the umbilicus is chosen because it gives a better cosmetic result.
- Through this incision, a Veress needle is introduced into the peritoneal cavity (**FIG 9**). A syringe with saline is attached to the Veress needle. First, aspirate the syringe to rule out placement of the Veress needle in the lumen of intestine or a vessel. Then infuse saline to determine if it will flow through the needle without resistance. This finding signifies that the needle is in the peritoneal cavity and not in the subcutaneous tissues. The insufflation tubing is attached to the Veress needle and pneumoperitoneum is achieved with 15 mmHg of CO_2.
- Next, a 0-degree laparoscope is inserted in a 5-mm OptiView port, and the port is inserted in the peritoneal cavity through the same incision under direct vision (**FIG 10**).
- Alternatively, if the patient has a midline scar and a history of multiple intraabdominal procedures, entry into the peritoneal cavity is achieved through an incision in the left subcostal area just inferior to the rib in the anterior axillary line.

FIG 9 ● Placement of the Veress needle.

FIG 10 ● With the laparoscope inserted in a 5-mm port, the surgeon places the first port under direct vision. Notice that the surgeon watches the monitor as he advances the port.

PLACEMENT OF THE OTHER PORTS

- Once the first port is in place, inspect the intestines immediately beneath the incision to rule out any inadvertent injury. The 0-degree scope is replaced with a 30-degree scope that allows views through different angles.
- The patient is then placed in reverse Trendelenburg position. The gallbladder is typically easy to visualize following this maneuver.
- The next additional port to be placed is a 5-mm port in the patient's right flank. The port is placed in the anterior axillary line around two fingerbreadths below the costal margin. Through this port, the assistant surgeon grasps the fundus of the gallbladder and retracts the gallbladder and the liver in an anterior and cephalad direction toward the diaphragm. This facilitates visualization of the triangle of Calot. If the gallbladder is very distended and inflamed, making it hard to be grasped, the gallbladder may be deflated with an endoscopic needle.
- If the anatomy of the liver precludes visualization of the triangle of Calot, an additional 5-mm port is placed in the left anterior axillary line at the level of the costal margin and a liver retractor inserted.
- With this exposure, precise placement of the working port is determined. This is typically a 12-mm port that is placed in the epigastrium just below the xiphoid process and to the right of the falciform ligament. Ideally, the port is situated above the triangle of Calot just inferior to the liver edge.
- The third port placed is a 5-mm port in the midclavicular line allowing for adequate spacing between the ports (**FIG 11**).

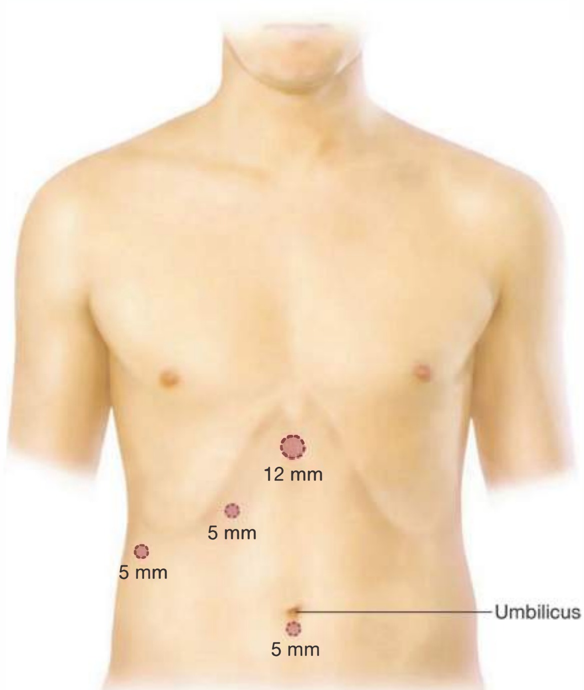

FIG 11 ● Placement of the four ports.

- The assistant surgeon holds the camera and the right flank port retracting the gallbladder, whereas the primary surgeon works through the epigastric and midclavicular ports.

EXPOSURE OF THE TRIANGLE OF CALOT

- With the use of a blunt dissector through the epigastric port, any adhesions between the gallbladder and the omentum or transverse mesocolon are divided, always taking such adhesions along the wall of the gallbladder to minimize bleeding (**FIG 12**).
- A grasping forceps, through the 5-mm midclavicular line port, is used to grasp the gallbladder at the Hartman's pouch and provide lateral traction (**FIG 13**). This maneuver retracts the gallbladder away from vital structures and puts the cystic duct at a 90-degree angle to the common bile duct, minimizing the risk of inadvertent injury to the hepatic or common bile ducts.
- The peritoneum is then bluntly dissected off the gallbladder to expose the infundibulum–cystic duct junction. This is done by stripping the peritoneum at the lateral edge of the gallbladder just below where the infundibulum is grasped (**FIG 14**).
- As the peritoneum is dissected from the gallbladder wall, the lymph node of Calot is also often identified. The lymph node overlies the cystic artery and thus is a useful landmark. Peritoneal attachments around the node of Calot can be taken with hook electrocautery in order to minimize bleeding.

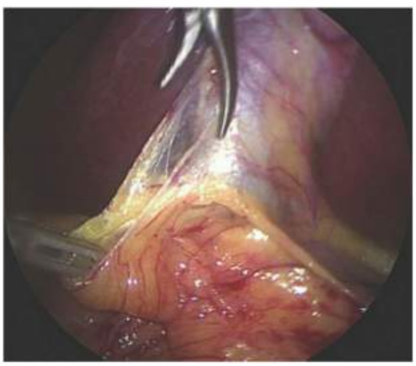

FIG 12 ● Omental adhesions are stripped off from the gallbladder.

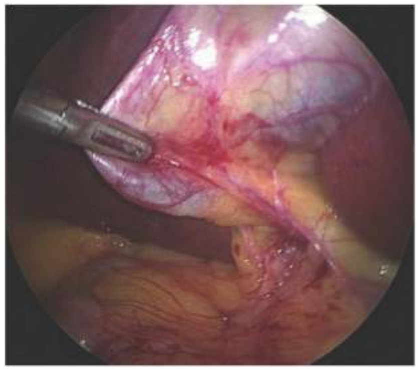

FIG 13 ● The infundibulum is grasped and retracted lateral to the patient's right side. This is a very important maneuver as it places the cystic duct at a 90-degree angle to the common bile duct and minimizes confusion and potential injury to the common bile duct.

- This initial dissection exposes the triangle of Calot, also known as the hepatocystic triangle, bounded by the cystic duct, the common hepatic duct, and the edge of the liver. The content of the triangle is the cystic artery (**FIG 15**).

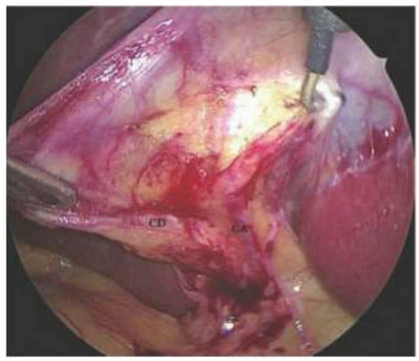

FIG 14 ● The peritoneum is dissected off the gallbladder and the structures are becoming visible, exposing the triangle of Calot. Notice the dissection is carried high along the body of the gallbladder so that injury to the hepatic or common bile duct is avoided. *CA*, cystic artery; *CD*, cystic duct.

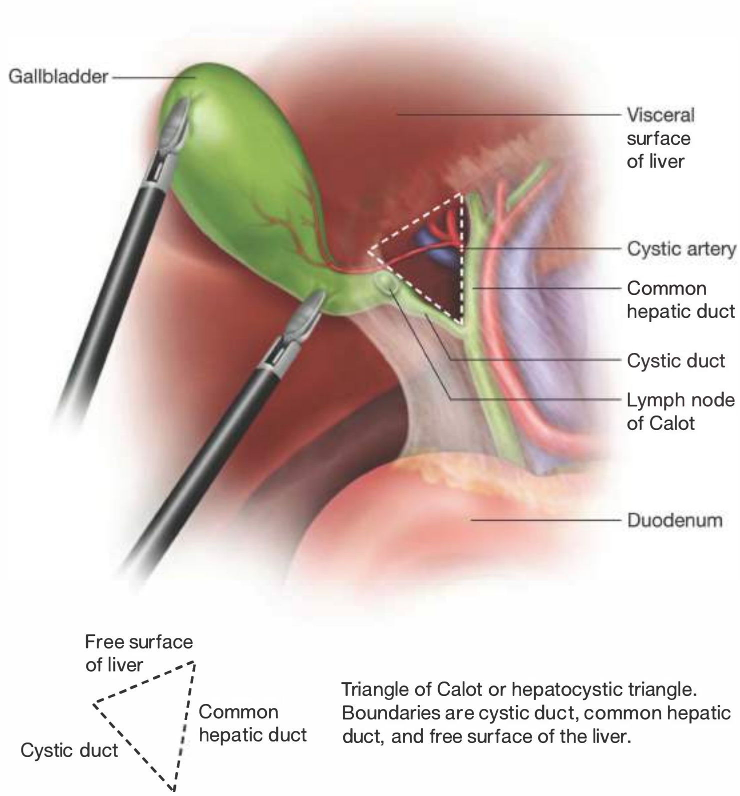

FIG 15 ● Schematic drawing showing the triangle of Calot, its borders and the content of the triangle, and the cystic artery. The *interrupted lines* represent the borders of the triangle. Notice the lymph node of Calot, immediately above the cystic artery. It can act as landmark for identification of the cystic artery.

EXPOSURE OF THE REVERSE TRIANGLE

- The reverse side of the hepatocystic triangle is bordered by the cystic duct, the inferior lateral border of the gallbladder, and the right lobe of the liver.
- In order to expose the reverse triangle, the infundibulum is retracted medially and superiorly and then peritoneal attachments are taken bluntly or with the hook electrocautery (**FIG 16**). This enables one to further identify the cystic duct and cystic artery, and maneuvering the infundibulum from medial to lateral, exposure of both triangles is realized and the ability to circumferentially dissect the cystic duct and cystic artery.
- Importantly, division of the posterior triangle peritoneum early in the dissection can dramatically impact exposure to the anterior triangle by facilitating retraction of the infundibulum away from other portal structures.

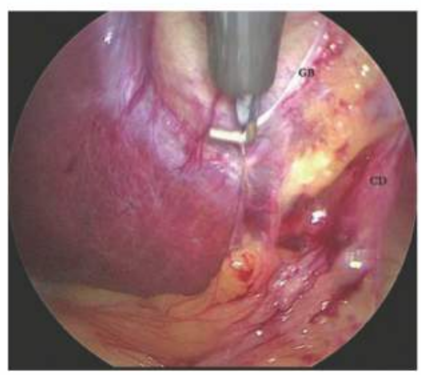

FIG 16 ● Exposure of the reverse triangle. The gallbladder *(GB)* is retracted medially and the reverse triangle can be exposed by dissection of the peritoneum off the structures. *CD*, cystic duct.

THE CRITICAL VIEW

- It is of paramount importance to obtain a critical view of the cystic duct and artery prior to clipping or dividing any structures. This view is obtained when both the cystic duct and cystic artery are circumferentially dissected and windows have been created between the two structures and medial to the cystic artery (**FIG 17**). Ideally, the medial wall of the gallbladder is dissected up to the liver. This visualization minimizes the risk of dividing the hepatic or common bile duct or an aberrant branch of the right hepatic duct. The dissection medial to the cystic artery reduces the risk of injuring a meandering right hepatic artery that is also at risk for inadvertent injury.

- Should this dissection and exposure be limited by inflammation or other factors such as an intrahepatic gallbladder, a hypertrophied left lobe of the liver, or aberrant anatomy, a retrograde dissection of the gallbladder as is classically done during the open procedure can be considered or the decision for conversion to an open procedure should be made.

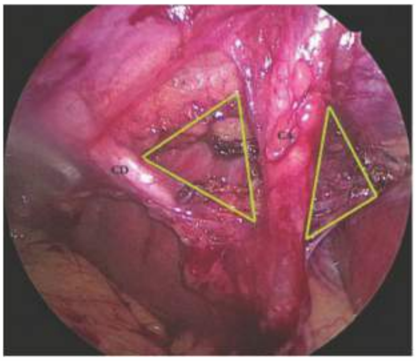

FIG 17 ● The critical view. The two triangles show the windows that need to be formed between the cystic duct and the cystic artery and medial to the cystic artery. The surgeon should be able to see the visceral surface of the liver through these windows. *CA*, cystic artery; *CD*, cystic duct.

DIVISION OF THE CYSTIC DUCT AND CYSTIC ARTERY

- Once the critical view is obtained, the two structures can safely be clipped and divided with laparoscopic shears. A clip applier is introduced through the epigastric port, and the cystic artery and cystic duct are clipped with two to three clips proximally and one clip distally (**FIG 18**). The posterior jaw of the clip applier should be visualized across the structure to assure that the clip will traverse the entire lumen of each structure. Once both structures are divided, the clipped stumps of the two structures are inspected (**FIG 19**). An alternative approach for a large caliber cystic duct or friable tissues is the use of a laparoscopic endoloop or stapling device to control the duct.

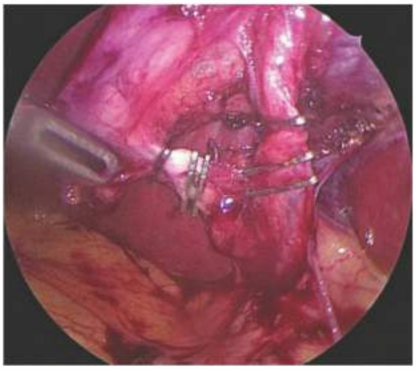

FIG 18 ● Clipping of the cystic duct and cystic artery.

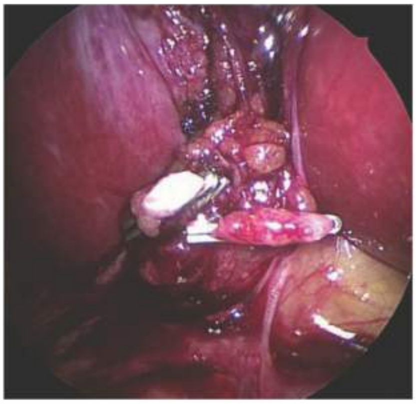

FIG 19 ● Inspecting the clipped stumps of both structures.

DISSECTION OF THE GALLBLADDER OFF THE GALLBLADDER FOSSA

- Next, the gallbladder is dissected from attachments to the undersurface of the liver using hook and/or spatula electrocautery. The infundibulum is grasped and elevated toward the anterior abdominal wall and lateral to create tension and the body of the gallbladder is dissected off the gallbladder fossa (**FIG 20**). In order to dissect the lateral side of the gallbladder, the infundibulum is retracted medially and superiorly and again the hook electrocautery dissects the whole length of the lateral wall of the gallbladder (**FIG 21**). Prior to completely freeing the gallbladder, it can be used as a handle to lift the liver and inspect the operative bed for bleeding. The gallbladder is then completely separated from the liver (**FIG 22**).

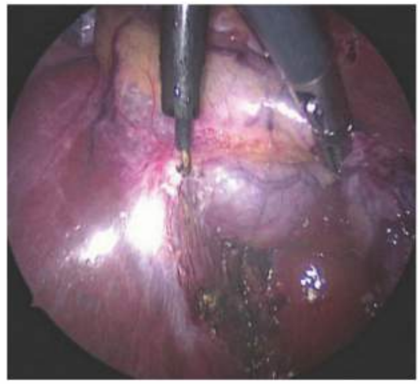

FIG 21 ● Dissection of the lateral wall of the gallbladder off the gallbladder fossa.

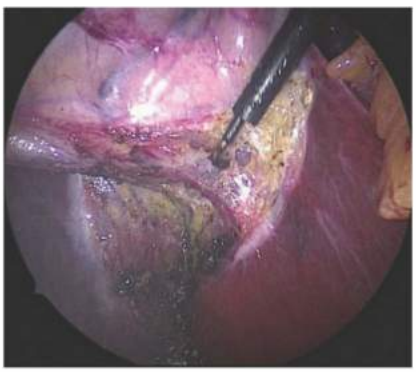

FIG 20 ● Dissection of the gallbladder fossa with electrocautery.

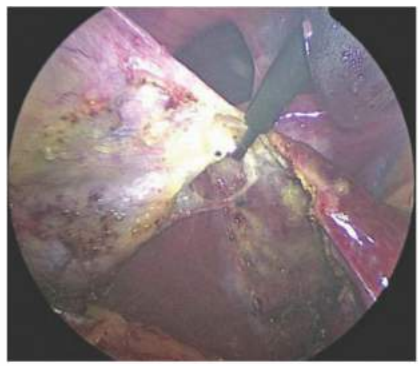

FIG 22 ● The gallbladder is pulled away from the liver, and the tip of the fundus is divided from the liver to complete the gallbladder dissection.

EXTRACTION OF THE GALLBLADDER

- The gallbladder is now completely dissected off the liver. A 10-mm specimen bag is introduced through the epigastric port and opened facing the camera. The gallbladder is placed in the specimen bag (**FIG 23**) and then extracted through the port site. If the gallbladder is too big or contains large stones, the port incision may need to be extended to accommodate the bigger gallbladder.
- The specimen is sent to pathology for histologic examination.

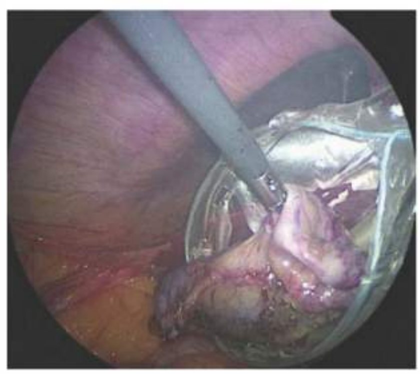

FIG 23 ● The gallbladder is placed in an EndoCatch bag.

CLOSURE

- The epigastric port is closed at the fascial level with the use of a transfascial suture passer and 0 braided absorbable suture (**FIG 24**).
- The other ports are retrieved under direct vision to rule out hemorrhage at the port sites.
- Once hemostasis is confirmed at the port sites, the peritoneum is deflated and the skin incisions are closed with subcuticular 4-0 monofilament absorbable suture.

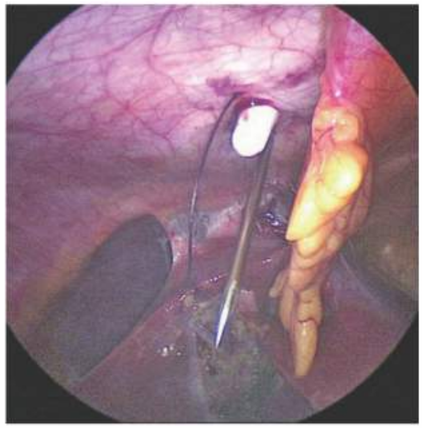

FIG 24 ● The incision is reapproximated with a transfascial suture passer and 0 braided absorbable suture.

PEARLS AND PITFALLS

Placement of 12-mm port	■ Many authors place the 12-mm port in the umbilicus. We advocate placement of the 12-mm port in the epigastrium because the umbilicus is the weakest point of the abdominal wall and the risk of incisional hernia is higher. Furthermore, if a hernia develops at the epigastric port, the risk of bowel incarceration is very low because the port is very high and above the liver, minimizing the risk of strangulation or incarceration.
Intraoperative cholangiogram	■ A surgeon performing laparoscopic surgery should be facile and comfortable performing an intraoperative cholangiogram. We do not advocate routine performance of cholangiograms, but there should be a **very low threshold** for performing a cholangiogram in cases of questionable anatomy or suspicion of injury.
Dissection of triangle of Calot	■ Dissection of the peritoneum to identify the structures should be done *as close* to the gallbladder as possible. This minimizes the risk of injury to the hepatic or common bile duct which lies deeper.
Two-handed skills	■ In the above description, the primary surgeon uses two hands to retract the gallbladder and dissect at the same time. In a teaching institution, or when a laparoscopic novice is performing the cholecystectomy, two-hand laparoscopic cholecystectomy is a very good starting procedure to obtain bimanual dexterity before embarking on more complex laparoscopic cases.
Spilled stones	■ Every effort should be made to avoid perforation of the gallbladder and spillage of gallstones. If this happens, all gallstones should be retrieved to avoid associated complications such as postoperative granulomas or abscesses.

POSTOPERATIVE CARE

- The majority of laparoscopic cholecystectomies are performed as outpatient surgery and thus patients are discharged home on the same day. If the procedure is performed in the setting of resolved pancreatitis or choledocholithiasis on a patient who was already hospitalized, an overnight postoperative stay is the norm. A diet can be initiated immediately.

COMPLICATIONS

- The overall perioperative mortality varies between 0% and 0.3%.[2,3]
- The overall incidence of bile duct injuries requiring corrective surgery varies between 0.1% and 0.3%. Corrective surgery for bile duct injury carries its own risks including perioperative mortality (1% to 4%), secondary biliary cirrhosis (11%), anastomotic stricture (9% to 20%), and cholangitis (5%).[4,5]
- Other complications include the following:
  - Bile leak treated conservatively (0.1% to 0.2%), radiologically (0% to 0.1%) or endoscopically (0.05% to 0.1%), or by operation (0% to 0.05%).
  - Peritonitis requiring reoperation, typically from a missed, inadvertent enterotomy (0.2%)
  - Postoperative bleeding requiring operation (0.1% to 0.5%)
  - Intraabdominal abscesses requiring operation (0.1%)

Chapter 2

Open Cholecystectomy

Sean P. Montgomery   Preston B. Rich

DEFINITION

- Removal of the gallbladder for benign disease using an open technique when the laparoscopic technique is not prudent.

DIFFERENTIAL DIAGNOSIS

- Acute cholecystitis
- Symptomatic biliary colic
- Acalculous cholecystitis
- Diseases that can present similarly and are not treatable by simple cholecystectomy include peptic ulcer disease, hepatitis, pancreatitis, cholangitis, gallbladder cancer, colitis, irritable bowel syndrome, and atypical appendicitis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Biliary colic (symptomatic cholelithiasis) is typically a right upper quadrant (RUQ) or epigastric postprandial pain. Symptoms classically start 30 to 90 minutes after eating and association with high-fat meals may be described. Nausea and bloating are common. The pain typically will resolve within 6 hours. Pain lasting more than 6 hours and/or fever is suggestive of acute cholecystitis.
- On physical examination, tenderness will usually be present in the RUQ. The presence of a Murphy's sign (inspiratory arrest with RUQ palpation) is suggestive of acute cholecystitis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A fasting RUQ ultrasound is the "gold standard" for the diagnosis of gallstones and is frequently the only imaging necessary to diagnose acute cholecystitis. Gallstones are identified as mobile echogenic foci with posterior shadowing (**FIG 1**). Cholecystitis is suggested by gallbladder wall thickening (>3 mm), pericholecystic fluid, or inspiratory arrest elicited by placement of the ultrasound probe directly over the gallbladder (a sonographic Murphy's sign). The sensitivity and specificity of ultrasound for calculous cholecystitis are around 82%.[1] In critically ill patients with acalculous cholecystitis, the specificity drops significantly.
- The other common imaging study used to diagnose gallbladder pathology is a nuclear medicine test called either hepatobiliary scintigraphy or a hepatobiliary iminodiacetic acid (HIDA) scan (commonly referred to as a HIDA scan.) In this test, a radiolabeled substrate is intravenously administered, taken up by the liver, and excreted into the biliary tree (**FIG 2**). If the substrate fails to fill the gallbladder within 1 hour, the sensitivity is 96% for acute cholecystitis.[1] A HIDA scan will also provide information about obstruction of the common bile duct, as substrate will be seen accumulating in the duodenum if the duct is not obstructed. In the setting of hepatic failure or cholestasis, this study is not useful, as the liver often will not take up enough substrate to allow an adequate study. Gallstones are not revealed with this study, but rather, the presence or absence of cholecystitis is determined by assessing patency of the cystic duct regardless of the etiology. HIDA scintigraphy is generally performed if the clinical findings and ultrasound are inconclusive for calculous cholecystitis or in critically ill patients with suspected acalculous cholecystitis.[2]

SURGICAL MANAGEMENT

Preoperative Planning

- The vast majority of patients will be appropriate candidates for a laparoscopic cholecystectomy. Conversion from laparoscopy due to variable anatomy or severe inflammation is the most common indication for the open procedure. Rare patients in whom a primary open cholecystectomy should be considered are the following:
  - Septic patients on vasoactive agents for hemodynamic support that have failed percutaneous drainage
  - Patients with complicated anterior abdominal walls and/or severe adhesions. Specifically, if there are large pieces

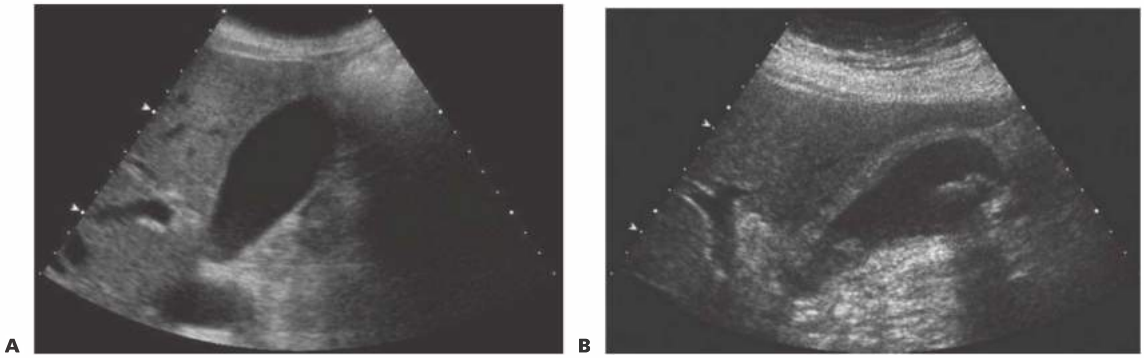

FIG 1 ● Gallbladder ultrasound. Figure **A** demonstrates the normal ultrasound appearance of the gallbladder. In Figure **B**, the presence of gallstones, thickening of the gallbladder wall, and gallbladder wall edema are suggestive of acute cholecystitis.

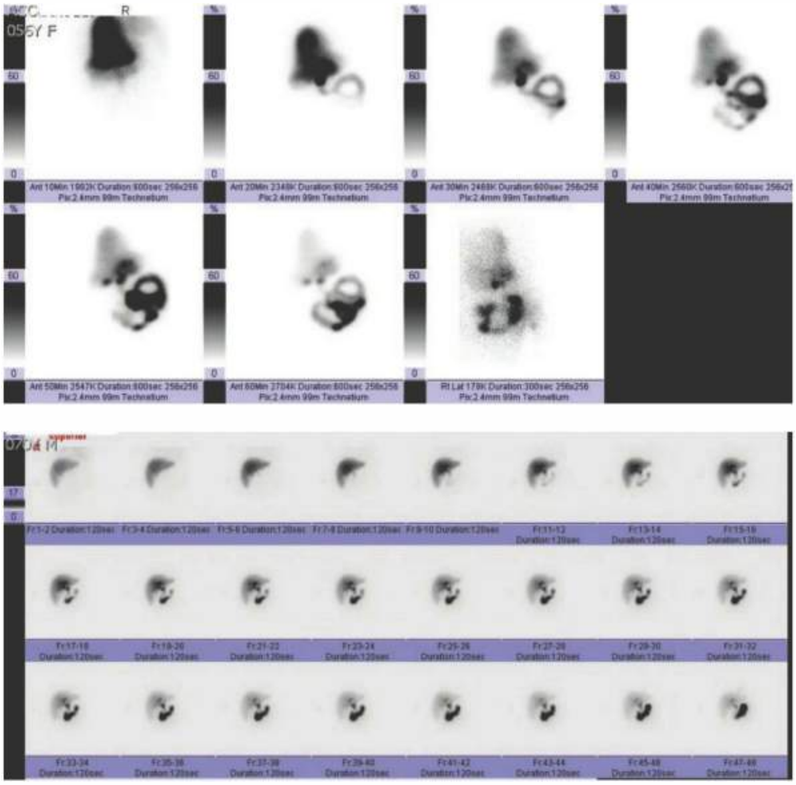

A

B

FIG 2 ● HIDA scintigraphy. In Figure **A**, tracer promptly fills the gallbladder and duodenum, demonstrating normal gallbladder physiology and a nonobstructed biliary system. In Figure **B**, nonfilling of the gallbladder at 1 hour following substrate injection is consistent with acute cholecystitis.

of prosthetic mesh in the umbilical and epigastric areas and/or prior RUQ surgery, laparoscopic completion of a cholecystectomy can be challenging.

- The need for concomitant open common bile duct exploration

Positioning

- The patient is positioned supine. Arms can be tucked by the side or extended out at right angles to the bed. An oral or nasal tube for gastric decompression is placed.

INCISION

- The gallbladder is most easily accessed through an oblique RUQ incision (**FIG 3**). The incision should be placed two fingerbreadths below the right costal margin to facilitate fascial closure. In patients with significant hepatomegaly, the incision may be moved inferiorly to two fingerbreadths below the palpable liver edge, but this should rarely be necessary. The incision is carried down to the fascia.

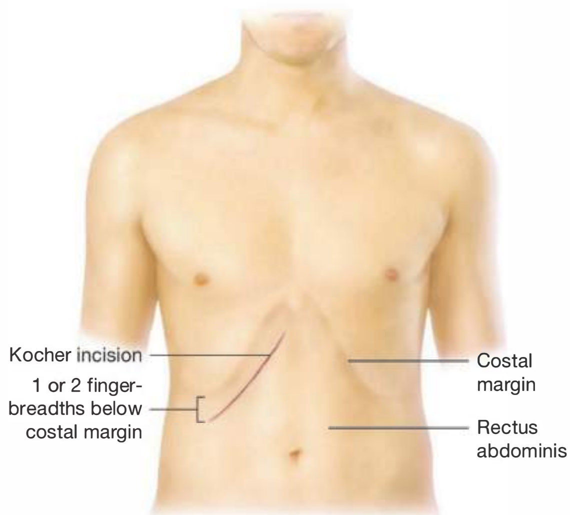

FIG 3 ● Incision. An oblique RUQ incision is created two fingerbreadths below the costal margin (Kocher's incision). The right rectus abdominis muscle is divided before entering the abdominal cavity.

OPENING OF THE ABDOMINAL WALL

- The anterior rectus fascia should be incised with electrocautery. A Kelly or other large clamp is placed under the lateral border of the rectus muscle, retracting it anteriorly, to facilitate division of the muscle with electrocautery. The superior epigastric vessels can be encountered, typically about halfway across the rectus. The vessels can be ligated or cauterized, or they can be reflected medially and preserved with the medial half of the rectus.

PLACEMENT OF RETRACTORS

- This step is the key to a successful operation. Safely keeping the bowel out of the operative field and delivering the gallbladder to the center of the wound will make the remainder of the case straightforward with proper exposure. A Bookwalter fixed retractor or other table-mounted retractor should be used (**FIG 4**). In cases of dense adhesions to the gallbladder, start with body wall retractors placed inferiorly and superiorly. In cases of minimal adhesions or after some initial adhesiolysis, use moist laparotomy pads to push the transverse colon and duodenum inferior and medial, respectively, away from the gallbladder. Malleable or long right-angle retractors for the retractor should be placed inferomedially and inferolaterally to hold these lap pads away from the gallbladder. A deep body wall retractor may be required inferiorly to adequately open the space between the duodenum and gallbladder. Superomedially, a flat deep retractor, such as a Harrington (or *Sweetheart*) or medium right-angle should be placed against the liver to pull it to the superior aspect of the wound. A superolateral body wall retractor can be progressively exchanged for deeper retractors as the gallbladder is progressively dissected from the gallbladder bed to elevate the liver and separate it from the gallbladder. A Kelly or large clamp is then placed on the infundibulum of the gallbladder to facilitate moving it within the space created.

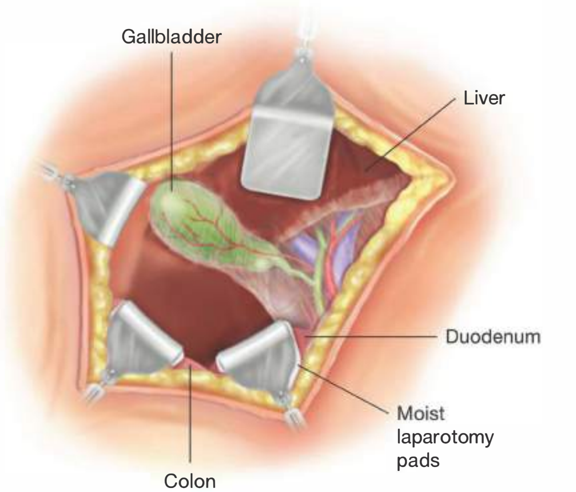

FIG 4 ● Placement of retractors. Correct application of a fixed retracting device (Bookwalter) is the key to a successful and safe open cholecystectomy. Inferiorly, moist laparotomy pads are carefully placed behind deep retractors to exclude the duodenum, colon, and small bowel from the operative field. Superiorly, additional retractors are placed to retain the liver. As the gallbladder is dissected free from its bed, the more lateral superior retractor can be progressively exchanged for deeper retractors placed over the dissected bed to improve visualization.

INCISION OF THE VISCERAL PERITONEUM

- The peritoneum is incised just off the liver edge at the most anterior point of the gallbladder (**FIGS 5** and **6**). A tonsil or other fine-tipped dissector is used to enter the plane between the peritoneum and the gallbladder. Electrocautery is then used to open the peritoneum. This is repeated for the other side of the gallbladder.

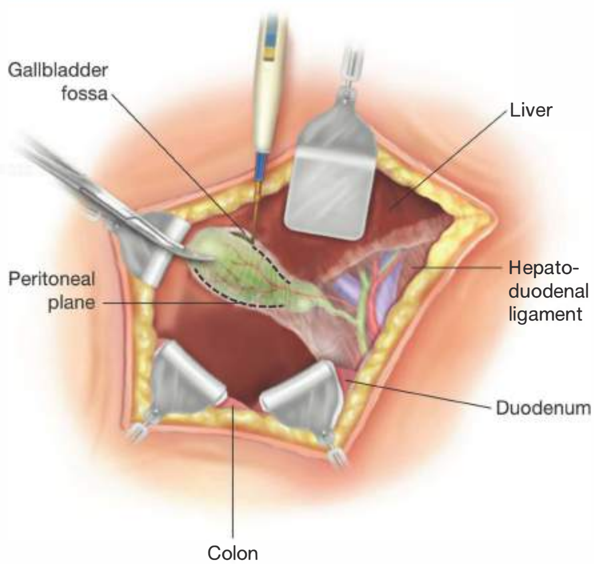

FIG 5 ● Incision of the peritoneum and dissection of the gallbladder from the gallbladder fossa. The infundibulum is grasped with a large clamp (Kelly) to facilitate mobilization. The peritoneum (serosa of the gallbladder) is incised 3 to 5 mm from the interface with the substance of the liver and the areolar tissue between the gallbladder and the liver is divided with electrocautery. The gallbladder is dissected in a top-down fashion toward the porta hepatis.

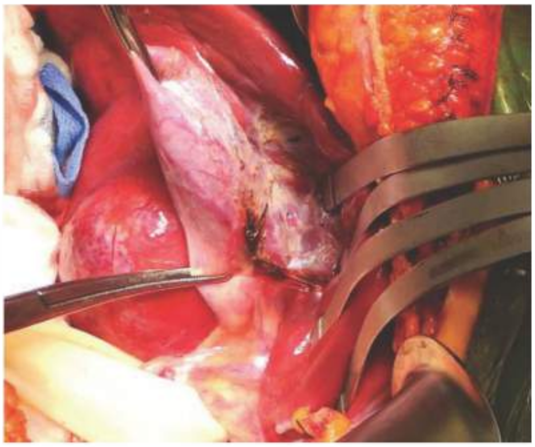

FIG 6 ● Ligation of the cystic duct and cystic artery. After the gallbladder has been dissected free from its bed, a combination of blunt and sharp dissection is used to isolate the cystic duct and cystic artery. Dissection should be directed from the gallbladder toward the portal structures to avoid injury. Both structures are divided separately between ligatures. Care should be taken to not apply electrocautery when in proximity to the colon, duodenum, or portal structures.

RETROGRADE DISSECTION OF THE GALLBLADDER OFF OF THE GALLBLADDER FOSSA

- Electrocautery is then used to dissect the gallbladder free from the liver. This is performed in a top-down fashion, starting anteriorly and continuing until the gallbladder is suspended from its pedicle.

LIGATION OF THE CYSTIC DUCT AND ARTERY

- After the gallbladder has been dissected free from its bed, a combination of sharp and blunt dissection is performed around the pedicle until the artery and duct are dissected free (**FIGS 7–9**). Tracing the cystic duct until its intersection with the common bile duct is not necessary if the duct is confirmed to be headed directly out of the gallbladder. Because the most common indication for an open cholecystectomy is the presence of severe inflammation, unnecessary dissection in the porta hepatis can be unsafe and should be avoided if possible. Simple

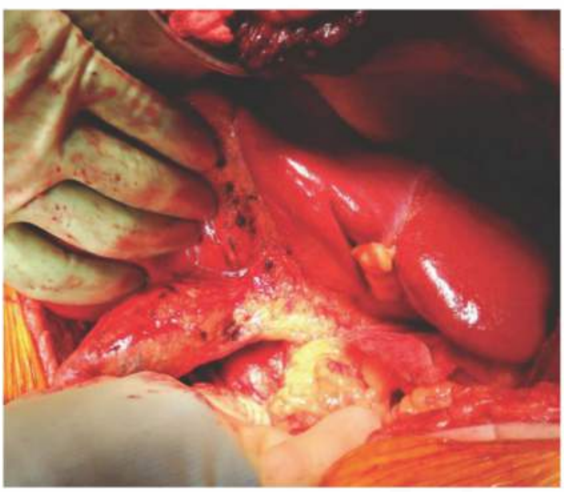

FIG 7 ● Operative photograph of a "top-down" dissection of the gallbladder from the undersurface of the liver. The peritoneum has been incised over the triangle of Calot, exposing adipose tissue around the infundibulum of the gallbladder and the key portal structures.

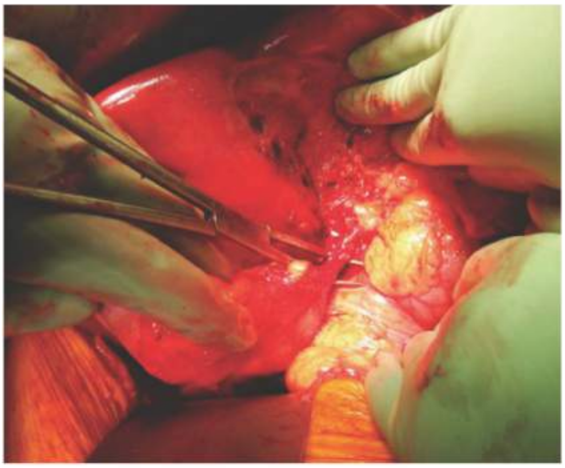
FIG 8 ● Isolation of the cystic artery. Inferior and lateral retraction facilitates identification of the cystic artery as shown.



ligation of the cystic duct and artery are accomplished with separate ties. The gallbladder is then excised free. If the gallbladder or cystic duct appears necrotic, a drain should be placed to control a bile leak should one occur.

FIG 9 ● Isolation of the cystic duct. Once the cystic artery has been ligated and divided, the cystic duct is circumferentially dissected.

ALTERNATIVE: SUBTOTAL CHOLECYSTECTOMY

- Open cholecystectomy is usually reserved for cases with severe inflammation. In some patients, the inflammation may be so severe that dissection around the neck of the gallbladder to identify the cystic duct becomes unsafe. If the cystic duct cannot be safely identified and dissected free due to adhesions, a subtotal cholecystectomy may be performed. In this case, the gallbladder neck is dissected to the region where inflammation prohibits further dissection. The gallbladder is then transected at that point and the internal opening of the cystic duct is ligated with suture (**FIG 10**). If a significant portion of the gallbladder wall remains, the remainder of the gallbladder fulgurated and then the edges of the wall are sewn closed with a running monofilament suture. In these cases, a drain should be left, as the incidence of bile leak after subtotal cholecystectomy can be in excess of 20%.[3] It is for this reason that a complete cholecystectomy is performed whenever the cystic duct can be safely identified.
- If significant bleeding from the liver is encountered, such as in unsuspected portal hypertension, the back wall of the gallbladder can be left adherent to the liver.[4,5] Fulguration of any viable mucosa is advised.

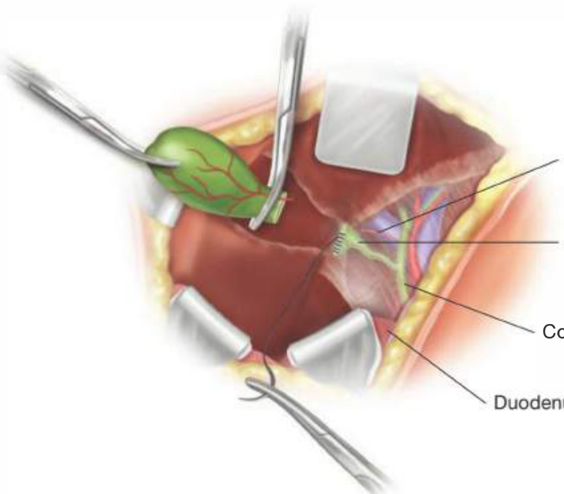


FIG 10 ● Subtotal cholecystectomy. In cases where severe inflammation is encountered, dissection to the cystic duct may be unsafe. In such case, the infundibulum of the gallbladder can be amputated at the junction where dissection must be stopped and the cystic duct opening closed with suture ligature. When a cuff of gallbladder remains, it is fulgurated with electrocautery and closed with a running absorbable monofilament suture.

CLOSURE

- The posterior and anterior fascia should be closed in separate layers. The skin is closed with staples due to the clean-contaminated nature of the procedure.

PEARLS AND PITFALLS

Electrocautery	■ To avoid injury, electrocautery should be avoided when dissecting near the duodenum, colon, biliary structures, or porta hepatis.
Visualization	■ If the colon or duodenum is crowding the operative space, consider a deeper blade for the retractor that is "toed in" slightly on laparotomy pads.
Common bile duct injury	■ If the inflammation is so severe that it is difficult to dissect the cystic duct at the neck of the gallbladder, consider a subtotal cholecystectomy. In this circumstance, leave a drain.
Bleeding	■ During surgery for acute cholecystitis, inflammatory bleeding is often encountered from the gallbladder fossa during top-down dissection. When present, this can usually be best controlled with a laparotomy sponge and pressure applied directly to the raw surface following separation of the gallbladder from its liver bed. Often, a deeper retractor blade can be placed between the gallbladder and its bed to maintain pressure while also improving visualization.

POSTOPERATIVE CARE

- Ileus is unusual after open cholecystectomy, so diet can be rapidly advanced. Narcotic requirements will be higher than for laparoscopic cholecystectomy and a 2- to 3-day hospital stay may be necessary for adequate pain control.[6] If a cystic duct leak occurs, it will often not be clinically apparent for several days after the original operation (an average of 2.3 days).[7] Therefore, if drains were placed due to a high-risk cystic duct stump, they should be left for several days before being removed.

OUTCOMES

- Long-term outcomes after cholecystectomy are excellent. Short-term morbidities include cystic duct leak, the incidence of which averages about 0.4% for elective patients and threefold higher for emergent cholecystectomies. After subtotal cholecystectomy, issues from the remnant gallbladder are rare.[4,5]

COMPLICATIONS

- Cystic duct leak
- Common bile duct injury (<1/1,000).
- Wound infection
- Hemorrhage from the liver

Chapter 3 Radical Cholecystectomy

Richard J. Bold

DEFINITION

- Radical cholecystectomy is defined as the resection of the gallbladder and gallbladder fossa and is usually combined with a supraduodenal lymphadenectomy for the treatment of gallbladder cancer.[1] The extent of the hepatic resection may include nonanatomic parenchymal resection of the gallbladder fossa to a standard segment IVb/V resection (**FIG 1**), with data suggesting superior survival from segment IVb/V resection over standard cholecystectomy.[2] The goal of the resection is complete resection of all histopathologic disease, which may necessitate resection of the common hepatic duct/common bile duct if clearance of all disease cannot be obtained by division at the cystic duct/common hepatic duct junction.

DIFFERENTIAL DIAGNOSIS

- A variety of other conditions may mimic adenocarcinoma of the gallbladder. These include benign intraluminal polyps (due to the mass appearance on imaging), chronic cholecystitis (due to collapse of the lumen and associated mural thickening due to chronic inflammation), or hepatic masses within the gallbladder fossa (due to presence of a hepatic mass adjacent to the gallbladder).[3]

PATIENT HISTORY AND PHYSICAL FINDINGS

- The majority of early-stage gallbladder cancers are clinically silent and will not be diagnosed preoperatively but instead will be recognized on final pathology following cholecystectomy performed for other conditions, such as symptomatic cholelithiasis or cholecystitis.[4,5]
- Occasionally, polypoid gallbladder cancers will present with right upper quadrant pain similar to cholecystitis, presumably from the intraluminal mass effect or the obstruction of the fundus/cystic duct. In addition, should the tumor extend down the cystic duct to the common hepatic duct, patients may present with painless jaundice.
- Symptoms of abdominal bloating and/or weight loss should be concerning for the presence of malignant ascites due to peritoneal metastasis, a common site of spread. The liver is the most other common site of metastasis.
- The incidence of gallbladder cancer is three times higher in women than in men.[6]
- Hispanics, American Indians, and Mexican Indians have been identified as high-risk groups for gallbladder cancer.[6]
- Large, multiple gallstones have an increased association with gallbladder cancer; gallstones are present in 60% to 80% of patients with gallbladder cancer.[3]
- Obesity is a risk factor for both gallstones and gallbladder cancer; furthermore, obesity increases the risk for the development of nonalcoholic liver disease, particularly nonalcoholic steatohepatitis (NASH), which may impact the suitability for radical cholecystectomy.[7]
- Radical cholecystectomy involves a partial hepatic resection, and therefore, risk factors for cirrhosis (e.g., alcohol abuse, chronic hepatitis virus infection) are important aspects of the patient's history and evaluation for tolerability of hepatic resection.[8]
- Early-stage gallbladder cancer is usually not apparent on physical examination. Physical findings suggesting advanced disease include the presence of ascites (peritoneal metastasis); painless jaundice (either direct extension into the common hepatic duct or bulky portal adenopathy causing external biliary dilation); and a nontender, palpable gallbladder (concerning for extensive mural involvement). In addition, physical findings of end-stage liver disease raise the suspicion of underlying cirrhosis and therefore preclude radical cholecystectomy.

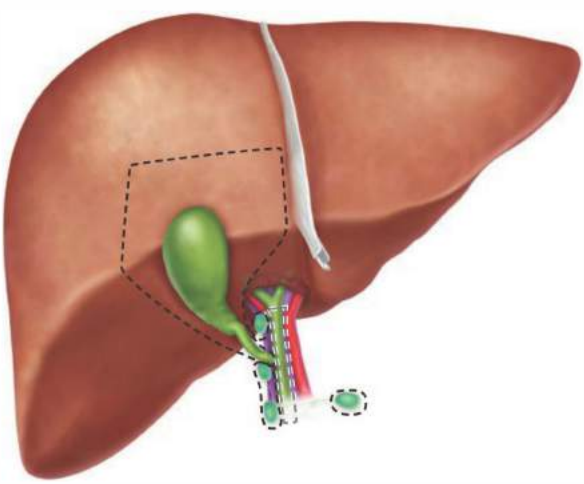

FIG 1 ● Schematic representation of radical cholecystectomy by resection of hepatic segments IV/V *(black dotted lines)* and the gallbladder. Optional resection of the extrahepatic biliary tree is also shown *(gray dotted lines)*.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radical cholecystectomy is appropriate only for those patients with T1b, T2, or T3 (primary tumor thickness) or N0 or N1 gallbladder cancer (**FIG 2** and Table 1).[9–14]

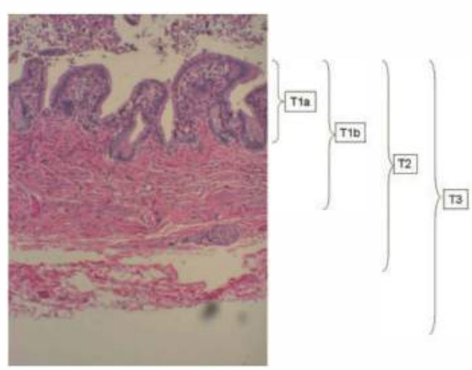

FIG 2 ● Histology of the gallbladder wall with corresponding extent of T1a, T1b, T2, and T3 carcinoma of the gallbladder.

Table 1: American Joint Commission on Cancer Staging System for Gallbladder Cancer

Primary Tumor (T)	Histopathologic Characteristic
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1a	Tumor invades lamina propria
T1b	Tumor invades muscle layer
T2	Tumor invades perimuscular connective tissue; no extension beyond serosa or into liver
T3	Tumor perforates serosa and/or directly invades into the liver and/or one other adjacent organ or structure
T4	Tumor invades main portal vein or hepatic artery or involves multiple extrahepatic structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

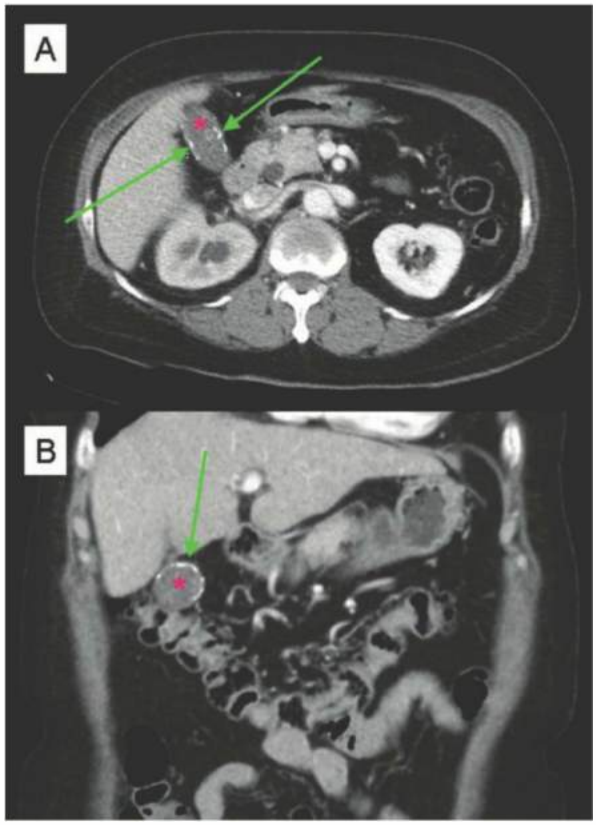

FIG 4 • Axial **(A)** and coronal **(B)** contrast-enhanced CT findings of porcelain gallbladder. The calcification of the gallbladder wall *(green arrows)* is seen as a diffuse process, outlining the lumen of the gallbladder *(red asterisks)*.

- The majority of patients will undergo an initial ultrasound for evaluation of right upper quadrant pain and suspected cholelithiasis. The presence of a gallbladder polyp within the lumen raises the suspicion for gallbladder cancer (**FIG 3**). Given the intraluminal aspect of any polyp, percutaneous biopsy is not usually feasible in the absence of any invasive features beyond the gallbladder wall.[15]
- There is only a weak association between patients with a calcified gallbladder ("porcelain gallbladder") and an underlying gallbladder cancer, such that prophylactic cholecystectomy may no longer be routinely advocated.[16] The calcification of the gallbladder wall may not be readily visible on ultrasound but is clearly seen on contrast-enhanced computed tomography (CT) scans (**FIG 4**). This radiologic finding should prompt concern for gallbladder cancer, even in the absence of any symptoms or associated findings on radiologic imaging.

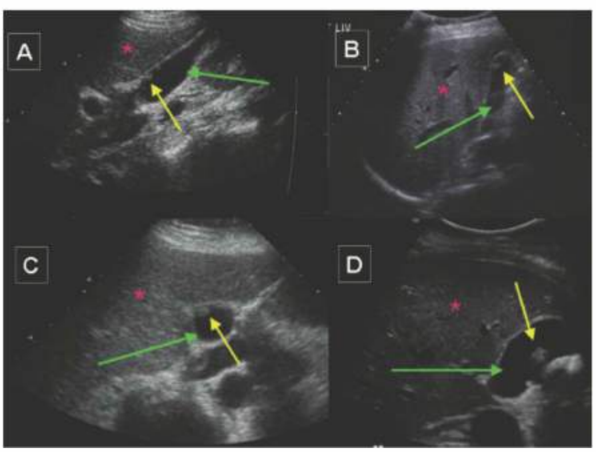

FIG 3 • Longitudinal **(A,B)** and transverse **(C,D)** ultrasonographic imaging of the gallbladder. A polypoid mass *(yellow arrows)* is seen within the gallbladder lumen *(green arrows)*. The relationship of the polypoid mass to the liver *(red asterisks)* can be roughly determined as in **A–C**, likely adjacent to the hepatic fossa, or **D**, likely on the peritoneal/free aspect of the gallbladder.

- If history, physical examination, or ultrasound findings raise concern for gallbladder cancer, contrast-enhanced CT is useful for characterization of the extent of the gallbladder cancer. Radiologic findings of gallbladder cancer on CT include a mass within the gallbladder that typically extends into the lumen or diffuse wall thickening (**FIG 5**).[15]
- Magnetic resonance imaging (MRI) may additionally be useful to characterize any mass seen on either ultrasound or contrast-enhanced CT scan given the ability to differentiate water density (i.e., bile) as well as evaluate any potential involvement of the biliary tree through use of magnetic resonance with cholangiopancreatography (MRCP). Findings on MRI are similar to that of CT scan, including a mass within the gallbladder lumen that is distinct from the density of the hepatic parenchyma and therefore useful for the determination of direct hepatic invasion (**FIG 6**).[17]
- Unfortunately, many gallbladder cancers are not diagnosed preoperatively but identified in the final pathology specimen for early-stage disease after laparoscopic cholecystectomy for cholelithiasis; up to 10% of all laparoscopic cholecystectomies performed for benign conditions such as cholelithiasis will harbor an incidental gallbladder cancer.[18] Additionally, some

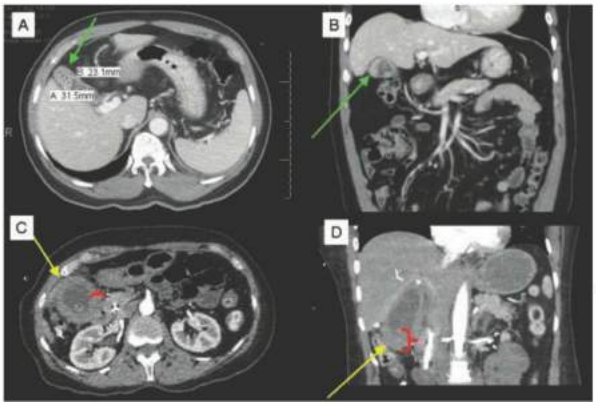

FIG 5 ● Axial **(A,C)** and coronal **(B,D)** contrast-enhanced CT findings of gallbladder cancer. Typical appearance may include that of a mass with intraluminal extension (*green arrows*; panels **A,B**) or diffuse thickening of the gallbladder wall (*yellow arrows noting region of gallbladder, and red brackets noting thickened area*; panels **C,D**) with a measured wall thickness in excess of 2 mm.

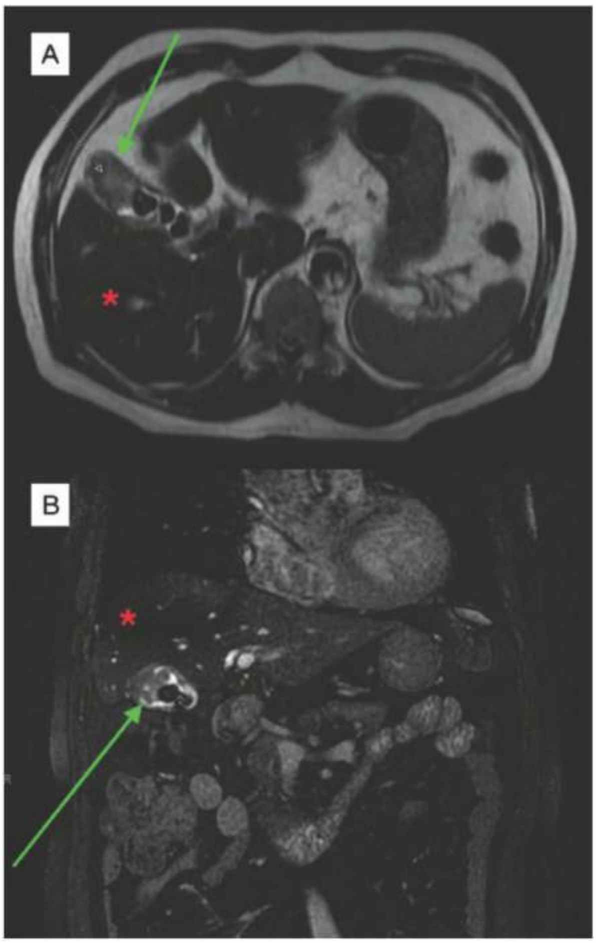

FIG 6 ● Axial **(A)** and coronal **(B)** contrast-enhanced MRI findings of gallbladder cancer. A focal thickening of the gallbladder wall is noted *(green arrows)* adjacent to the normal hepatic parenchyma *(red asterisks)*.

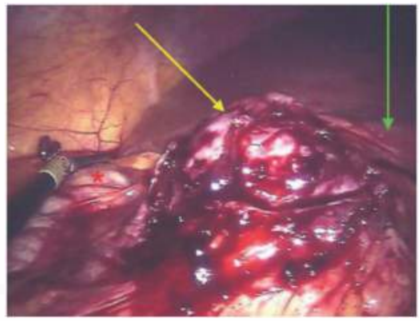

FIG 7 ● Laparoscopic identification of a gallbladder cancer with diffuse, firm, nodular thickening of the gallbladder wall *(yellow arrow)* with direct invasion of the hepatic flexure of the colon *(red asterisk)* as well as the hepatic parenchyma *(green arrow)*.

advanced-stage tumors may be mistaken for chronic cholecystitis preoperatively and only identified in the operating room. These tumors will have preoperative imaging of a contracted gallbladder with thickened walls. Intraoperatively, these tumors are clearly identified as malignant, with laparoscopic findings of nonpliable tissue, extremely thickened gallbladder wall, and often invasion into adjacent structures (e.g., omentum, liver, duodenum, hepatic flexure of the colon) (**FIG 7**).

- The tumor markers carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9) may be elevated in patients with gallbladder cancer but are neither sensitive nor specific for diagnostic purposes, or correlation with extent of disease.[19]

SURGICAL MANAGEMENT

Preoperative Planning

- Radical cholecystectomy may involve resection of up to two segments (IVb/V). Therefore, careful preoperative evaluation of hepatic function and the evaluation for the presence of cirrhosis are critical in determining whether the patient will have suitable hepatic reserve following parenchymal removal. Biochemical scoring systems such as Child-Pugh classification or the Model for End-Stage Liver Disease (MELD) can be useful for predicting morbidity and mortality following resection in cirrhotic patients. In addition, functional tests such as indocyanine green clearance can be a useful functional test, which can be used with computer software to preoperatively estimate the amount of resected hepatic tissue.[8,20–22]
- Although infections are uncommon following hepatic resection, prophylactic antibiotics should be administered to cover skin flora. If the patient has had recent biliary instrumentation, including the presence of a decompressive biliary stent, antibiotics should include coverage of intestinal flora.

Positioning

- Radical cholecystectomy is performed through a right subcostal incision. To facilitate exposure of the inferior aspect of the liver, the operative table may be slightly extended or a roll can be placed transversely under the patient's lower thoracic region (**FIG 8A**). These maneuvers elevate the costal margin and increase operative exposure of the liver.

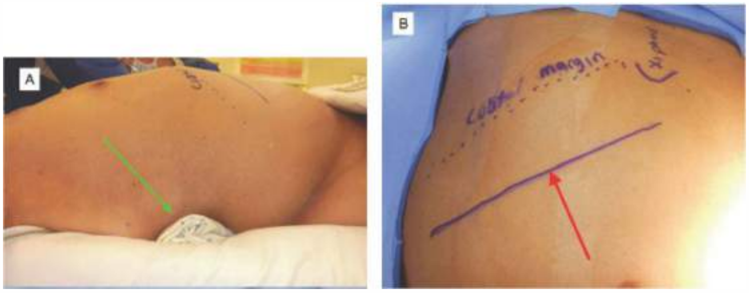

FIG 8 ● Patient position for a radical cholecystectomy with a lateral view **(A)** demonstrating a rolled sheet *(green arrow)* under the back to allow flexion of the patient, which may be combined with flexing of the operative table, and the planned right subcostal (Kocher) incision (*red arrow*, panel **B**) approximately two fingerbreadths below the costal margin.

INCISION AND EXPOSURE

- A right subcostal incision offers excellent exposure of the gallbladder, hepatic fossa, and porta hepatis (**FIG 8B**).
- The falciform ligament is divided to allow exposure and mobilization of the anterior hepatic lobes. A self-retaining retractor is placed, which allows for retraction of the right costal margin and inferior abdominal wall (**FIG 9**).
- Exploration of the abdomen is performed to exclude metastatic disease, which would preclude radical cholecystectomy. This would include hepatic metastasis, peritoneal metastases (including port site disease if the patient had a previous laparoscopic cholecystectomy), or lymph node disease of the common hepatic artery or celiac axis.
- The lesser omentum (also termed the gastrohepatic ligament) is divided to allow exposure of the common hepatic artery as well as the medial aspect of the porta hepatis. The porta hepatis is encircled with an umbilical tape that can be used as a Rommel tourniquet during a Pringle maneuver if vascular inflow occlusion is desired.

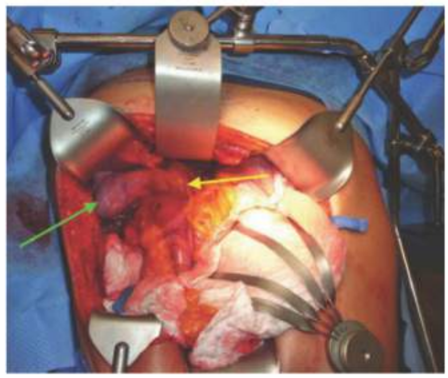

FIG 9 ● Exposure of the gallbladder with placement of a self-retaining retractor to allow complete exposure of the gallbladder *(green arrow)* as well as the porta hepatis *(yellow arrow)*. Costal margins are retracted superiorly as well as the hepatic flexure of the colon inferiorly.

INTRAOPERATIVE ULTRASOUND

- Ultrasound of segments IVb/V of the liver is performed to evaluate any extent of direct invasion of the hepatic fossa by the malignancy. A T-shaped linear array transducer with a broad frequency range (e.g., 4 to 10 MHz) provides excellent resolution, especially when coupled with Doppler scanning mode to facilitate identification of vascular inflow structures for surgical planning (**FIG 10**).

FIG 10 ● Intraoperative ultrasound is performed using a T-shaped linear array transducer *(yellow asterisk)* to allow interrogation of the hepatic parenchyma after the falciform ligament *(green arrow)* has been divided, as well as evaluation of the hepatic vascular inflow, and the possible extent of the cancer from the gallbladder *(yellow arrow)* into the hepatic fossa.

RESECTION OF SEGMENTS IVb/V

- Although nonanatomic resection of the hepatic fossa has been reported and the exact extent of parenchymal resection remains a point of controversy, formal resection of segments IVb (inferior aspect of segment IV) and V has traditionally been considered the appropriate segments of resection for radical cholecystectomy (see Part 3, Chapter 15, Surgical Anatomy, FIG 2).
- The hepatic parenchymal transection can be performed using a variety of techniques including clamp-crushing technique, ultrasonic dissection, thermal-sealing devices (e.g., LigaSure, Harmonic), radiofrequency-sealing devices (TissueLink), or water jet dissection (see Part 3, Chapter 21, Segmental Hepatic Resection).
- Major hepatic vasculature can be ligated with either traditional suture ligation or stapling devices using vascular staple loads (**FIG 11**).
- Should significant bleeding be encountered, the Rommel tourniquet can be used for temporary vascular inflow control (Pringle maneuver) to allow direct suture ligation or hemoclip application to ensure hemostasis.

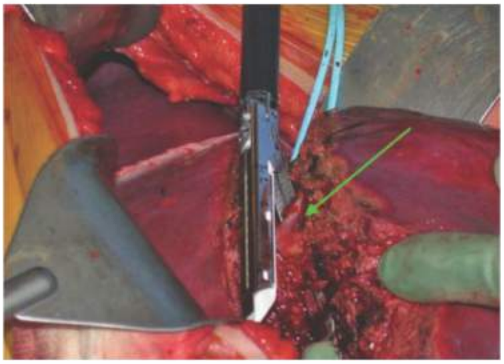

FIG 11 ● Following division of the hepatic parenchyma to segments IVb/V, a vascular stapler can be used to divide the portal venous branch *(green arrow)* to segments IVb/V.

- Following removal of segments IVb/V, the specimen should be oriented for the pathologist with intraoperative gross assessment of the margins if there is concern of significant tumor ingrowth into the hepatic fossa.
- The hepatic parenchymal surface is inspected for hemostasis and any evidence of biliary leak (**FIG 12**). Hemostasis can be obtained with either hemoclips or suture ligations; open biliary radicals should be directly suture ligated. The role of fibrin sealants may be to facilitate achieving hemostasis but has not been shown to reduce the incidence of bile leakage.[23]
- An omental flap should be mobilized from the hepatic flexure of the colon and placed into the parenchymal cavity. This may facilitate closure of small bile leaks. A closed suction drain is then placed into the abdomen over the omental flap ensuring that it provides drainage for the full extent of the hepatic parenchymal raw surface.

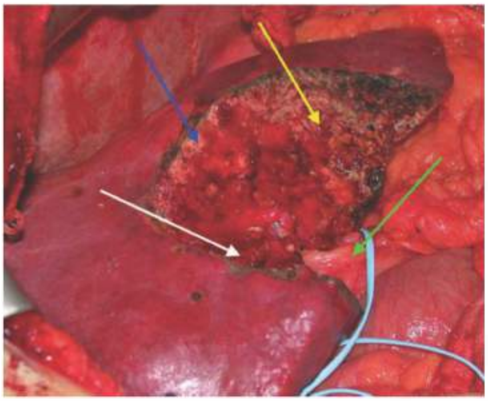

FIG 12 ● Completed radical cholecystectomy with raw surface of the boundary of resection. The margin between segments III and IVb *(yellow arrow)*, segments IVa and IVb *(blue arrow)*, and segments V and VI *(white arrow)* define a resected radical cholecystectomy. The porta hepatis *(green arrow)* can be controlled with a vessel loop (blue vessel loop).

PORTAL LYMPHADENECTOMY AND OPTIONAL RESECTION OF THE EXTRAHEPATIC BILIARY TREE

- If the cystic duct margin status is unable to be assessed or positive, or biliary obstruction is present, excision of the extrahepatic biliary tree is indicated.
- Lymphadenectomy should be performed regardless but may lead to ischemia to the extrahepatic biliary tree, resulting in delayed presentation of biliary stricture. Thus, some surgeons advocate routine excision of the extrahepatic biliary tree as a fundamental component of radical cholecystectomy.
- The peritoneum of the porta hepatis is circumferentially incised just below the liver plate and at the level of the first portion of the duodenum (**FIG 13**).
- The hepatic artery and portal vein are circumferentially dissected of associated lymphatics and splanchnic nerves. Ligation or bipolar electrocautery should be employed as these structures are rich in vascular supply. Care is taken to include the hepatic lymph nodes (**FIG 13**) in this dissection. Note that the majority of the portal lymph nodes are posterior and lateral to the preserved structures.
- If indicated, the common bile duct is divided as it enters the pancreatic parenchyma. The distal lumen should be oversewn with a running, monofilament suture of absorbable material. Assessment of this margin intraoperatively is controversial.
- The proximal hepatic duct is divided just distal to the confluence of the right and left hepatic ducts. An assessment of the proximal margin intraoperatively may be reasonable if an additional margin is feasible.
- Reconstruction of the biliary tree via Roux-en-Y hepaticojejunostomy is reviewed in detail in Part 3, Chapter 14.

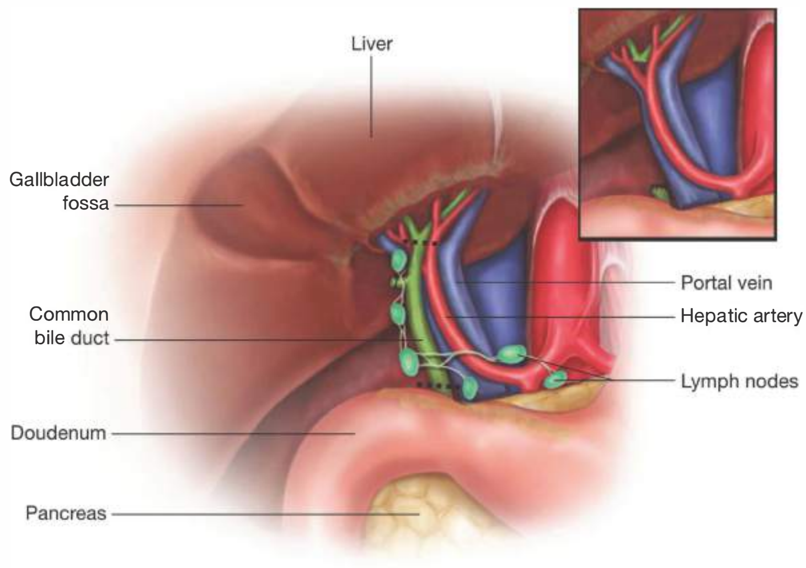

FIG 13 ● Portal lymph node dissection and optional resection of the extrahepatic biliary tree *(dashed lines)*. The hepatic artery and portal vein are dissected free of all surrounding lymphatics and splanchnic nerve tissue. The biliary tree is divided (optional) just distal to the confluence of the left and right hepatic ducts and at the level of insertion into the parenchyma of the pancreas *(inset)*.

PEARLS AND PITFALLS

Indications	■ Preoperative abnormalities on ultrasound should be further evaluated with contrast-enhanced CT scans to rule out advanced/unresectable disease. ■ Liver function should be carefully and thoroughly evaluated to ensure tolerability of hepatic bisegmentectomy. ■ Gallbladder cancers diagnosed on postoperative pathology from laparoscopic cholecystectomy should be reimaged with contrast-enhanced CT scans to rule out advanced disease not identified at laparoscopy.
Placement of incision	■ Right subcostal incisions should be placed approximately 2 cm below the costal margin to ensure sufficient exposure yet allow adequate fascia for closure. ■ If the gallbladder cancer is diagnosed following laparoscopic cholecystectomy, consideration should be given to excising the previous port site incisions.
Parenchymal transection	■ Care should be taken during parenchymal transection (independent of the method used) to seal major biliary radicals to reduce the incidence of a postoperative biliary leak. ■ Marking of the planned lines of parenchymal transection can facilitate complete resection of segments IVb/V, especially posteriorly at the porta hepatis.
Vascular control	■ Preresection intraoperative ultrasound can be useful to identify the major vascular inflow to ensure ligation at the initiation of parenchymal transection. ■ An umbilical tape around the porta hepatis can be a useful adjunct to allow rapid initiation of a Pringle maneuver to allow for hemostasis; care should be taken to minimize the time of vascular inflow clamping.
Closure	■ The closed suction drain should be placed to allow complete drainage of the hepatic operative bed but not placed directly adjacent to the parenchyma but instead over the transposed omental flap.

POSTOPERATIVE CARE

- Adequate pain control is critical to the postoperative recovery of patients undergoing major hepatic resection. Thoracic epidural catheters may be beneficial in environments with sufficient expertise for placement and care.
- Laboratory assessment of coagulation profile should be routinely checked and treated if abnormal to ensure adequate hemostasis.
- Elevated serum bilirubin levels can be a harbinger of bile leak, hepatic insufficiency, or vascular thrombosis. A contrast-enhanced CT scan should be used to differentiate the three etiologies.
- The fluid effluent from the closed suction drain can be evaluated for bilirubin content to evaluate for a bile leak. The drain should be removed as soon as there is no concern for a postoperative bile leak.

OUTCOMES

- Long-term hepatic function should not be adversely affected if the patient had normal preoperative hepatic function.
- Hepatic and peritoneal sites are the most common location for recurrent gallbladder cancer; outcomes are dependent

on the initial TNM stage. Early-stage disease (i.e., stage I) may be associated with 60% to 80% 5-year survival rates, whereas advanced-stage disease (i.e., stage III) is associated with less than 20% 5-year survival.

COMPLICATIONS

- Hemorrhage
- Bile leak
- Abscess formation
- Delayed stricture of the common hepatic duct/common bile duct due to devascularization associated with portal lymphadenectomy

Chapter 4

Endoscopic Retrograde Cholangiopancreatography

Shailendra S. Chauhan

DEFINITION

- Endoscopic retrograde cholangiopancreatography (ERCP) is an endoscopic technique whereby a specialized side-viewing upper endoscope (duodenoscope) is passed through the mouth to the major papilla in the second portion of the duodenum.
- Using various instruments through the working channel of the duodenoscope, access can be gained into the bile and pancreatic ducts and a variety of complex interventions can be performed. The ducts are usually visualized with x-ray after injection of a contrast medium into the ducts. Alternatively, direct visualization of the ducts is also possible via smaller scopes usually passed through the working channel of the duodenoscope or directly into the ducts without use of the duodenoscope.
- ERCP allows for minimally invasive management of pancreatic and biliary disorders, but it can be a challenging technique to learn and has higher potential for complications than other standard endoscopic procedures.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Prior to ERCP, a thorough patient history and physical exam should be performed to select appropriate laboratory and imaging studies for workup. These preprocedural studies will enable the proper selection of patients to benefit most from ERCP. A careful history of pancreatic and biliary symptoms and previous endoscopic and surgical therapy of the biliary tree or pancreas is essential. In addition, previous intestinal surgery may make ERCP technically difficult or impossible (such as a previous Roux-en-Y gastric bypass). Finally, complicating medical conditions can be elicited, which might impact the safety of anesthesia or increase the risk of complications of ERCP (such as anticoagulation).
- ERCP is indicated for patients with a variety of biliary tract and pancreatic disorders.[1] For patients with such disorders, specific symptoms may include abdominal pain (location, character, frequency, duration, alleviating and exacerbating factors), nausea and vomiting, jaundice, change in color of stools and urine, pruritus, steatorrhea, weight loss, and hyper or hypoglycemia. Physical exam should evaluate for jaundice, detailed abdominal exam, and signs of malnutrition or cachexia, which may suggest underlying chronic disease or malignancy.
- Key aspects of social history include tobacco use and alcohol. In those patients with suspected malignancy, it is important to elicit any family history of similar malignancies.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Specific laboratory work obtained to decide the need for ERCP usually includes liver enzymes (transaminases, alkaline phosphatase, direct and indirect bilirubin) and pancreatic enzymes (amylase and lipase). In suspected malignancy, certain tumor markers such as carbohydrate antigen 19-9 (CA 19-9), carcinoembryonic antigen (CEA), and α-fetoprotein (AFP) may be obtained as deemed appropriate. Typically, coagulation parameters (platelets, prothrombin time [PT], international normalized ratio [INR], and partial thromboplastin time [PTT]) are not obtained unless the patient is on anticoagulation or history suggests coagulopathy.
- Imaging studies for suspected biliary and pancreatic disease may include transabdominal ultrasound; high-quality, cross-sectional imaging such as abdominal computed tomography (CT) scan; or magnetic resonance imaging (MRI) or magnetic resonance cholangiopancreatography (MRCP). Transabdominal ultrasound is typically not adequate for accurate visualization of the entire pancreas. Endoscopic ultrasound (EUS), however, can provide valuable information about pancreatic ductal and parenchymal anatomy and biliary anatomy for proper selection of patients for ERCP.

SURGICAL MANAGEMENT

- ERCP has evolved from a diagnostic to an almost exclusively therapeutic procedure.[1] Imaging studies that have been described in the previous section (transabdominal ultrasound, CT, MRI/MRCP, intraoperative cholangiography, EUS) should provide diagnostic information for proper selection of patients requiring therapeutic ERCP. In general, a careful assessment of pancreatic ductal and biliary anatomy by one of these techniques is required prior to considering ERCP. ERCP should almost never be used for diagnostic purposes only, as the risk of ERCP outweighs the benefit in this circumstance.
- ERCP is not indicated in the evaluation of abdominal pain of obscure origin in the absence of other objective findings suggesting biliary tract or pancreatic disease.[1]
- ERCP is indicated in patients with various pancreaticobiliary disorders. Specific biliary indications include therapy for choledocholithiasis, management of benign and malignant biliary strictures (including tissue sampling, stricture dilation, stenting), and evaluation and treatment of bile leaks.[1]
- Pancreatic diseases that can be evaluated and treated with ERCP include recurrent acute pancreatitis, management of pain in chronic pancreatitis patients with obstruction of pancreatic duct due to stones and/or strictures, pancreatic duct leaks, drainage of fluid collections that communicate with the pancreatic duct, and pancreatic cancer causing pancreatic duct and/or bile duct obstruction.[1]
- Other specific conditions that can be evaluated and treated with ERCP include ampullary stenosis, sphincter of Oddi dysfunction (SOD), type III biliary cysts (choledochocele), pancreas divisum causing recurrent acute pancreatitis, and treatment of ampullary cancers and adenomas.[1]
- Table 1 outlines indications for therapeutic ERCP.

Table 1: Indications for Therapeutic Endoscopic Retrograde Cholangiopancreatography

Biliary
Choledocholithiasis
– High preoperative probability
– Intraoperatively diagnosed
– Definitive diagnosis prior to surgery
Strictures
– Benign
– Malignant
Postoperative bile leaks
Choledochocele (type III biliary cyst)
Biliary sphincter of Oddi dysfunction
– Type I
– Type II
Pancreatic
Chronic pancreatitis
– Stricture
– Stones
– Both
Pancreatic duct disruption
Transpapillary pseudocyst drainage
Strictures
– Benign
– Malignant
Acute pancreatitis
– Acute biliary pancreatitis
– Recurrent acute pancreatitis
– Pancreas divisum causing recurrent acute pancreatitis
Pancreatic sphincter of Oddi dysfunction
– Type I
– Type II
Other
Ampullary cancer or adenoma

Preoperative Planning

- ERCP is usually performed as an outpatient procedure, but postprocedural observation may be prolonged due to the potential complexity of the procedure as compared to other standard endoscopic procedures.
- Prior to initiation of the procedure, the endoscopist should be absolutely certain of the indication of the procedure taking into account all of the preprocedural workup. The importance of having a well-defined therapeutic goal for the procedure cannot be overemphasized. ERCP should not be performed for diagnostic purposes only.
- Informed consent should be obtained, explaining all the potential benefits, risks, and alternatives. This should include a discussion of the risk to that individual patient, taking into account the patient and procedural factors which influence the rate of postprocedure complications.
- Table 2 details risk factors for overall complications of ERCP.
- Patients are kept NPO overnight prior to the procedure. Antibiotics with broad-spectrum coverage should be considered periprocedurally in only limited circumstances of biliary ductal obstruction or transpapillary pancreatic pseudocyst drainage.

Positioning

- The patient lies in a left semiprone position on the fluoroscopy table with both arms at their side. The right chest/shoulder is usually propped up slightly so that the head faces the endoscopist (**FIG 1**). A plain radiograph (scout film) is usually taken to ensure the field is clear of any radiopaque material such as monitoring wires and to document the presence/absence of any devices such as drains, stents, feeding tubes, and so forth.
- Sedation can be either conscious sedation (combination of benzodiazepine and opiate) administered under the supervision of the endoscopist or monitored anesthesia care (MAC). Most units now use either MAC or general anesthesia, depending on patient and case specifics.

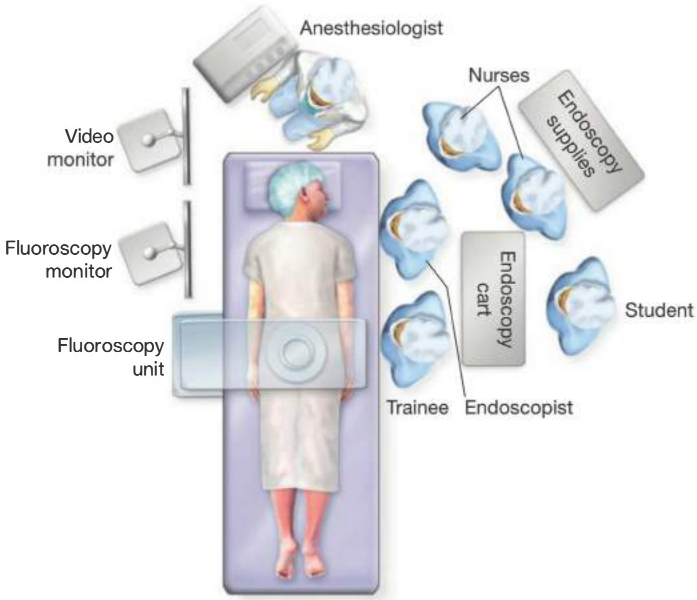

FIG 1 ● Positioning of patient for ERCP.

- Depending on the indications, various maneuvers may be performed during ERCP. However, passage of the scope to the major papilla in the duodenum and selective cannulation of the desired duct is essential to every successful ERCP.

INTUBATION OF ESOPHAGUS AND PASSAGE OF SCOPE TO DUODENUM

- Because the duodenoscope is a side-viewing instrument, passage through the oropharynx and esophagus is more by feel than direct visualization. Before intubation, ensure that instrument is in proper working order. The up-and-down and lateral movement dials should be unlocked and the elevator checked to ensure proper functioning; the elevator should be in a relaxed (down) position during insertion. The light source and attachments to the scope, that is, irrigation, suction, insufflation should be checked. Once the patient is adequately sedated, the back of the scope is lubricated (taking care not to smear over the lens) and the scope is guided over the patient's tongue to the upper esophageal sphincter. With gentle pressure, the scope should pass into the patient's esophagus and down to the stomach. If any abnormal resistance is encountered while intubating the esophagus, the scope should not be forced. It may need to be removed and the anatomy reviewed with a forward-viewing gastroscope.
- Once the scope enters the stomach, slight air insufflation may be required to orient the tip toward the antrum. The scope is then passed along the greater curvature toward the pylorus. Once the exact location of pylorus is determined, the scope tip is angled upward and advanced through the pylorus. Because of the side-viewing nature of the scope, the pylorus will not be seen as the scope passes through it.
- The scope is then passed carefully under direct vision to the level of the second portion of the duodenum. Full forward vision is not possible with this scope, and duodenal perforation is possible if an attempt is made to obtain a full forward view of the lumen. At this point, the scope is usually in a "long position." A shortening maneuver is performed by torqueing the scope shaft clockwise and pulling the scope out of the patient's mouth while the right wheel is locked in a full rightward position. This usually leads to paradoxical forward motion of the scope tip such that the scope ends up in the preferred "short position" (**FIG 2**). From this position, small adjustments can be made with a combination of movement of up-and-down and lateral movement dials as well as the endoscopist changing his/her stance slightly left or right. These motions ultimately bring the major papilla into an adequate en face cannulating position. At this point, depending on endoscopist preference, the scope dials may be locked for a more stable position.

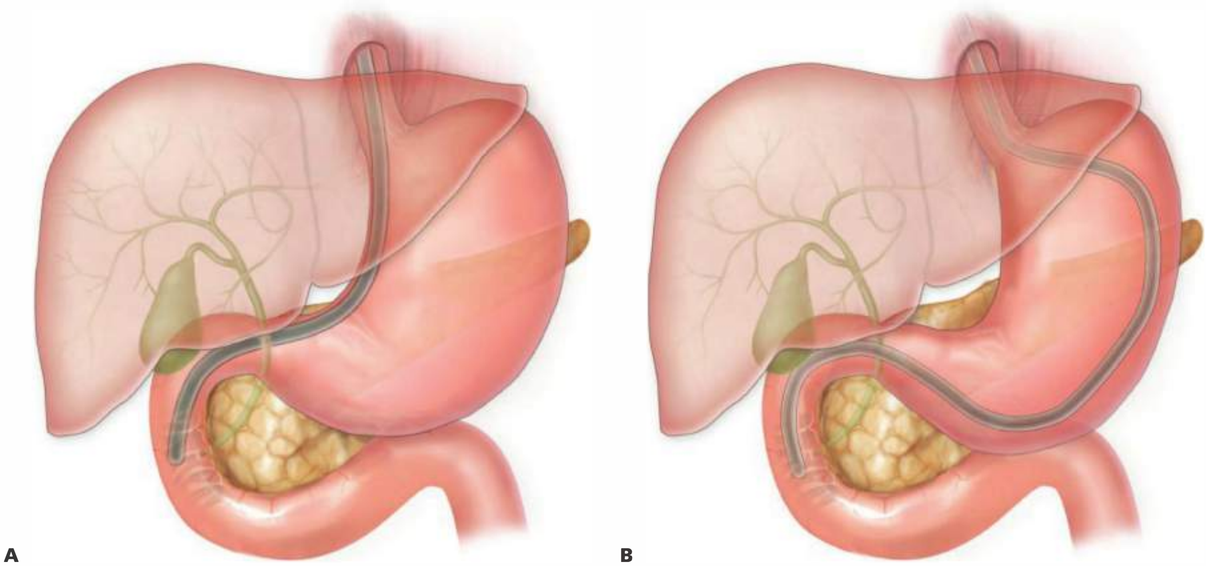

FIG 2 ● Short **(A)** and long **(B)** positions of duodenoscope for major papilla cannulation.

MAJOR PAPILLA CANNULATION

- Selective cannulation of the desired duct is the most important and most difficult skill to master for successful ERCP. Knowledge of normal papillary anatomy is essential, as is adequate training and experience. The most common reason for failure is inability to cannulate the duct of interest. Studies suggest that 180–200 cases in training are necessary before even moderate rates of cannulation are achieved.[2] Furthermore, it has been suggested that it takes about 1000 cannulations to become truly comfortable with the technique and several thousand more to become expert.[3] Various cannulation techniques have been described but all involve the use of catheters and guidewires. Typically, catheters with cutting wires (sphincterotomes) and preloaded guidewires are used for therapeutic ERCP. Another general principle is to avoid too much contrast injection until the endoscopist is reasonably sure that the cannulating device is at least superficially in the desired duct. This serves to avoid too much fluoroscopic exposure, avoid submucosal injection, and reduce the risk of post-ERCP pancreatitis.
- Selective biliary cannulation is initially achieved by superficially probing the major papilla usually at the 10 o'clock to 12 o'clock position, thereby staying superior to the intraductal septum and aiming the catheter upward (FIG 3). Once the catheter tip has advanced slightly into the duct orifice, either the guidewire can be advanced further or contrast can be injected to confirm position. If inadvertent pancreatic duct cannulation is achieved, it is important to avoid or limit any contrast injection (unless pancreatic duct cannulation is desired). Once superficial biliary cannulation is confirmed, the guidewire is advanced further proximally into the duct followed by catheter advancement to achieve deep cannulation.
- Selective pancreatic cannulation is achieved by approaching the papilla generally at its center but aiming at the 2 o'clock position. This usually aligns the catheter tip axis below the septum toward the pancreatic duct orifice (FIG 3). Using a combination of guidewire and catheter advancement, deep cannulation can be achieved. An important aspect is to limit contrast injection to small amounts so as to avoid acinarization of the pancreas, thereby decreasing the potential for post-ERCP pancreatitis.
- In certain instances where selective cannulation of the desired duct may not be easily achieved due to abnormal or pathologic anatomy (such as periampullary diverticulum,

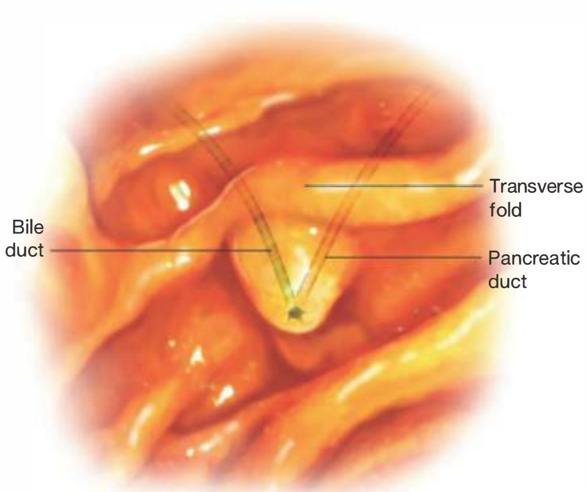

FIG 3 ● Approach to major papilla for selective cannulation of bile and pancreatic ducts.

malignancy, postsurgical anatomy), special techniques and/or devices may need to be used. These may include performance of a "precut" or "access" sphincterotomy, use of rotatable cannulating devices, placement of a pancreatic stent (to facilitate biliary cannulation and reduce risk of postprocedure pancreatitis), and the use of specific guidewires which may differ in caliber or hydrophilic nature. In certain cases of postsurgical anatomy, ERCP may be impossible with duodenoscopes. In these instances, enteroscopes (device or nondevice assisted) may be required, which can make the procedure more technically challenging. Patients who have undergone bariatric surgery in whom the stomach and proximal small bowel is bypassed pose a special challenge. In such patients, the procedure can be attempted with enteroscopes, but laparoscopic-assisted ERCPs (with the assistance of a surgical team) are becoming the preferred approach.

- In patients whom biliary cannulation is initially unsuccessful, the procedure can be reattempted in a day or two if the clinical situation allows. Referral to a center with expertise in ERCP is also reasonable. However, if delay is not feasible, patients generally proceed to percutaneous biliary catheter placement by interventional radiology. Depending on case specifics and endoscopist expertise, EUS-guided biliary access can be performed too.
- Pancreas divisum anatomy poses specific cannulation challenges because the major drainage of the pancreas is via the duct of Santorini via the minor papilla. These cases can be challenging since they may require a "long" scope position, use of smaller caliber catheters and guidewires, and possibly even a pancreatic secretagogue such as secretin, which may allow for the opening of the ductal orifice.

SPHINCTEROTOMY

- Once deep access of the desired duct is obtained, biliary and/or pancreatic sphincterotomy is generally required to perform further therapeutic manipulations. The most common type of device for this maneuver is a traction-type sphincterotomes in which the cutting wire carries the electrosurgical current and bends the tip of the sphincterotome. These are used when deep guidewire access of the desired duct has been attained. Such sphincterotomes may be rotatable (depending on manufacturer) and can be especially helpful in postsurgical anatomy. Additionally, a "needle-knife" sphincterotome may be required in difficult cannulation cases. Occasionally, needle-knife sphincterotomes can be used to perform an over-the-stent sphincterotomy. Electrosurgical current for sphincterotomy generally uses a blend current (mixture of cutting and coagulation) and it is commonplace to use an electrosurgical generator with pulse cutting so as to avoid inadvertent longer than desired or too rapid cuts ("zipper-cuts").
- Biliary sphincterotomy is performed when deep biliary access has been achieved and the guidewire is passed into the proximal biliary tree. Once the scope and sphincterotome are in a stable position, the sphincterotome tip is bowed such that the cutting wire is aiming in the 11 o'clock position. It is important to keep as little of the wire in contact with the tissue so as to get a precise cut and avoid coagulation which causes more of a charring effect. Using the shaft of the scope, the cut is guided toward the 11 o'clock position, taking care to not cut past the transverse fold (**FIG 3**). The size of the sphincterotomy generally depends on the therapeutic maneuver planned. In general, large biliary sphincterotomies are only required for removal of large biliary stones. Furthermore, if an adequate sphincterotomy has been performed but passage of stones is still difficult, balloon dilation of the biliary orifice can be performed (**FIG 4**).
- Pancreatic sphincterotomy is performed with similar technique to biliary sphincterotomy, but the cutting wire is aiming at the 2 o'clock position. In general, pancreatic sphincterotomies should be smaller in length compared to biliary. Some endoscopists prefer to initially place a pancreatic stent as a guide and perform an over-the-stent cut using a needle-knife sphincterotome.

STONE EXTRACTION

- Stones are typically extracted using balloon catheters or baskets. Factors that influence success of stone extraction include their size and shape (especially in relation to duct size) and absolute number. Additionally, pancreatic stones can be much harder to remove compared to biliary due to associated strictures and inflammation from chronic pancreatitis. An adequate sphincterotomy is essential prior to extraction. Occasionally, balloon dilation of the ductal orifice can be performed if the sphincterotomy is deemed to be adequate but further cutting could cause bleeding or perforation (**FIG 4**).
- Typically, balloons are used first line, but if this fails, metal baskets are used to capture stones for removal

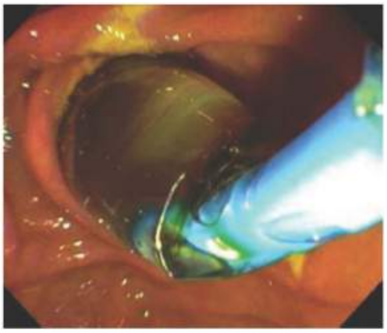

FIG 4 ● Balloon dilation of biliary orifice.

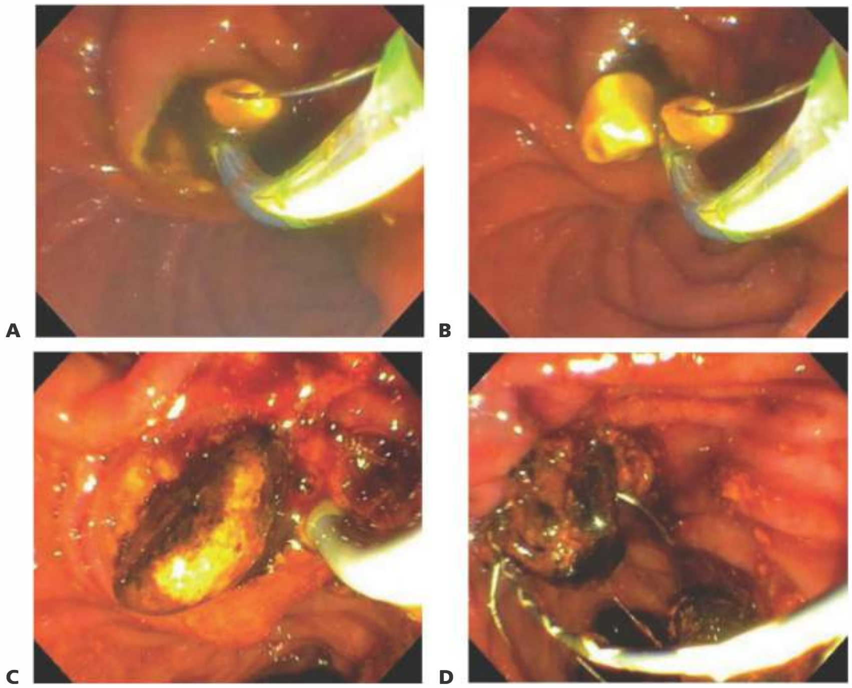

FIG 5 ● Stone extraction from bile duct. In **A** and **B**, small stones may pass spontaneously after adequate biliary sphincterotomy. In **C**, a balloon extraction catheter is deployed proximal to a stone and the stone is being extracted. In **D**, an expanding wire basket has been deployed, enveloping the stone, and then withdrawn back into the duodenum leading to crushing and/or removal of the calculus.

(**FIG 5**). Occasionally, the baskets may become impacted with a stone and difficult to remove due to stone shape and/or ductal anatomy. In this case, mechanical lithotripsy with various accessories can be performed. If complete stone removal is not possible in a single ERCP session, a stent is inserted to ensure ductal drainage prior to next ERCP.

- In cases of failed stone extraction or mechanical lithotripsy, other techniques such as electrohydraulic lithotripsy (EHL), holmium laser lithotripsy, or extracorporeal shock wave lithotripsy (ESWL) may be employed. Surgical removal of biliary stones is rarely required. For failed pancreatic stone extraction, surgery may be indicated to improve patient symptoms from chronic pancreatitis.

STRICTURE DILATION

- Devices for biliary and pancreatic stricture dilation are available. Stricture dilation is indicated for both benign and malignant indications. The general principle is that the dilating device is passed through the working channel of the scope over the preplaced guidewire until it is positioned across the stricture. Dilation is usually performed under fluoroscopic guidance to ensure that the device does not slip proximal or distal to the strictured area.
- Cylindrical-shaped balloon dilation catheters that exert radial force are typically used for dilation of biliary strictures. The balloons can be filled with contrast material and hence are visible on fluoroscopy as the balloon is inflated while ensuring the balloon is centered on the strictured area. The typical balloon diameter sizes for biliary dilation range from 4 to 10 mm. The lengths of the balloons are typically 2 to 4 cm.
- Dilation of pancreatic strictures can be performed using similar balloon dilation catheters as biliary strictures. However, owing to the smaller size of the pancreatic duct, the sizes of the balloons used are smaller. Additionally, smaller graduated bougie type dilators are also available for dilating smaller and tighter pancreatic duct strictures. These dilators provide axial force in addition to radial force and can be quite helpful in patients with chronic pancreatitis and resultant fibrotic strictures.
- Occasionally, larger diameter dilators are required for biliary indications. In cases where the bile duct is dilated proximal to a stricture or dilation of a biliary sphincterotomy orifice is needed for large stone passage, graduated esophageal balloon dilators can be used. In principle, these devices, designed for esophageal strictures, work similarly to dedicated biliary and pancreatic balloon dilators.

STENT INSERTION

- Various biliary and pancreatic stents are available and they differ in terms of material (plastic or metal), diameter, length, and design. Whereas the practice of plastic stent insertion has not changed much over the years, the use of metal stents has expanded greatly (**FIG 6**). Previously, metal mesh stents were used for palliation of malignancy but newer, covered metal stents are available. Such stents are easily removable and hence are being used for benign indications. The general purpose of stents is to serve as a conduit for duct drainage across an obstruction. Stents can be placed temporarily for benign indications or as a bridge to definite therapy. Additionally, they can be permanently placed for palliation in the setting of nonoperable malignancy.
- The general technique for stent insertion is over a guidewire advanced deeply into the desired duct. While keeping guidewire access, the stent is deployed using endoscopic and fluoroscopic guidance through the duodenoscope using a pushing catheter. It is important to keep the scope tip close to the papilla, making sure the stent is aiming in the axis of the desired duct as it is being deployed. If too much of the stent is exposed into the duodenal lumen, it can lead to bowing of the stent and difficulty in passage. This is especially important in trying to pass stents across tight strictures. Whether or not to dilate strictures prior to stent deployment depends on stricture characteristics and endoscopist preference.

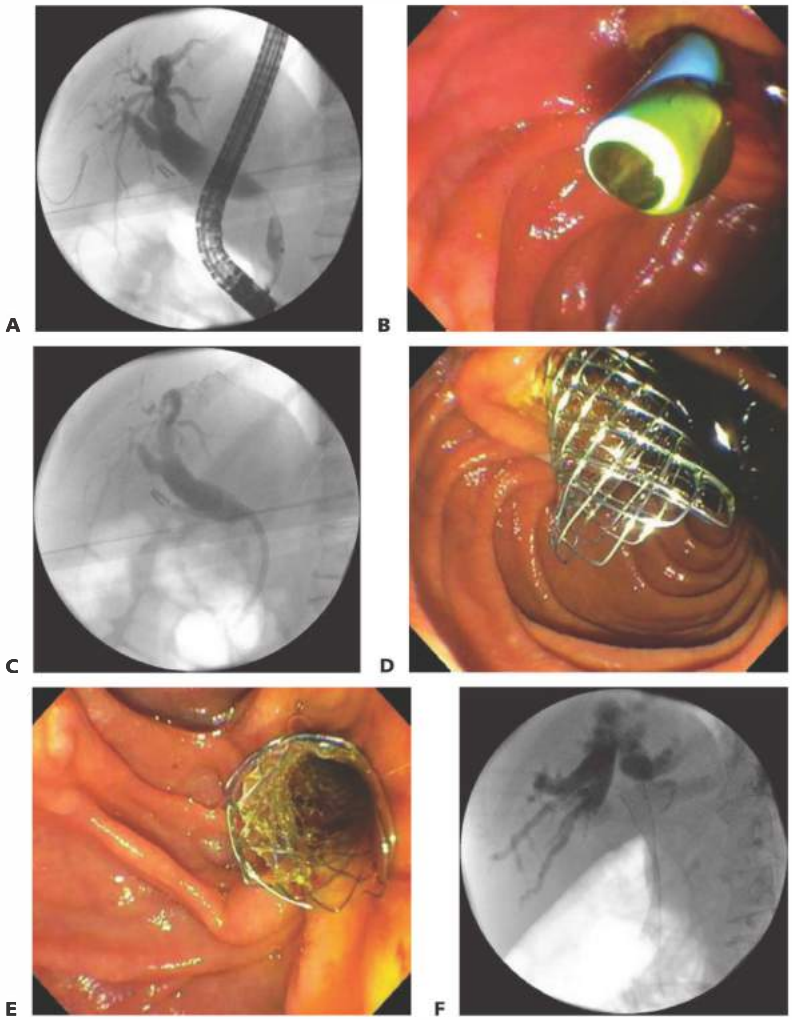

FIG 6 ● Endoscopic and fluoroscopic views of plastic and metal biliary stents. **A.** Fluoroscopic view of a biliary stricture. **B.** Endoscopic image of a deployed plastic biliary stent. **C.** Radiographic appearance of a plastic biliary stent. **D,E.** Endoscopic views of a well-positioned metal biliary stent. **F.** Fluoroscopic appearance of a metal biliary stent.

TISSUE ACQUISITION

- Tissue can be acquired from the biliary or pancreatic ducts for histologic and cytologic examinations. Typically, this tissue is acquired from strictures when the etiology, that is, benign versus malignant, is in question. The usual devices for histology and cytology are cold biopsy forceps and brushes, respectively. These are passed through the working channel of the duodenoscope into the duct and advanced under fluoroscopic guidance to the area in question. Under real-time fluoroscopy, the endoscopist can then take biopsy specimens or brushings, which are then sent to the appropriate laboratory for analysis.
- Occasionally, specimens can be taken under direct visualization of the interior of the duct during choledochoscopy or pancreatoscopy (see next section for details).

CHOLANGIOSCOPY AND PANCREATOSCOPY

- In certain situations, direct visualization of the interior of ducts may be required. The two main indications at the current time are visualization of indeterminate strictures (and tissue acquisition under direct endoscopic guidance) and lithotripsy of large stones. Older systems used a "mother-daughter" system in which a smaller scope was inserted through the duodenoscope directly into the ducts. These "daughter" scopes were prone to damage from the elevator of the duodenoscope. Disposable, multilumen, steerable catheter devices are presently used. These can be inserted through the duodenoscope channel into the pancreatic and biliary ducts. Through these catheters, a reusable optical fiber is passed for visualization and specially designed biopsy forceps can be used for tissue acquisition. Newer systems aimed to provide improved optics and tissue acquisition are being developed.
- Usage of cholangioscopes and pancreatoscopes can be technically challenging because the endoscopist has to maintain simultaneous control of the duodenoscope and the smaller scope. Usually, once guidewire access of the desired duct is achieved, the device with its control dial end is attached to the duodenoscope and the catheter end is advanced through the duodenoscope into the duct. Using both fluoroscopic guidance and endoscopic visualization of the interior of the duct, the endoscopist can evaluate for presence or extent of malignant-appearing lesions, obtain biopsy specimens, examine the duct for any stones, or perform lithotripsy of large stones.
- In specific situations when the duct caliber is very large, it may be possible to insert a forward-viewing gastroscope directly into the biliary or pancreatic ducts (without the use of a duodenoscope). Although such procedures may be technically challenging, the potential advantages include improved visualization, ability to pass standard size biopsy forceps, and capture/removal or mechanical lithotripsy of large stones under direct view. This procedure has been associated with air venous embolism, so the use of carbon dioxide (CO_2) as an insufflating agent is required.

SPECIAL SITUATIONS

- ERCP can be used in special situations such as SOD, performance of ampullectomy, or in the pediatric setting.
- SOD is a somewhat controversial topic but has been implicated as a potential cause of pancreatic or biliary disease. Patients with SOD are especially high risk for post-ERCP pancreatitis, and the procedure should only be undertaken if there is objective evidence to support the diagnosis or an extensive prior workup has been unrevealing. It is generally classified as biliary or pancreatic and further subclassified depending on presence/absence of dilation of the duct and presence of laboratory abnormalities (elevated liver or pancreatic enzymes). Specialized, graduated manometry catheters are passed into the ductal orifices and pressure is measured. A sustained pressure over 40 mmHg is considered abnormal and is an indication for sphincterotomy. Postprocedurally, patients should be well hydrated with intravenous (IV) fluids and a prophylactic, temporary pancreatic stent should always be placed to reduce the risk of post-ERCP pancreatitis. Newer data suggests that the use of postprocedural rectal, nonsteroidal antiinflammatory drugs (NSAIDs) can also reduce the risk of post-ERCP pancreatitis in such high-risk groups.[4]
- ERCP can be used to perform ampullectomy for obstructing adenomas (**FIG 7**). If the lesion is large, EUS should be performed first to ensure endoscopic resectability. Various techniques for ampullectomy have been described; if possible, an attempt should be made to perform an en bloc hot snare resection. A submucosal injection of saline may be performed initially to provide a cautery cushion prior to removal. If the lesion is too large for en bloc resection, piecemeal ampullectomy with cauterization of the edges of the resection base can be performed. Placement of a prophylactic pancreatic stent and biliary sphincterotomy are recommended to reduce the risk of postprocedure pancreatitis and cholangitis, respectively.
- ERCP is less common in the pediatric population but is usually performed for biliary stone extraction. For small children, a specialized pediatric duodenoscope is used. It is limited by the small-sized accessory devices, which can be accommodated through its working channel. For older children and adolescents, generally, the standard duodenoscope with accessories can be used. Other less common indications could include postoperative strictures, traumatic or postoperative bile or pancreatic leaks, or chronic pancreatitis due to a genetic etiology.

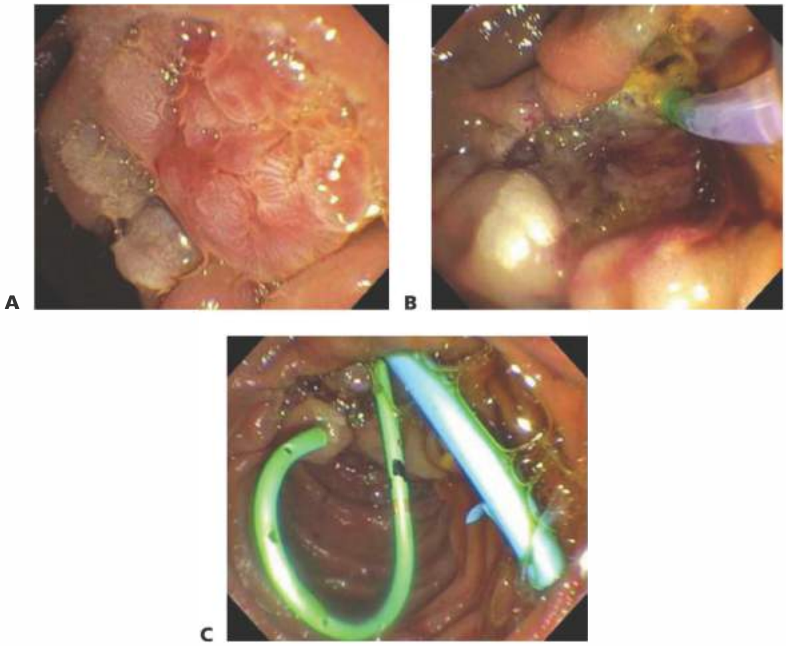

FIG 7 ● Pre- and postampullectomy endoscopic images. **A.** Endoscopic visualization of a sessile, ampullary polyp. **B.** Endoscopic ampullectomy has been performed and catheter access to pancreatic duct is achieved. The biliary orifice is seen above. **C.** Protective stents in both the bile duct **(right)** and pancreatic duct **(left)** are an essential component of endoscopic ampullectomy.

PEARLS AND PITFALLS

Indications	■ ERCP should be performed with a therapeutic intent and not for diagnostic purposes only. ■ The endoscopist should obtain diagnostic information from patient history and physical, imaging, and laboratory parameters to carefully select those patients who will benefit most from therapeutic ERCP.
Intubation of esophagus	■ Due to the side-viewing nature of scope, passage through oropharynx and esophagus is mostly by feel and not direct visualization. ■ If patient's history suggests abnormal or post-surgical anatomy or any difficulty is encountered with the duodenoscope, the anatomy should be evaluated with a forward viewing scope.
Cannulation	■ Selective cannulation of the desired duct is the key to successful ERCP and requires expertise and patience. ■ Successful cannulation is achieved by knowledge of normal papillary anatomy, proper scope position, and aligning the cannulating device to the axis of the duct of choice. ■ The cannulating device should never be forced into the duct.
Post-ERCP complications	■ Patients that are highest risk for post-ERCP complications (especially pancreatitis) are often the ones that do not have a firm indication for the procedure. ■ In those with high risk for pancreatitis, ensure that they receive adequate intra- and postprocedure IV fluids, placement of temporary pancreatic stent, and/or rectal NSAIDs. It may be wise to admit these patients postprocedurally for observation. ■ If complication is suspected or confirmed, admit the patient and treat accordingly. Keep patient and family fully informed of patient progress.

POSTOPERATIVE CARE

- Generally, ERCP can be done as an outpatient procedure; however, patients may need to be observed longer than those undergoing standard endoscopic procedures. High-risk patients (such as those with SOD) or those with difficult cannulation have higher rates of post-ERCP pancreatitis and may be prophylactically admitted to the hospital for observation.
- Once patients recover from the procedure, they can resume their normal activities, medications, and diet. In patients who need to restart anticoagulation, it is generally safe to resume postprocedurally.

OUTCOMES

- ERCP itself has high procedural success rates when performed by skilled endoscopists, but patient outcomes ultimately depend on the indications of the procedure.
- For biliary indications, the procedure has excellent immediate success rates for stone clearance, reestablishing bile flow in benign and malignant strictures, and resolution of bile leaks.
- ERCP in patients with chronic pancreatitis should be in well-selected patients that are maximized on medical therapy. In such patients, it has potential for good short-term results, but due to the nature of the disease, may ultimately need surgical therapy. In patients with pancreatic malignancy causing biliary obstruction, ERCP can reestablish immediate bile flow, but ultimate outcome will depend on the clinical stage of the disease.

COMPLICATIONS

- Table 3

Table 3: Complications of Endoscopic Retrograde Cholangiopancreatography

Post-ERCP pancreatitis (1.5%–20%)
Hemorrhage (0.1%–2.0%)
Perforation (<1%)
Infection (<1%)
Cardiopulmonary (1%)
Miscellaneous
Stent related (migration, occlusion, perforation, acute cholecystitis, biliary or pancreatic duct injury)
Ileus
Hepatic abscess
Pneumothorax/pneumomediastinum
Duodenal hematoma
Portal venous air
Impaction of therapeutic devices (stone retrieval baskets)
Perforation of colonic diverticula

Chapter 5 Intraoperative Cholangiogram

Chasen A. Croft   Dawood G. Dalaly

DEFINITION

- Intraoperative cholangiography (IOC) is the use of radiography with contrast media injected directly into the biliary tree to determine biliary anatomy, assess the biliary tree for obstructive processes, and to evaluate for potential injury to the biliary tract.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Many surgeons routinely perform cholangiography as a part of every cholecystectomy. Others selectively use cholangiography based on the results of preoperative testing or intraoperative findings. A preoperative common bile duct (CBD) diameter greater than 6 mm, obstructive jaundice (direct bilirubin >4.0 g/dL), pancreatitis, and small stones in the gallbladder have all been forwarded as indications for IOC. Intraoperative indications would include palpating stones in the CBD, unclear biliary anatomy, or to evaluate for inadvertent injury to the biliary tree.[1]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Prior to proceeding with cholecystectomy with IOC, patients should have an ultrasound evaluation of their biliary tree to assess for cholelithiasis, cholecystitis, and to determine the diameter of the extrahepatic CBD. Note that abdominal ultrasound is not a sensitive indicator of choledocholithiasis as CBD gallstones are often located in the distal CBD within the intrapancreatic portion and are thus obscured by air in the overlying stomach and/or are beyond the depth of penetration of ultrasound.
- In the absence of cholangitis, but presence of ultrasound or laboratory findings suggestive of choledocholithiasis, one forwarded option is to preoperatively evaluate the biliary tree with magnetic resonance cholangiopancreatography (MRCP) to determine the cause of biliary tree obstruction. Should biliary obstruction be present, preoperative endoscopic retrograde cholangiopancreatography (ERCP) is then performed to clear the duct of stones prior to cholecystectomy or identify more ominous etiologies of the biliary obstruction.
- Alternatively, others have advocated directly proceeding to cholecystectomy with IOC in this clinical setting, arguing that current modalities lack accuracy in identifying clinically significant choledocholithiasis and performance of an IOC often clears the duct of small stones. As such, these surgeons argue that the presurgical probability that an ERCP is necessary is low and this approach is more cost-effective by avoiding unnecessary ERCP.

SURGICAL MANAGEMENT

Positioning

- The patient should be placed in the supine position on the operating room table. The left arm is preferentially tucked against the torso to provide room for C-arm fluoroscopy. The table should be positioned with respect to the supporting pedestal so as to allow the fluoroscopy C-arm to slide underneath the operating table unobstructed (**FIG 1**).

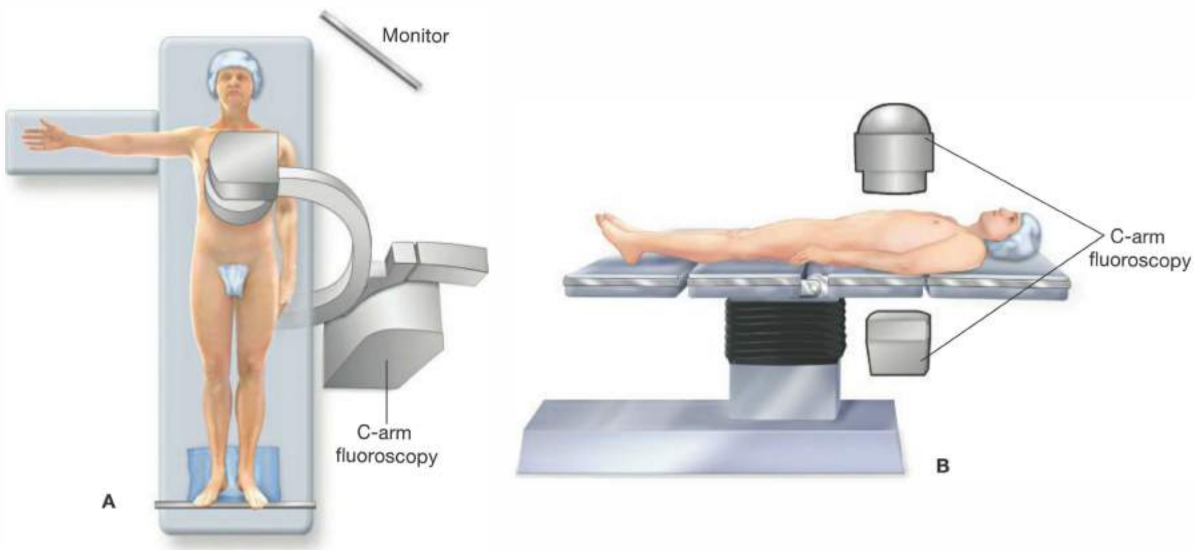

FIG 1 ● **A.** The patient is positioned supine with the left arm tucked. A footboard is placed. The C-arm fluoroscopy unit is positioned to the patient's left, with the monitor readily visible to the operating surgeon who is on the patient's right. **B.** The patient must be positioned with respect to the pedestal of the operating table so that there is adequate room for the C-arm. *(continued)*

C

FIG 1 ● *(continued)* **C.** Photograph demonstrating a clear path beneath the abdomen of the patient for the C-arm.

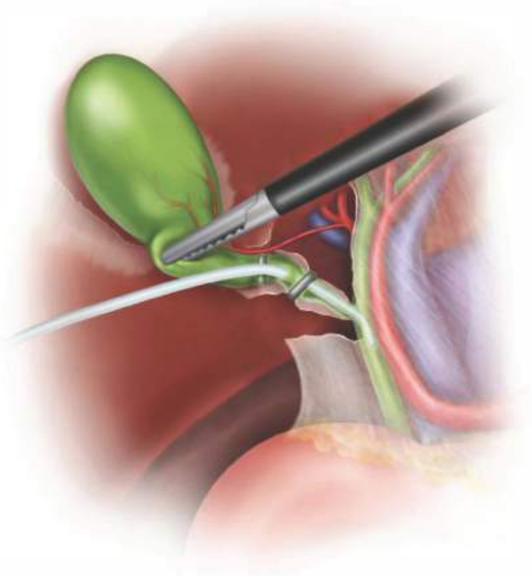
- The C-arm fluoroscopy unit should be positioned to the patient's right with the screen monitor clearly visible to the operating surgeon.
- The bed should have a footboard placed and the patient should be well secured to the operating table, as reverse Trendelenburg position is required during the procedure.

Radiation Safety

- The surgeon must be knowledgeable in the use of fluoroscopy. This should include successful completion of institutional training including certification for use of fluoroscopy in the operating theater.
- All operating room personnel should don appropriate protective garments prior to scrubbing and gowning.

CHOLANGIOCATHETER PLACEMENT

- Cystic duct approach
  - The gallbladder infundibulum should be mobilized and dissection of Calot's triangle should identify the cystic duct and artery entering the infundibulum.
  - Once the cystic duct is circumferentially dissected, a clip should be placed across the cystic duct as proximal as possible to the infundibulum (**FIG 2**).
  - A ductotomy should be made along the cystic duct, leaving adequate length for subsequent double clip ligation. Care must be taken to avoid fully transecting the duct with this maneuver. An intact posterior-cephalad cystic duct wall is essential to maintain exposure and facilitate placement of the cholangiogram catheter (**FIG 3**). Note that it is typical for the ductotomy to enlarge with the necessary lateral retraction to provide exposure or with manipulation with the cholangiogram catheter. Furthermore, the skeletonized cystic duct typically lacks intrinsic strength and can tear easily with aggressive retraction once a ductotomy has been made.
- Two techniques for placement of the cholangiocatheter for laparoscopic IOC have been described:
  - The first technique employs a 5-Fr cholangiocatheter inserted through an introducer sheath (**FIG 4**). This sheath, available as a component



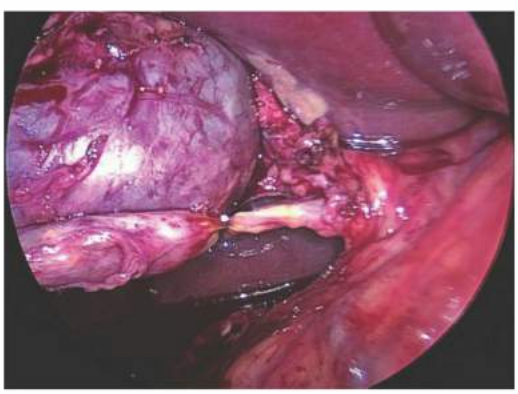


FIG 2 ● After circumferential dissection of the cystic duct, a clip is applied at the junction with the infundibulum.

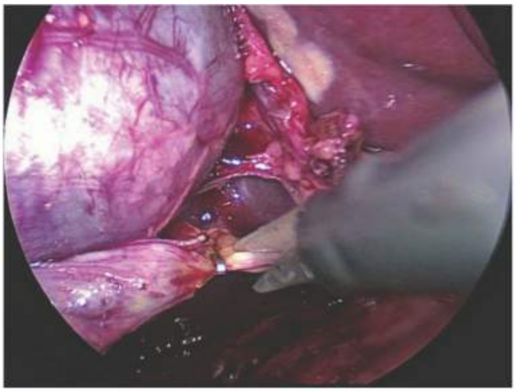
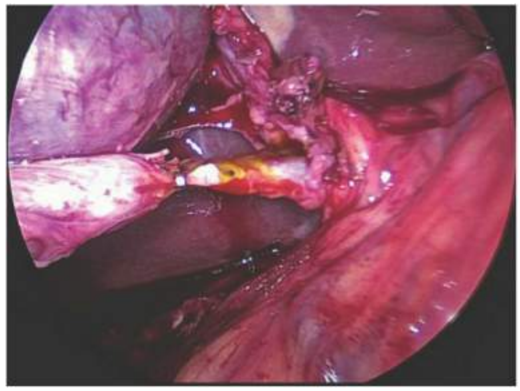


A



B

FIG 3 ● **A.** A ductotomy is sharply incised. **B.** The ductotomy should just be large enough to admit a small-caliber catheter. Note the majority of the cystic duct remains intact.

of commercially available cholangiogram catheter kits, is inserted through a separate incision along the right subcostal margin. Placement of this incision should be guided by location of the ductotomy. Ideally, the catheter enters the abdomen lateral and caudad to the cystic duct (**FIG 5**).

- The catheter is then gently guided into the cystic duct with atraumatic technique and secured with a partially occluding clip placed just distal to the ductotomy.
- An alternative technique is to use an Olsen-Reddick clamp (**FIG 6**). This device has a channel through the center of the clamp to accommodate a 5-Fr cholangiocatheter. The clamp is advanced though a laterally placed trocar. Once intraabdominal, the jaws of the clamp are opened and the cholangiocatheter is inserted through the center channel until the catheter tip extends beyond the jaws of the clamp. The catheter is then directed into the cystic duct. Once in place, the jaws of the clamp are closed around the cystic duct and cholangiocatheter, preventing leakage of contrast through the ductotomy (see **FIG 2**).
- This method remove the use of clips along the cystic duct during IOC.

- Infundibular approach
  - This approach is less technically demanding than direct cannulation of the cystic duct. It is also of value should identification of the cystic duct be difficult secondary to inflammation or scarring of the porta hepatis; however, in this clinical setting, the cystic duct may be occluded, precluding the approach.

FIG 4 ● The cholangiogram catheter is inserted into the cystic duct. The catheter depicted has an expandable cuff that can be appreciated within the cystic duct.

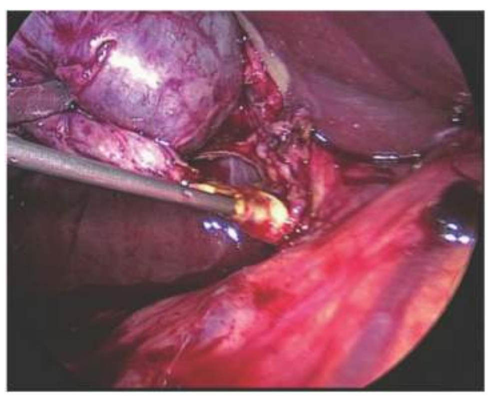


FIG 5 ● Cannulation of the cystic duct using a flexible 5-Fr cholangiogram catheter. A clip is placed across the cystic duct just proximal to infundibulum of the gallbladder and a second, nonoccluding clip is placed across the cystic duct and catheter to prevent retrograde leakage of contrast material.

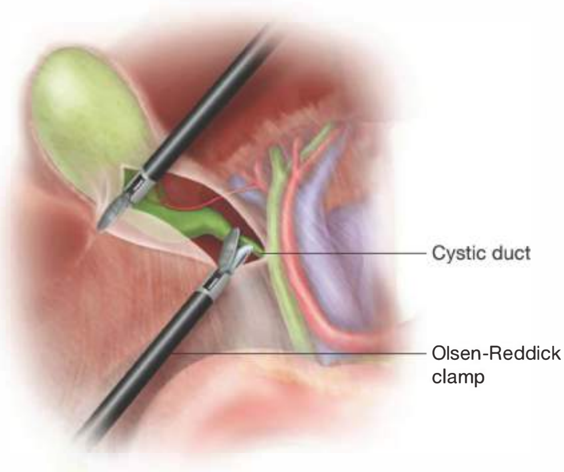

FIG 6 ● An Olsen-Reddick clamp can be used to stabilize and expose the cystic duct. The clamp has a channel for passage of the cholangiogram catheter.

- The peritoneum should be incised and the infundibulum dissected free from the hepatic bed. Once the infundibulum is mobilized, a Kumar clamp should be inserted through a laterally placed subcostal trocar. This clamp has long, atraumatic jaws, which completely occlude the infundibulum, and a side channel for the introduction of a needle-tipped cholangiocatheter. The clamp is applied along the lower body of the gallbladder, just above Hartmann's pouch (**FIG 7**).
- Advance the Kumar catheter through the side channel and visualize the needle as Hartmann's pouch is punctured.
- Once the catheter is placed, aspiration of bile contents ensures adequate biliary access.

- Fundus approach
  - If neither cystic duct nor infundibular approaches are feasible, a cholangiocatheter can be inserted directly through the fundus of the gallbladder. This technique is similar to that of the cystic duct approach. During IOC, a larger volume of contrast must be used as the entire gallbladder must fill prior to visualizing the cystic duct.

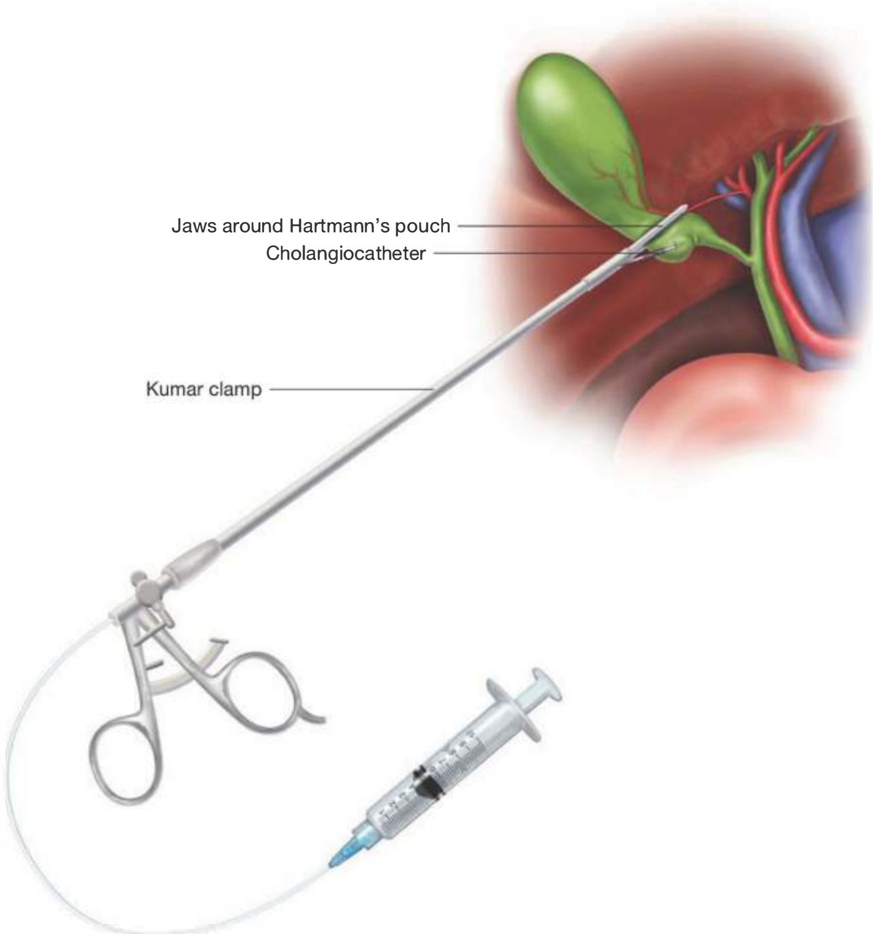

FIG 7 ● A Kumar clamp is used when performing an IOC by injecting the infundibulum of the gallbladder. This is the least technically demanding approach to IOC but not an option in the setting of acute cholecystitis.

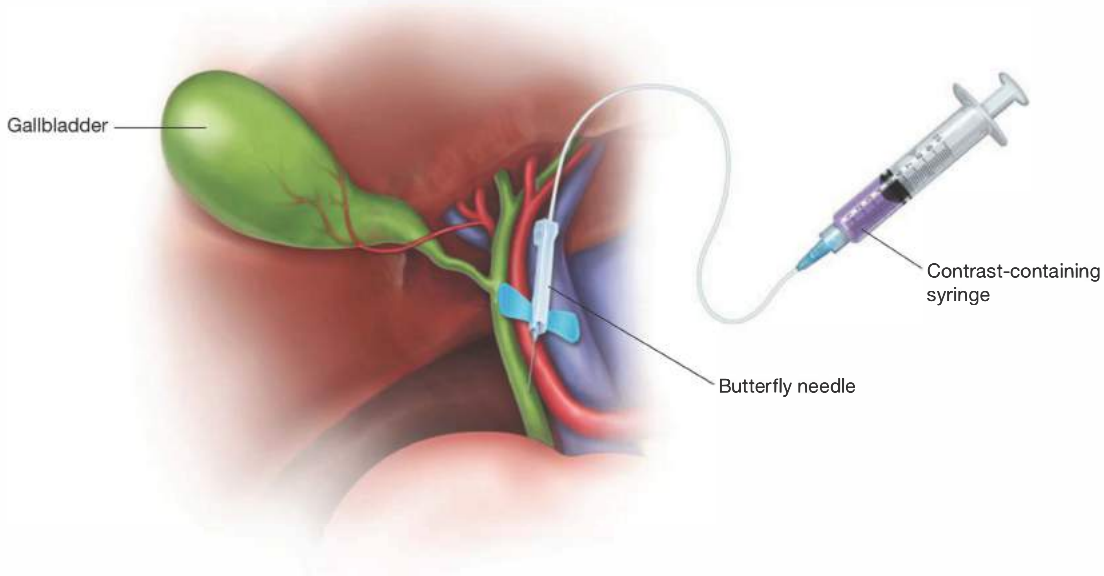

FIG 8 ● A 25-gauge butterfly needle can be directly inserted into the CBD. When performed laparoscopically, one of the flanges of the needle can be removed to facilitate passage through the trocar.

- Needle cholangiogram approach
  - In the clinical situation of acute cholecystitis where inflammation is extensive and the primary indication for cholangiography is defining the anatomy of the biliary tree, the CBD can be directly cannulated with a small-gauge butterfly needle (**FIG 8**). Once complete, the puncture site should be closed with an interrupted 4-0 absorbable monofilament suture.
- Open technique
  - During open hepatobiliary surgery, IOC may be performed by inserting a cholangiocatheter in a similar fashion using any of the aforementioned laparoscopic techniques.

CHOLANGIOGRAM

- Prior to insertion, the cholangiogram catheter should be flushed with saline to avoid injection of air bubbles that can easily be misinterpreted as CBD stones.
- Once the cholangiogram catheter has been successfully placed, the catheter should be gently flushed with saline to ensure no leakage of contrast will occur during cholangiography.
- The fluoroscopy C-arm should be moved into position, taking care to maintain sterility (**FIG 9**).
- The accessory laparoscopic instruments and camera should be removed.

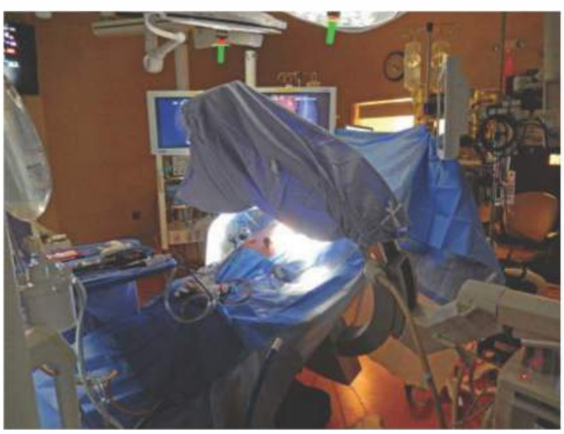

FIG 9 ● Operative photograph of appropriate C-arm positioning.

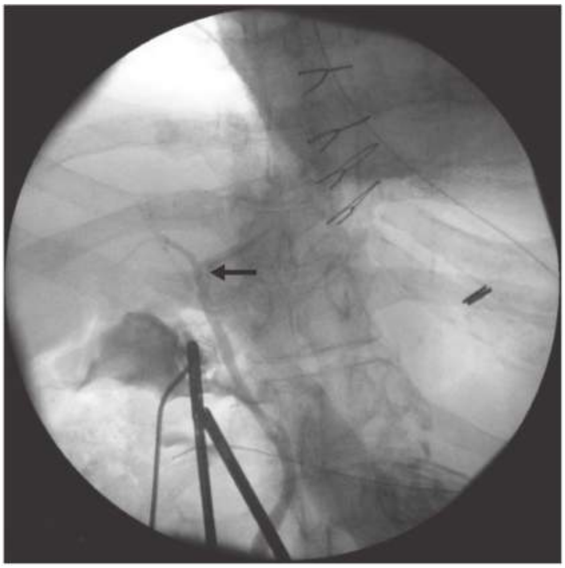
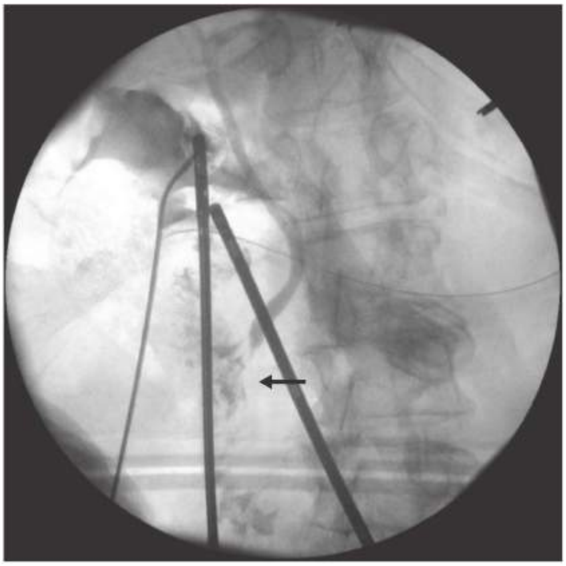


A



B

FIG 10 ● Normal cholangiogram. Note visualization of the entire biliary tree including the intrahepatic ducts *(arrow)* **(A)**. Passage of contrast into the duodenum without filling defects is also demonstrated *(arrow)* **(B)**.

- A test cholangiogram should be performed to verify adequate positioning of the fluoroscopic C-arm.
- After position is verified, the IOC is performed. Ten to 25 mL of low osmolar, radiopaque contrast is usually required for visualization of the entire biliary tree. The authors typically dilute the water-soluble contrast 1:1 in normal saline. An IOC is not adequate until the cystic duct, CBD, left and right hepatic ducts, and passage of contrast into the duodenum are all visualized. This may be facilitated by altering patient positioning, using Trendelenburg, reverse Trendelenburg, and lateral rotation of the patient (see **FIG 6**).
- Examples of distal obstruction remove from malignancy, inflammation, or calculi are shown in **FIGS 10** to **12**.

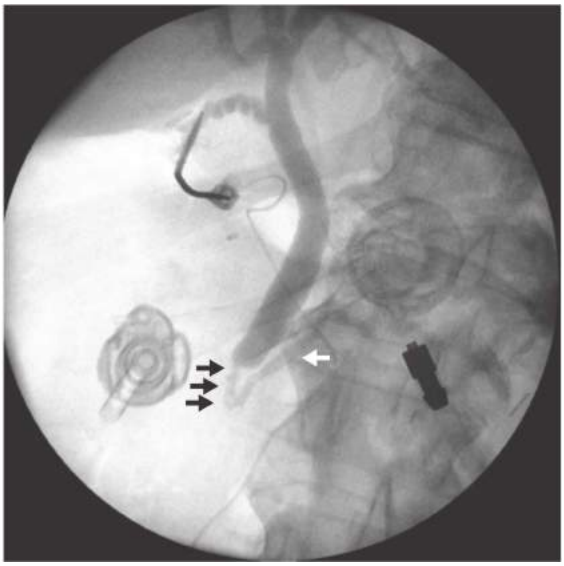


FIG 11 ● Visualization of a CBD stone by IOC. A filling defect is noted in the distal CBD; there is lack of flow of contrast material into the duodenum despite adequate pressure *(black arrows)*. Incidental filling of the pancreatic duct can also be appreciated in this example *(white arrow)*.

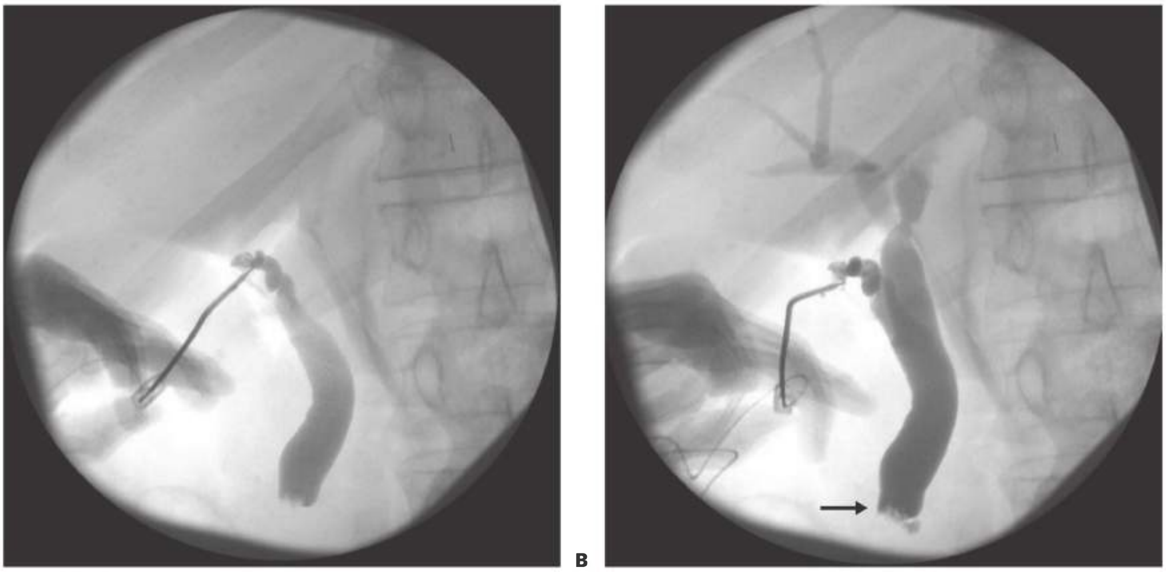

FIG 12 ● **A.** Biliary obstruction due to malignancy. **B.** Note the irregular border of the malignant "shelf" *(arrow)*.

PEARLS AND PITFALLS

Patient selection	■ Routine versus selective application of IOC is a subject of controversy.
Surgical management	■ Positioning of the patient with respect to the pedestal of the operating table is essential for access of the C-arm fluoroscopy unit. ■ The semicircular valves of the cystic duct can impede the advancement of the cholangiogram catheter. Care must be taken to not cause a laceration while advancing the catheter into the duct.
Operative decision making	■ Intraoperative cholangiogram during cholecystectomy should be used whenever anatomy is confusing. ■ If the cystic duct cannot be adequately mobilized, either the infundibular or fundus approaches are acceptable alternatives for placement of the cholangiocatheter.
Cholangiogram interpretation	■ Flush the catheter prior to insertion to avoid the introduction of air into the CBD. The bubbles that form cannot be easily differentiated from stones. ■ If the entire biliary tree cannot initially be visualized during IOC, the patient should be repositioned to ensure flow of contrast is not being inhibited by hydrostatic pressure. If, after repositioning, the biliary tree cannot be seen in its entirety, one should suspect an obstructive process or inadvertent ductal injury. ■ If distal obstruction is identified, ligate the cystic duct rather than clip it to reduce the risk of postoperative bile leak. Leave a drain.

POSTOPERATIVE CARE

- Postoperative care does not differ from that described for cholecystectomy.

OUTCOMES

- The selective application of IOC versus routine IOC remains a subject of controversy; differences in outcomes between the two approaches have not been well demonstrated.[2,3]
- IOC with CBD exploration versus postoperative endoscopic retrograde cholangiography has been shown to be more cost-effective than routine preoperative assessment of CBD stones.[4]

COMPLICATIONS

- Laceration of the cystic duct or CBD
- Bile leak
- Radiation injury to the skin

Chapter 6

Percutaneous Transhepatic Biliary Imaging and Intervention

Brian S. Geller

DEFINITION

- Cholangiography is the term used to describe the evaluation of the biliary system by fluoroscopy after injection of radiopaque material (contrast). The introduction of contrast can be performed either in a retrograde (via endoscope) or an antegrade manner.
- The antegrade introduction of contrast requires percutaneous transhepatic access into the biliary system. A percutaneous transhepatic cholangiogram (PTC) is commonly performed when a magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) were inconclusive or unable to be performed.
- When an obstruction of the biliary system cannot be managed by endoscopic means, a drainage catheter can be placed. This procedure is known as percutaneous transhepatic drainage (PTHD).
- Numerous biliary pathologies are routinely managed by the percutaneous route: stone/debris removal, stricture dilation, long-term catheter drainage, and metallic stent placement.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A PTC is an invasive procedure and as such, non- or less invasive imaging of the biliary system should be attempted; these include MRCP and ERCP. If these options fail to make the diagnosis or cannot be performed due to the patient's anatomy, then a PTC should be performed.
- Indications for cholangiography include biliary stenosis or obstruction, or bile leak. The underlying pathology includes stones, malignancy, infection, inflammation, fibrosis/scarring, and iatrogenic complications.
- Patients with biliary obstruction or moderate- to high-grade stenosis usually present jaundice with elevations of the alkaline phosphatase (ALP) and total bilirubin (TB). ALP is a more sensitive identifier of biliary pathology and typically precedes elevation of the TB. If the bile has become infected, the patient can also present with fever, leukocytosis, and sepsis. Bile leaks present with abdominal pain (secondary to a chemical peritonitis), fever, leukocytosis, nausea/vomiting, and jaundice.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Ultrasound (US) or computed tomography (CT) can be used to diagnose biliary dilation. Note: Posttransplant livers do not normally have dilated ducts when obstructed.
- First-line imaging of the biliary system is routinely a US. This modality is readily available, inexpensive, and uses no radiation. US is optimal for detection of biliary dilation, gallbladder pathology, and ascites. It also serves a role in the identification and characterization of hepatic masses and Doppler mode provides information regarding potential vascular pathology (**FIG 1**).
- When a broader view of the abdomen is needed, a CT scan can be performed. Intravenous (IV) contrast is routinely administered, and due to the nature of the exam, the patient will be exposed to radiation (equivalent of ~100 chest x-rays) (**FIGS 2** and **3**).
- MRCP can also be performed to evaluate the biliary system and surrounding liver parenchyma. Note that the nature of the magnetic resonance (MR) protocol that is required to optimally visualize, the biliary system, does not optimally assess surrounding structures, thus limiting the evaluation of nonbiliary pathology (**FIG 4**).

FIG 1 ● Axial US image of the liver demonstrating marked intrahepatic biliary ductal dilation.

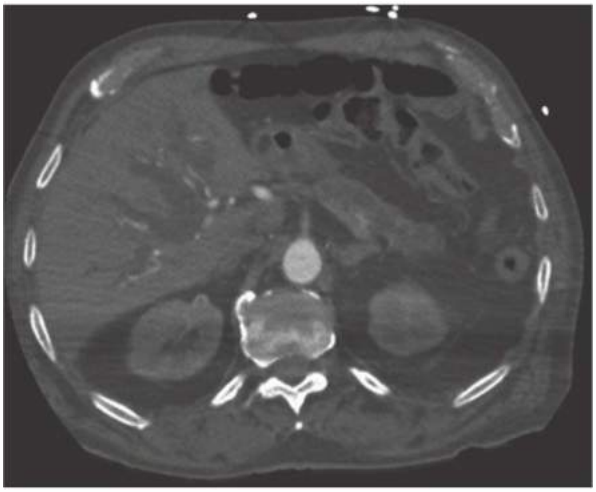

FIG 2 ● Axial CT image with marked intrahepatic biliary ductal dilation and pancreatic ductal dilation.

FIG 3 ● Axial CT image with biloma and free fluid. The patient was following right hepatectomy.

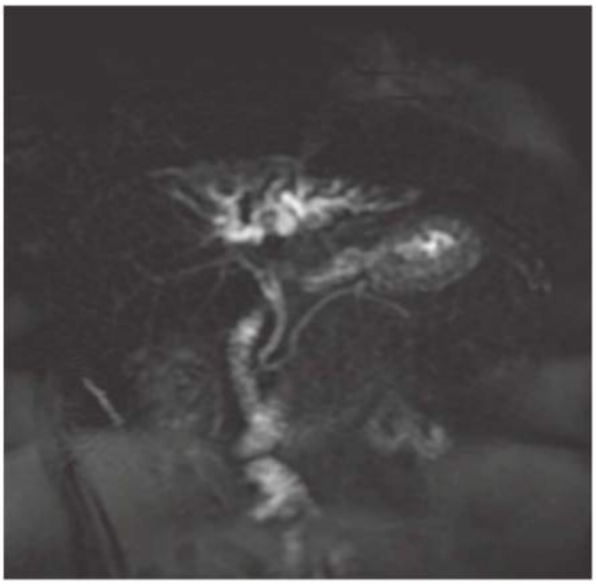

FIG 4 ● Coronal image from MRCP demonstrating dilation of the right anterior and left hepatic ducts. The right posterior, common hepatic, and pancreatic ducts are of normal caliber.

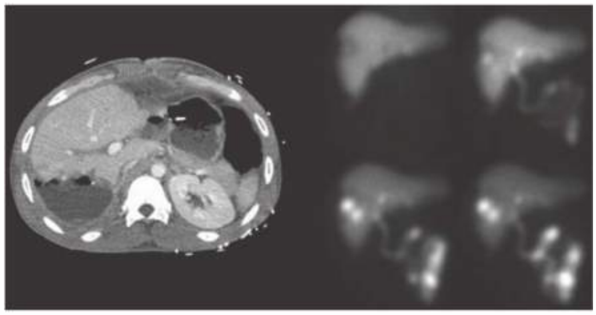

FIG 5 ● Images from a HIDA scan (four images on right) of a trauma patient with a liver laceration. There is tracer accumulation in the region of the right hepatic lobe, which corresponds to an increasing fluid collection on CT.

- When evaluating for a bile leak, cholescintigraphy (also known as a hepatobiliary iminodiacetic acid [HIDA] or diisopropyl iminodiacetic acid [DISIDA] scan) can be performed. The radiopharmaceutical is taken up by the liver and excreted into the bile. When the tracer is seen accumulating outside of the liver, or in intrahepatic cavities, the diagnosis of leak can be confirmed (**FIG 5**).

SURGICAL MANAGEMENT

Preprocedure Planning

- All related imaging to the patient's condition should be reviewed. A PTC/PTHD can be performed either under conscious sedation or with general anesthesia (preferred). Thus, the patient ideally will be *nil per os* for at least 6 hours prior to the procedure.
- For any procedure that manipulates the biliary system, there is an increased risk of septicemia and endotoxemia. The patient should receive antibiotics within 1 hour of start time. The mix of gastrointestinal flora should guide antibiotic choice (gram negatives and anaerobes). At our institution, piperacillin/tazobactam 3.375 g is routinely used. In patients who are penicillin allergic, ciprofloxacin 400 mg and metronidazole 500 mg are given.
- Unless the left-sided ducts are unilaterally dilated, a right-sided approach is routinely used, as this will drain a larger portion of the liver and will decrease radiation exposure to the interventionalist.

Positioning

- Biliary procedures are performed with the patient in the supine position, arms at the side.

PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY

Immediate Preprocedure

- The patient's abdomen should be cleaned and prepped from the nipple line to the left midaxillary line to 5 cm below the umbilicus and beyond the right posterior axillary line.
- When right-sided access is warranted, a hemostat should be placed at the right midaxillary line at the selected access site during deep inspiration (**FIG 6**). This is used to verify that the entrance site is below the greatest diaphragmatic excursion. Access above this mark should *not* be attempted as it exposes the patient to the risk of violating the pleura, resulting in pneumothorax or biliary–pleural fistula.
- Local anesthetic should be used and a small incision (2 to 3 mm) made to facilitate needle passage.

FIG 6 ● Placement of hemostat to mark the entrance site.

FIG 7 ● Fan pattern of needle passes (*solid line*, initial pass; *dashed line*, subsequent passes). *Yellow* indicates midaxillary line.

Duct Cannulation

- Duct cannulation can be performed with a 15-cm, 21- or 22-gauge Chiba needle. These needles are relatively small (thereby reducing bleeding risk) and can accept a 0.018-in wire.
- When left-sided access is required, US is routinely used to localize a relatively superficial duct. The duct is then cannulated under direct US guidance.
- Due to the overlying ribs, right-sided access is usually accomplished with a "blind" technique, which can either be subclassified into an antegrade or retrograde approach.
- When using the retrograde approach, the Chiba needle is advanced from the liver margin to the midaxillary line. The stylet is removed, and under fluoroscopy, a small amount of dilute contrast is injected as the needle is pulled back.
- When using the antegrade approach, the stylet is removed from the Chiba needle, and under fluoroscopic guidance, the needle is advanced while injecting dilute contrast until reaching the midclavicular line.
- Regardless of approach, multiple passes through the liver at different obliquities (cranial–caudal *and* anterior–posterior) are often required before a duct is cannulated (**FIG 7**). The technical challenge and number of passes required for successful cannulation is directly related to the extent of intrahepatic biliary dilation. This is particularly problematic in the setting of bile duct injury with a biliary tree that is fully decompressed into the peritoneal space.
- Peripheral cannulation is the goal. Cannulation of centrally located duct increases the risk of arteriobiliary or venobiliary fistula and hemorrhage.

Cholangiogram

- It is very easy for a well-placed needle to dislodge while the patient is breathing. To prevent this from occurring, a 0.018-in wire is placed through the Chiba needle and coiled within the biliary system. The needle is exchanged for the inner portion of an AccuStick catheter. A Tuohy-Borst sidearm introducer is then placed over the wire and attached to the catheter, allowing for contrast injection without loss of wire access.
- While injecting dilute contrast, either an angiographic run or static images are obtained in multiple obliquities (**FIG 8**).
- Once adequate images are obtained, the catheter and wire are removed.

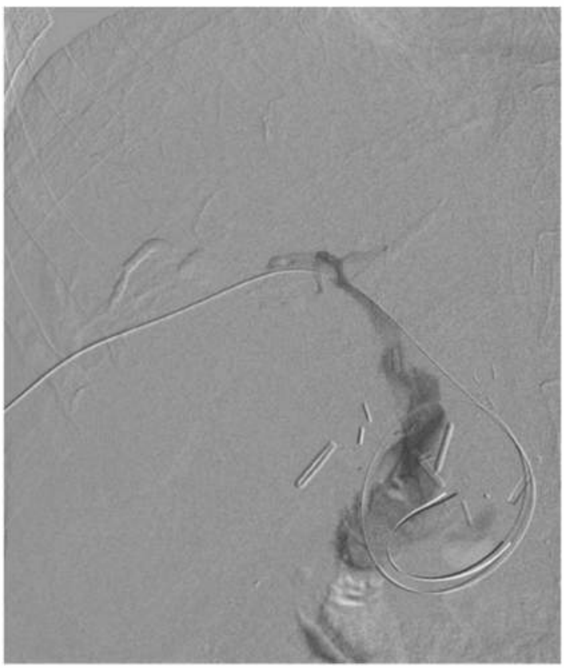

FIG 8 ● PTC in a patient following liver transplant with history of hepaticojejunostomy stricture. Cholangiogram demonstrates no evidence of stricture. Intrahepatic ducts were normal on other images (not shown).

PERCUTANEOUS TRANSHEPATIC DRAIN

- If durable access to the biliary tree is indicated, once a 0.018-in wire is coiled within the biliary system, a fully assembled AccuStick is advanced and the inner metallic cannula and 4-Fr catheter are removed. A hydrophilic wire and hockey-stick catheter are then used to cannulate the small bowel.

FIG 9 ● Internal/external biliary drainage catheters in both the right anterior and posterior ducts.

- The hydrophilic wire is removed and exchanged for a stiff wire through the hockey-stick catheter. The tract is dilated to accommodate a biliary drainage catheter, which is positioned so the proximal side holes are draining the intrahepatic ducts and the distal pigtail is in the bowel (**FIG 9**).
- The catheter should then be sutured to the skin and placed to external drainage for 24 to 48 hours, after which it can be capped.
- If the area of stenosis cannot be crossed, an external drain can be placed with the pigtail coiled within the intrahepatic biliary ducts (**FIG 10**). This catheter must be kept to gravity bag drainage.

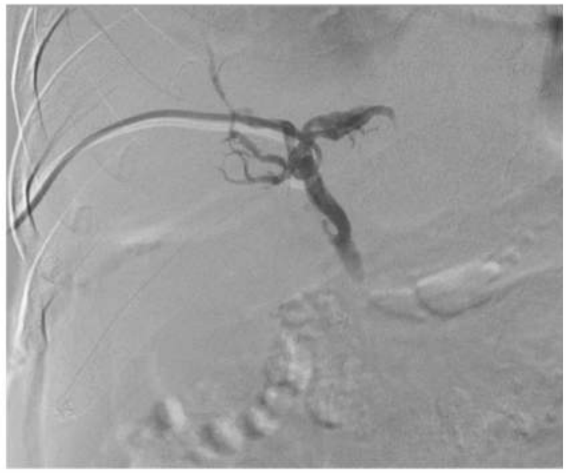

FIG 10 ● Digital subtraction angiography (DSA) image of an 8-Fr external drainage catheter within the main hepatic duct.

BALLOON DILATION

Dilations

- Postsurgical or focal inflammatory scarring can routinely be treated with serial balloon dilation.
- With a stiff wire in place, serial dilations, starting with balloons 1 to 2 mm smaller than the area of stenosis and then 2 to 3 mm larger than normal ducts, are performed. The length of the balloon can be either 2 or 4 cm in length, depending on the area of stenosis.
- When a regular balloon is not adequate, a scoring balloon or a cutting balloon can be used in certain circumstances, which are dependent on the anatomic relationship of the stricture to the hepatic vasculature (**FIG 11**).
- After dilation, the same size or larger internal/external biliary drain is replaced.
- Dilations are performed every 2 to 3 weeks, for a total of three dilations.

Challenge

- When the patient returns 2 to 3 weeks after the third dilation, a TB is drawn preoperatively.
- If the cholangiogram shows that the area of stenosis is patent, an external drainage catheter is placed with the pigtail peripheral to the area in question and capped (**FIG 10**).

Success or Failure

- The patient returns in 1 to 2 weeks after challenge. A TB is drawn preoperatively.
- A cholangiogram is performed through the existing catheter. If the area in question remains patent and the bilirubin is normal, the catheter is removed.
- If either the cholangiogram is abnormal or the bilirubin is elevated, the external drainage catheter is replaced with an internal/external catheter (**FIG 12**).
- Until definitive surgical management, the patient will require routine (every 3 months) changes of this catheter.
- Alternatively, if anatomically feasible, an endoscopically retrievable stent can be placed until definitive surgical management (see following discussion of "Stent Placement").

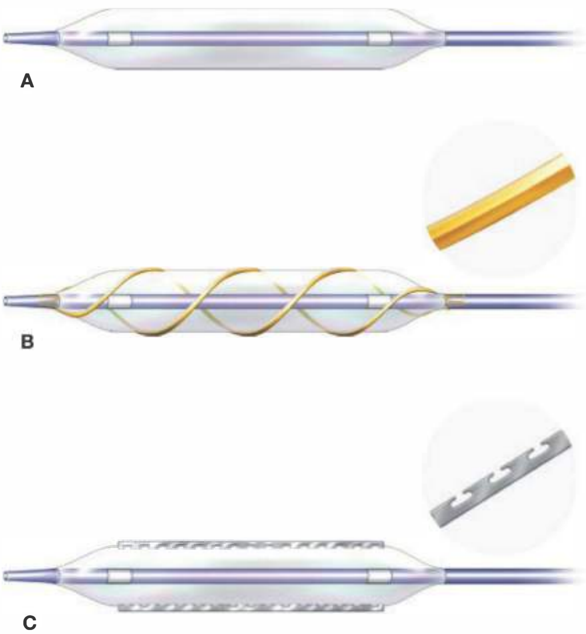

FIG 11 ● **A.** Standard noncompliant balloon. **B.** A modified balloon allows for the scoring of the ductal walls, which has shown to increase the chances of successful dilation. **C.** A cutting balloon for extremely difficult stenoses. Due to the risk of perforation, great care should be taken when using this balloon.

FIG 12 ● Arrow indicates residual high-grade anastomotic stricture after challenge. Patient required replacement of the internal/external drainage catheter.

STENT PLACEMENT

Evaluation

- Only until recently, metallic stents were permanent and reserved for those patients with a life expectancy of less than 6 months, as there is a 50% occlusion rate at this interval.[1] With introduction of the covered metal stents that can be endoscopically exchanged, patients with longer life expectancies can benefit from indwelling metallic stents (FIG 13). However, in patients whose biliary systems are not endoscopically accessible, these stents cannot be changed.
- Once a PTHD has been performed and the biliary system has had time to drain (24 to 72 hours), a formal cholangiogram is performed.
- There must be an adequate landing zone (proximally and distally) for a metal stent to be used. Additionally, each area of stenosis will usually require a stent. In most situations, a single central area of stenosis of either the right, left, and/or main hepatic ducts are amendable

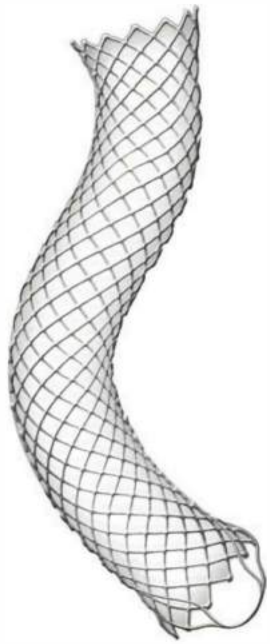

FIG 13 ● A covered, self-expanding metal biliary stent.

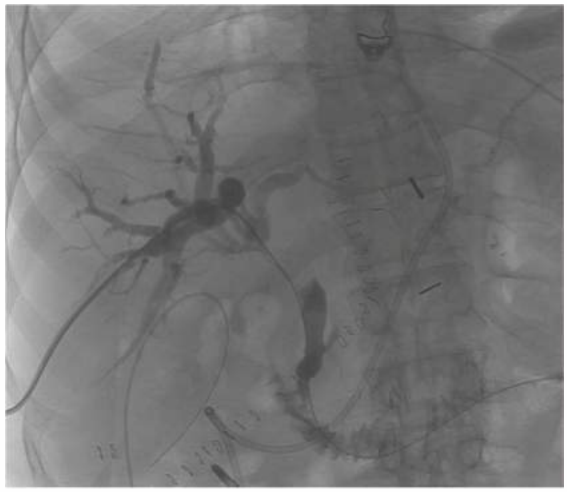

FIG 14 ● Cholangiogram demonstrating multiple central intrahepatic biliary strictures as well as a long-segment stricture of the peripheral common bile duct consistent with a Klatskin tumor. Due to the number of strictures, this patient was not a stent candidate.

to stent placement. Patients with Klatskin tumors, who present with multiple areas of stenosis, are typically not candidates (**FIG 14**).

Placement

- Over a stiff wire, a properly sized stent is advanced and deployed (**FIG 15**).
- If the stenosis involves the distal common bile duct, a short segment of stent (1 to 2 mm) should extend into the small bowel. When there is an associated duodenal stricture that also requires stenting, a longer segment of the biliary stent should extend into the bowel, alongside the duodenal stent.
- A small catheter should remain across the stent for 24 to 72 hours.

Follow-up

- The patient should return for a cholangiogram in 24 to 72 hours to determine if the stent remains patent. If the stent is patent, the catheter can be removed.
- If the stent is occluded, an internal/external catheter should be placed. The patient should return for routine catheter changes every 3 months.

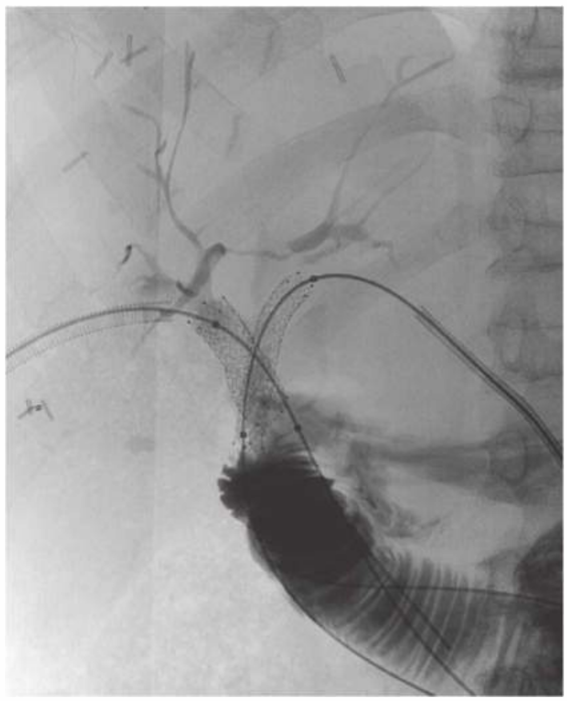

FIG 15 ● With sheaths and wires through both the right and left biliary ducts, self-expanding stents were deployed. In each stent is an angioplasty balloon, which will be inflated simultaneously to prevent one from crushing the other.

MISCELLANEOUS BILIARY INTERVENTIONS

Brushings/Biopsy

- Once a PTHD has been performed, the area of stenosis crossed and the biliary system has had time to drain, and any associated blood that is invariably present after the initial access procedure had cleared, biopsies can be performed. Both brushings and a forceps biopsy are routinely performed to increase in the likelihood of diagnosis (**FIG 16**).
- To obtain brushings, a sheath must be placed across the stenosis, through which the brush system is advanced. The sheath is pulled back to expose the brush system. The brush is advanced out of its catheter multiple times to collect the cells. The brush is removed and placed in cytology solution.
- When performing a forceps biopsy, the sheath is placed just proximal to the lesion and two to three samples are obtained and placed in formalin.

Stone and Debris

- After adequate drainage, a sheath is placed through which a noncompliant angioplasty balloon is advanced to dilate any common bile duct stricture, if present.
- Using a compliant balloon, debris and small stones are swept into the common duct and then pushed into the bowel.
- When the stone is too large to be pushed into the bowel, a stone-crushing basket can be used to break the stone into smaller pieces.

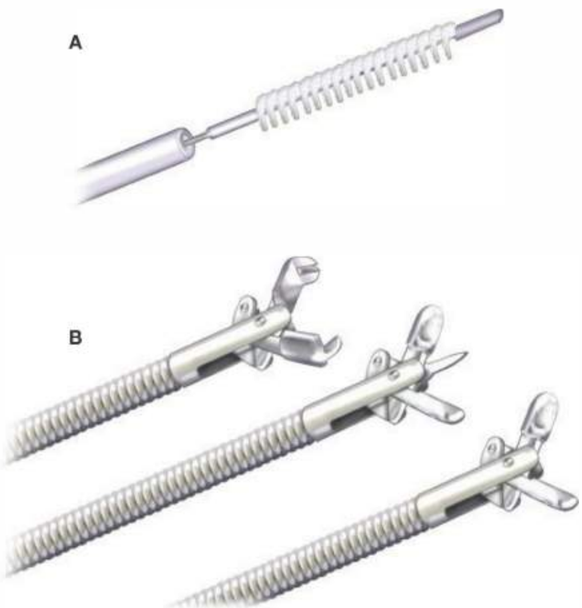

FIG 16 ● **A.** Biliary brush. **B.** Biliary introducer forceps.

PEARLS AND PITFALLS

Patient history and physical findings	■ Biliary dilation does not normally occur in posttransplant livers.
Operative technique	■ Defining maximum inspiration is important to prevent pleural transgression. ■ To prevent septicemia and endotoxemia, dilated biliary systems should be drained for 24 to 72 hours after catheter placement. Further intervention should be delayed. ■ Crossing the midclavicular line during duct cannulation increases the risk of a left-sided cannulation as well as traversing central vessels in the porta hepatis. ■ Minimizing the ductal entry angle allows for a proper force vector when dilating the tract and advancing the catheter. ■ Each puncture of the liver capsule increases the risk of bleeding. When redirecting the needle, care should be made not to remove it completely from the liver.
Postoperative care	■ Upper endoscopy should not be performed for up to 6 weeks after PTHD to prevent lethal air embolus from possible biliary to hepatic vein fistula.

POSTOPERATIVE CARE

- Drainage catheters should be flushed twice a day with 10 mL of sterile 0.9% saline.
- Patients with internal/external biliary catheters that are capped should be instructed to uncap the catheter and place it to gravity bag drainage if they experience abdominal pain, fevers, leakage, or pruritus. They should be evaluated in the next 24 to 48 hours.
- During the process of a "challenge," it is not uncommon for there to be some leakage around the biliary catheter; this should resolve in a few days. If it does not resolve, it may indicate a challenge failure.
- When a patient is draining externally, the possibility of dehydration and electrolyte loss must be taken into consideration. Patients should replace the amount of bile loss with an oral fluid that contains electrolyte replacement.

OUTCOMES

- For a PTC, the success rate is linked to whether the ducts are dilated. For a dilated system, the success rate nears 100%, however, in a non-obstructed system the success rate is considerably lower (65%).[2]
- The success rate for all biliary interventions is dependent on the technical success of cannulating the biliary tree. The success rate for a dilated system is significantly higher than for a nondilated system (including transplants), 99% and 74%, respectively.[2,3]
- Once cannulated, internalization of the catheter is successful in 78% of native livers but only 59% in transplanted livers.[4]
- Technical and clinical success rates for balloon dilation of benign strictures are 93% to 100% and 75% to 94%, respectively.[5] However, there is a wide variation based on the location of stenosis.[6]
- Average patency of metallic stents for malignant strictures is about 6 months.[1]

COMPLICATIONS

- The risk of all complications is <3%[7] and include:
  - Hemorrhage
  - Bile leak
  - Bile peritonitis
  - Sepsis
  - Pancreatitis
  - Pleural transgression
  - Contrast reaction
  - Death

Chapter 7

Surgically Assisted Endoscopic Retrograde Cholangiopancreatoscopy

Kfir Ben-David Steven J. Hughes

DEFINITION

- Surgical assistance to successfully perform endoscopic retrograde cholangiopancreatoscopy (ERCP) is necessary when intestinal continuity has been surgically modified such that the ampulla of Vater cannot be accessed via the mouth.
- Previous gastric bypass with a long Roux-en-Y limb is the surgical procedure that leads to the need for surgically assisted ERCP.
- The presence of a gastric remnant is essential to the performance of surgically assisted endoscopic retrograde cholangiopancreatoscopy (SA-ERCP).
- Rarely, a clinical scenario may arise where surgical access to a gastric remnant may be indicated to facilitate endoscopic ultrasound (EUS).
- As magnetic resonance cholangiopancreatography (MRCP) provides a noninvasive means to assess the pancreaticobiliary duct systems in most patients, ERCP is generally not indicated merely as a diagnostic modality—therapeutic intent is the indication for ERCP; this concept must be emphasized when considering SA-ERCP.

DIFFERENTIAL DIAGNOSIS

- Choledocholithiasis
- Sphincter of Oddi dysfunction
- Ampulla of Vater pathology
- Intraductal papillary mucinous neoplasm (IPMN)
- Chronic pancreatitis
- Disrupted pancreatic duct syndrome

PATIENT HISTORY AND PHYSICAL FINDINGS

- Historically, the most common indication for SA-ERCP was for the diagnosis and treatment of sphincter of Oddi dysfunction (SOD)—a condition thought to be elicited by gastric bypass surgery. However, results from a recent study have led to serious concerns about the value of therapeutic intervention for symptoms attributed to SOD.[1]
- A history of prior cholecystectomy must be obtained. If the gallbladder is in situ, a cholecystectomy is likely warranted as part of the SA-ERCP.
- The gastric bypass operative note must be reviewed. The location of the Roux limb with respect to the gastric remnant and transverse colon must be known preoperatively and this information factored into the counseling the patient as to the risks of the procedure—an antegastric and/or an antecolic Roux limb will increase the technical complexity and thus risk (**FIG 1**).
- Specifically review any potential allergy to iodinated contrast agents. Medical preparation to mitigate an allergic reaction may be indicated.

FIG 1 • Anatomic relationships of the Roux limb following gastric bypass **(A)** retrocolic, retrogastric; **(B)** antecolic, antegastric; and **(C)** retrocolic, antegastric.

SURGICAL MANAGEMENT

Preoperative Planning

- The potential need for serial ERCP procedures should be determined. A gastrostomy tube (G-tube) can be placed at the index procedure to facilitate subsequent endoscopic interventions. Potentially affected patients should be prepared for this possibility.
- These operations require significant coordination between multidisciplinary teams. The authors highly recommend that these procedures be scheduled as the first case of the day.
- The procedure needs to be scheduled in a room that can accommodate two teams, a C-arm fluoroscopy unit, and a mobile endoscopy cart.

Positioning

- The operative table should be configured so that C-arm fluoroscopy can be readily performed of the upper abdomen (**FIG 2**).
- After induction of general anesthesia, a urinary bladder catheter is placed. An orogastric tube is rarely necessary.
- The patient is positioned supine, ideally with both arms tucked to facilitate access for both C-arm fluoroscopy and the endoscopy team. A footboard is placed. A fixed liver retractor can be positioned on either side of the patient if needed.
- Venous thromboembolism prophylaxis (both mechanical and pharmacologic) should be used. Antibiotics are administered within the guidelines of Surgical Care Improvement Program (SCIP) criteria for a clean-contaminated procedure.

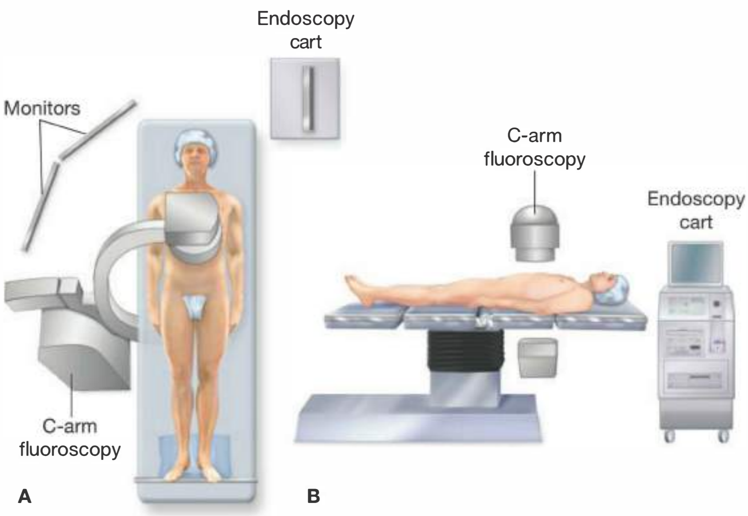

FIG 2 • The C-arm fluoroscopy unit is positioned on the patient's right, and the mobile duodenoscopy equipment on the patient's left.

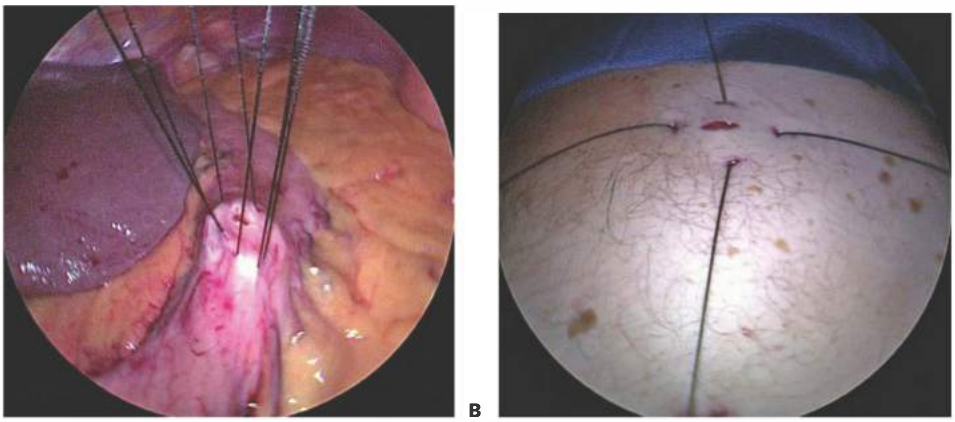
TROCAR PLACEMENT

- Trocar placement is depicted in **FIG 3**. Four trocars will be required for placement of stay sutures in the stomach, and one of these can be subsequently used for clamping of the small bowel. A subxiphoid, transgastric trocar is also necessary.
- Initial trocar placement is performed in the left midclavicular line at the level of the umbilicus following insufflation of the abdomen with a Veress needle. The authors prefer the use of an optical separator and a 30-degree scope.
- Subsequent trocars are placed under direct vision.

FIG 3 • Trocar placement for SA-ERCP. Pneumoperitoneum is established via a left midabdominal incision (alternatively, a periumbilical approach). The far right abdominal 5-mm trocar is used for grasping and the bowel clamp. The right, midclavicular line port (12 mm) is used for suture and stapler placement. The left abdominal 5- to 12-mm trocar is used for the camera and left port (5 mm) is used for grasping. The subxiphoid trocar *(X)* is placed transgastrically to provide access for the duodenoscope. It must be at least 15 mm in diameter.

GASTRIC PEXY

- The patient is placed in reverse Trendelenburg position and the location of the transgastric trocar placement determined and marked. Ideally, the trocar will enter the anterior gastric wall at the junction of the body and the antrum of the stomach at the midpoint between the mesentery of the greater and lesser curves.
- Determine the relationship of an antegastric Roux limb and the associated mesentery to the ideal target for the transgastric trocar. Dissection of the Roux limb or mesentery should be taken with great caution; injury to or vascular compromise of the Roux limb can be catastrophic. It is better to accept a more lateral target, including one that may require taking down some of the greater curve mesentery, than to engage in a significant dissection of the Roux limb from the stomach.
- Four stab wounds are placed around the planned site of the transgastric trocar.
- Starting with the cranial suture, four stay sutures are deeply placed in the gastric wall and snared using a Carter-Thomason device deployed through the appropriate stab wound. If a G-tube is planned, the Carter-Thomason should not be passed through the same tract so that the stay suture can ultimately be used to secure the gastric wall to the anterior abdominal wall (Stamm technique). Tag each suture without applying tension. The tension that will be subsequently applied to these sutures is significant and the risk of these sutures lacerating the stomach under this tension must not be underestimated. These sutures should be positioned in the stomach to create a 3 cm × 3 cm target for the transgastric trocar (**FIG 4**).



A B

FIG 4 ● **A.** Stay sutures are passed in all four quadrants to secure the stomach during placement of the transgastric trocar, facilitate closure of the gastrostomy, or serve as securing points for a Stamm gastrostomy. **B.** Close up of the subxiphoid, transgastric trocar site, and the associated stab wounds used for passage of the stay sutures.

PLACEMENT OF THE TRANSGASTRIC TROCAR

- Advance a 15-mm trocar through the abdominal wall (**FIG 5**). This larger trocar is absolutely necessary to accommodate the side-viewing duodenoscope. While applying gentle traction to the stay sutures, use an electrocautery device passed through the 15-mm trocar to create a small, anterior gastrotomy in the center of the target. This maneuver will facilitate falling away of the posterior gastric wall, thus mitigating the risk of inadvertent trocar injury to the posterior wall of the stomach.
- Advance the 15-mm trocar into the gastric lumen. This can be performed under direct vision through the trocar; alternatively, this maneuver can be visually supervised from the umbilical trocar. Intussuscept the trocar deeply into the stomach, directing it toward the pylorus while applying tension to the stay sutures. Confirm intraluminal location by passing the laparoscope into the lumen of the stomach via the trocar. Tag the stay sutures.

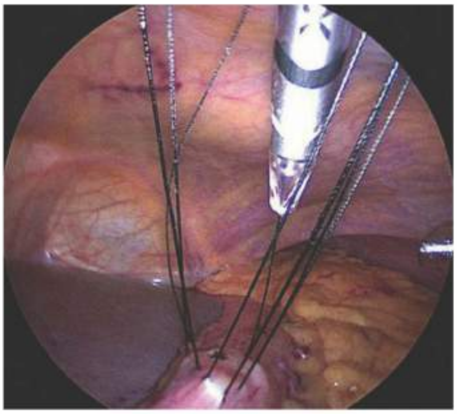


FIG 5 ● The transgastric trocar is first advanced across the abdominal wall. Electrocautery through this trocar establishes an anterior gastrostomy, centered in a 3 cm × 3 cm target zone, prior to advancing the trocar across the anterior gastric wall. This facilitates hemostasis and allows the posterior gastric wall to fall away, thus reducing the risk of posterior gastric wall injury as the trocar is advanced through the anterior wall.

ATRAUMATICALLY CLAMP THE PANCREATICOBILIARY LIMB

- Elevate the omentum and transverse colon to expose the ligament of Treitz. The reconstruction anatomy can dramatically impact the ease of this step.
- Identify the pancreaticobiliary limb and place an atraumatic bowel clamp through a right abdominal trocar to occlude the lumen and prevent gaseous distention of the small bowel (FIG 6).
- The authors routinely use a table-mounted fixed retractor that can stabilize this bowel clamp during the endoscopy phase of the procedure.
- Once this clamp is placed, transfer CO_2 insufflation to the transgastric trocar and confirm an airtight seal by the bowel clamp. This insufflation strategy can be maintained through the ERCP; it assists the endoscopist.

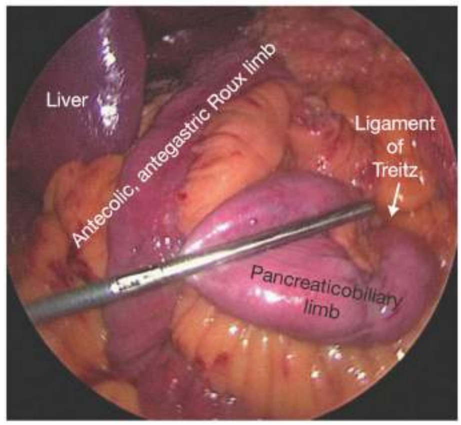

FIG 6 ● The pancreaticobiliary limb is atraumatically clamped to prevent distention of the small bowel from insufflation required during the ERCP.

DRAPE THE OPERATIVE FIELD AND PERFORM ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOSCOPY

- We prefer to cut a small hole in the center of a large laparotomy sheet and drape this over the entire patient so that only the 15-mm trocar is visible.
- ERCP then proceeds. We advise that the surgical team remain in the room during this portion of the procedure.
- At completion of the ERCP, desufflate the stomach via the transgastric trocar and move the insufflation to one of the remaining abdominal trocars. The duodenoscope and the 15-mm trocar (no longer sterile) are removed before the second surgical drape is removed.

GASTROSTOMY CLOSURE OR TUBE PLACEMENT

- The two lateral stay sutures are cut and removed, leaving the cephalad and caudad stay sutures in place to facilitate Endo GIA stapler closure of the gastrostomy.
- Alternatively, all stay sutures are left in place and used to secure the stomach to the anterior gastric wall.
- If indicated, a large-caliber G-tube with an inflatable balloon is advanced through the abdominal wall and into the lumen of the stomach (FIG 7). The balloon is inflated and the stay sutures secured under direct vision if possible. Occasionally, the pneumoperitoneum will lead to excessive tension of these sutures and securing them should be deferred until pneumoperitoneum is released.
- Consider placing a purse-string around the gastrostomy using monofilament suture. This will allow the caliber of the gastrostomy to equal that of the G-tube.

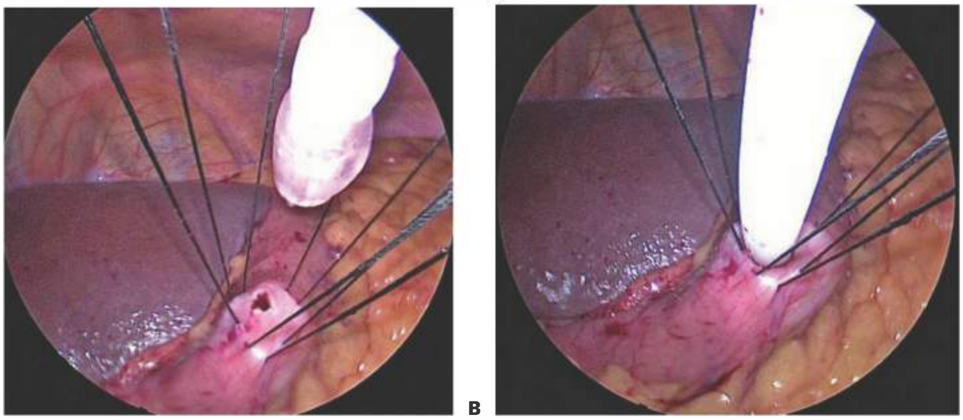

FIG 7 • A,B. Operative photographs of the laparoscopic placement of a G-tube. Inflate the balloon, release the pneumoperitoneum, and then tie the stay sutures.

PEARLS AND PITFALLS

Patient history and physical findings	■ You must know the reconstructive anatomy prior to surgery. An antegastric (and then potentially antecolic) Roux limb impacts the complexity and thus risk of the procedure. ■ Therapeutic management of SOD is now very controversial. Have clear therapeutic goals for the procedure before embarking on SA-ERCP.
Surgical management	■ Take large, deep bites of the stomach with the stay sutures. The stomach is prone to laceration by the sutures given the significant tension that is typically applied during this procedure. ■ A duodenoscope will not pass through a 12-mm trocar. Use a 15-mm trocar. ■ If you do not effectively occlude the pancreaticobiliary limb with a bowel clamp, you will not be able to see anything once the ERCP is completed. The bowel will be distended with gas.
Postoperative care	■ If multiple ERCP sessions are planned, leave a large-caliber, balloon-tipped, G-tube.

POSTOPERATIVE CARE

- Patients should be monitored overnight for evidence of complications.
- A liquid diet can usually be initiated the evening of surgery.
- If a G-tube has been placed, it should be left to gravity drainage overnight and can be clamped the morning of the first postoperative day prior to discharge.

COMPLICATIONS

- Devascularization or laceration to the Roux limb
- Posterior gastric wall injury
- Pancreatitis
- Other complications of ERCP (i.e., retroduodenal perforation)

OUTCOMES

- SA-ERCP should be successfully completed in a very high percentage of cases.[2] The supine position can be challenging for even experienced endoscopists.
- Outcomes should be equivalent to those reported for ERCP without the need for surgical access to a gastric remnant.

Chapter 8

Roux-en-Y Choledochojejunostomy

Shawnn Nichols Mark Bloomston

DEFINITION

- Choledochojejunostomy involves the anastomosis of the common bile duct (CBD) to the jejunum, thereby reestablishing continuity of biliary flow (**FIG 1**). It may be used for repair of biliary strictures, after traumatic or iatrogenic CBD injury, or following for surgical resection for benign or malignant disease of the distal CBD. It may also be incorporated in resection of duodenal, ampullary, or pancreatic tumors, such as in pancreaticoduodenectomy.
- Our discussion here is limited solely to choledochojejunostomy.

DIFFERENTIAL DIAGNOSIS

- Choledochal cyst excision (type I, II, or III)
- Repair of CBD strictures
- Repair after traumatic or iatrogenic injury of the CBD
- Diversion of biliary flow in the presence of distal obstruction or pending obstruction for palliation
- Orthotopic liver transplantation
- Reestablishing biliary continuity after resection of benign or malignant disease, including biliary, ampullary, duodenal, or pancreatic head neoplasms

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough medical history and physical exam is important in determining the possible etiology causing the need for reestablishing biliary continuity. The overall health of the patient must be considered in determining whether the patient is a surgical candidate. Past surgical history is essential to identifying those patients at risk of iatrogenic strictures.
- Symptoms of easy bruising, pruritus, acholic stools, nausea, vomiting, right upper quadrant pain, fevers, chills, mental status changes, and weight loss are important indicators of hepatic dysfunction and biliary obstruction.
- Physical exam findings of abdominal mass, abdominal pain, abdominal surgical scars, jaundice, and scleral icterus should be sought. Additionally, indicators of cholangitis should be identified and rapidly treated: Charcot's triad (right upper quadrant abdominal pain, jaundice, and fever) or Reynolds' pentad (Charcot's triad findings plus mental confusion and septic shock) indicate the need for preoperative biliary drainage.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Hilar anatomy must be evaluated prior to surgery, identifying any aberrant biliary or arterial anatomy and elucidating the possible etiology, site of injury, extent of obstruction, and planned surgical approach needed.
- Contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) should be used to properly identify the anatomy and assess for potential vascular involvement in neoplastic processes or injury in iatrogenic biliary injuries. Magnetic resonance cholangiopancreatography (MRCP) is particularly useful to elucidate the biliary and pancreatic ductal anatomy and adjacent structures (**FIG 2**). Imaging is useful and often helpful in predicting the etiology of benign or malignant neoplasms. Image-guided percutaneous

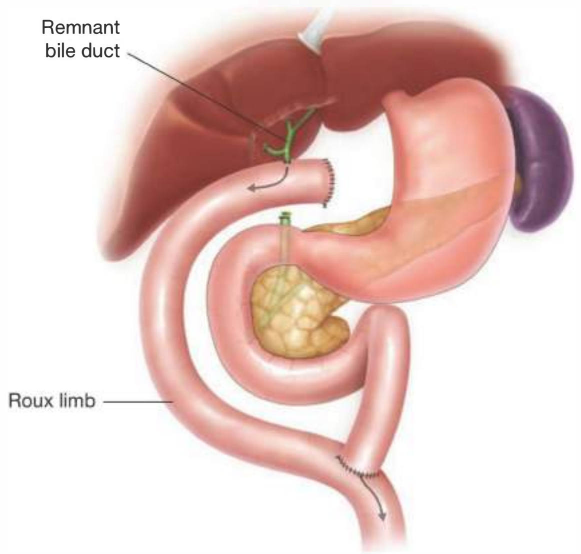

FIG 1 ● Illustration of a Roux-en-Y choledochojejunostomy.

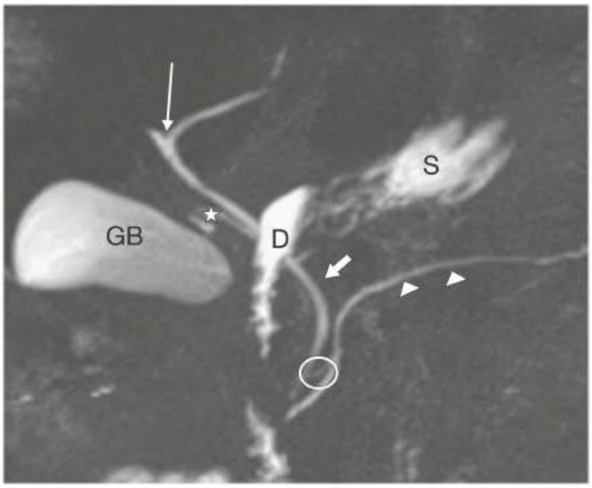

FIG 2 ● MRCP image depicting normal biliary anatomy. *S*, stomach; *D*, duodenum; *GB*, gallbladder; *arrowheads*, pancreatic duct; *thin arrow*, confluence of the right and left hepatic ducts; *thick arrow*, CBD; *star*, cystic duct; *white circle*, accessory pancreatic duct.

FIG 3 ● ERCP image reveals dilated intrahepatic and extrahepatic ducts, with the CBD dilated at 17 mm and narrowing of the distal portion at the ampulla in an ampullary cancer.

approaches with ultrasound or CT guidance may enable tissue biopsy of suspicious lesions.

- Evaluation with endoscopic ultrasound (EUS) or with endoscopic retrograde cholangiopancreatography (ERCP) offers another method to assess the anatomy and for tissue biopsy (**FIG 3**).
- In cases of cholangitis or biliary obstruction, biliary decompression by ERCP or percutaneous transhepatic cholangiography (PTC) may be warranted prior to surgical repair. It should be noted that biliary stenting in the face of asymptomatic mild to moderate hyperbilirubinemia, prior to elective surgery, may increase the postoperative risk of infection.[1]
- A previously obtained intraoperative cholangiogram (IOC) may be available and prove beneficial. Many cases of iatrogenic injuries occurring during laparoscopic cholecystectomy (LC) are identified by this technique (**FIG 4**).

SURGICAL MANAGEMENT

- Indications include:
  - Bypass of distal or ampullary strictures.
  - Reconstruction after traumatic or iatrogenic injuries.
  - Reconstruction following Choledochal cyst excision (type I, II, or III).
  - Benign or malignant disease: biliary, ampullary, duodenal, or pancreatic head neoplasms. It can be included for palliative diversion or following resection.
  - Reconstruction during Orthotopic Liver transplantation.

Preoperative Planning

- Standard optimization of comorbidities should be managed as permitted; for example, diabetes, hypertension, and cardiopulmonary status.

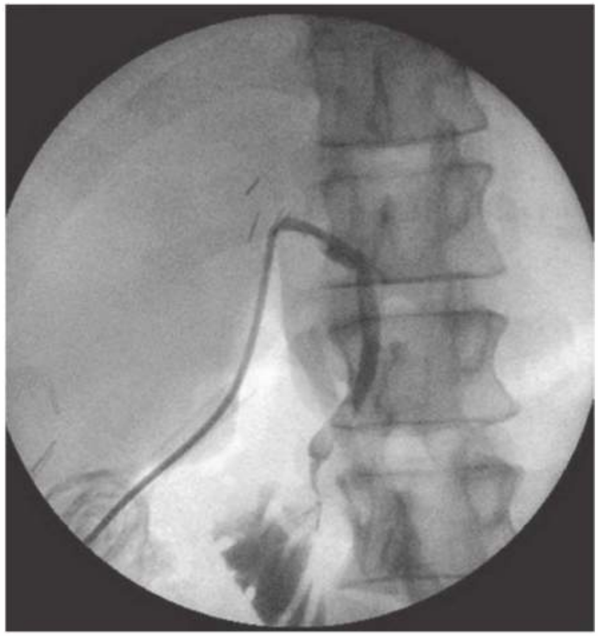

FIG 4 ● IOC image with identification of an iatrogenic duct injury occurring during an attempted LC for acute cholecystitis. Surgical clips are noted. Contrast is seen with antegrade flow into the duodenum, but no retrograde flow is appreciated, indicating iatrogenic occlusion of the proximal bile duct.

- Coagulation disorders, if present, should be corrected with vitamin K as required.
- In the appropriately selected jaundiced patient, preoperative stenting via ERCP and/or PTC may be necessary.
- Cholangitis, if present, should be treated with appropriate drainage and antibiotics. Common biliary pathogens include *Escherichia coli*, *Klebsiella* spp, *Enterococcus* spp, streptococci, *Enterobacter* spp, and *Pseudomonas aeruginosa*.
- In the absence of cholangitis, preoperative antibiotics should be given, and expanded in the presence of biliary stenting due to the increased risk of biliary contamination, even in asymptomatic patients.
- In malnourished patients, nutritional support may be considered preoperatively and continued into the postoperative period to minimize postoperative complications. Adequate nutrient absorption may be hindered preoperatively due to biliary blockage or diversion.
- In the face of malignant disease, preoperative workup should also be tailored to the assessment of the type and extent of disease present. Surgical resectability is of primary concern in malignant processes; however, choledochojejunostomy may be undertaken as a palliative biliary diversion in unresectable malignancies.

Positioning

- Patient is placed in supine position with both arms at 90 degrees, ensuring pressure points are protected and padded (**FIG 5**).
- We use a bilateral post, framed retractor system (**FIG 6**) to maximize exposure via a bilateral subcostal incision.

FIG 5 ● Proper patient positioning with arms at 90 degrees and placement of an airflow warming device over the patient's upper body to prevent hypothermia. *Solid line* denotes the costal margin. *Dotted line* depicts planned placement of bilateral subcostal incision.

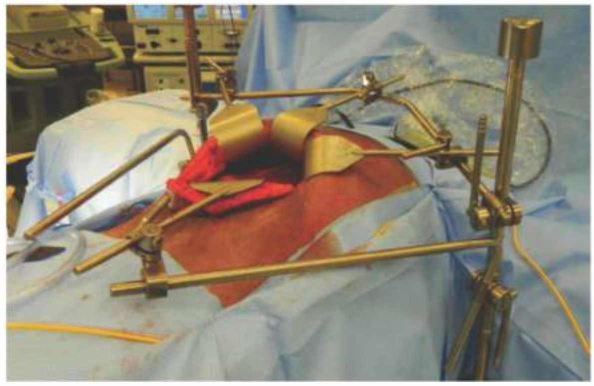

FIG 6 ● Bilateral subcostal incision with a bilateral post retractor system in place to maximize exposure.

PLACEMENT OF INCISION AND OPERATIVE EXPOSURE

- A bilateral subcostal incision provides optimal exposure. Once the peritoneum is entered, adhesions are cleared if present, and the falciform ligament is divided between ties or with an energy device. This further exposes the operative field and permits retractor placement (**FIG 6**).
- The abdomen is explored and all peritoneal surfaces are palpated if malignancy is suspected. The root of the mesentery is palpated early to assess for foreshortening due to tumor infiltration, inflammation, or previous surgery, which may impact the ability to develop a Roux limb for reconstruction.
- Exposure of the porta hepatis is begun by mobilizing the hepatic flexure of the colon, as necessary.
- Kocherization of the duodenum provides optimal exposure of the distal CBD.
- The gallbladder, if present, is removed in a top-down fashion. If the porta hepatis is involved in acute and/or chronic inflammation, the cystic duct should be traced to locate the common hepatic duct (CHD) and the CBD.
- Meticulous dissection of the porta hepatis is necessary to identify essential structures to prevent inadvertent injury. Care should be taken to search for and prevent injury to aberrant or replaced anatomic variations. A replaced right hepatic artery arising from the superior mesenteric artery will lie to the right and deep to the CBD and can be injured during CBD transection if not anticipated. The right hepatic artery commonly courses behind the CHD but on occasion the artery may lie anterior to the CHD. Biliary anatomic variations should also be expected (see Part 3, Chapter 15, FIG 17). The absence of aberrant anatomy on preoperative imaging should not usurp careful dissection with anticipation of variance.
- Dissection and exposure of the CBD may be difficult in the face of inflammatory changes resulting from prior surgeries, radiation exposure, and/or preoperative placement of a biliary stent. At times, intraoperative ultrasound may be helpful in proper identification of the structures within the porta hepatis. Another method to identify the CBD when dissection is difficult is to use a small-gauge needle and aspirate looking for bile.
- With proper identification and dissection of the CBD, the site of transection is selected proximal to the location of injury or obstruction. It should be noted that the arterial supply to the bile duct runs along the lateral and medial aspects of the CBD and CHD, and care should be taken to avoid extensive dissection or mobilization that may compromise this blood supply. When transection of the bile duct with end-to-side reconstruction is planned, the predominant blood supply will come from the right hepatic artery near the liver hilum. Thus, a higher point of transection is desired to optimize blood supply to the anastomosis. The margin of resection should be pathologically assessed intraoperatively in the face of malignancy.
- With the transection site selected, the CBD can be divided sharply or with electrocautery in cut mode to minimize thermal damage. If a stent has been placed preoperatively, it is removed at this point. Cultures of the bile fluid may be warranted. The proximal duct should be probed to ensure patency and confirm ductal anatomy—The probe should be guided up both the left and right hepatic ducts. Cholangioscopy can be undertaken if there is concern for proximal obstruction or hepatolithiasis. To control bile spillage and facilitate hemostasis, the proximal stump is temporarily closed with a vascular bulldog clamp.

CREATION OF THE ROUX LIMB

- Although choledochoduodenostomy or choledochojejunostomy using a loop of jejunum are reconstructive options that may be appropriate in the clinical setting of a short life expectancy or a particularly hostile abdomen due to adhesions, a defunctionalized segment of jejunum using a Roux-en-Y technique is preferred due to superior outcomes. Beginning at the ligament of Treitz, the jejunum is examined to the first point at which a loop can easily be brought up to the divided CBD without tension based on the length of the mesentery and at a point where the vascular arcade can be preserved to both limbs as determined by transillumination of the mesentery. A gastrointestinal anastomosis (GIA) stapler is used to divide the jejunum at this point. The mesentery is then divided down to its base using ligatures for hemostasis. Care must be taken to maintain proximal and distal orientation of the divided jejunum. A defect is created in the transverse mesocolon, to the right of the middle colic vessels, and the Roux limb is brought up in a retrocolic orientation to serve as the defunctionalized biliary-enteric limb and placed without tension near the divided CBD.

CHOLEDOCHOJEJUNOSTOMY ANASTOMOSIS

- The choledochojejunostomy is created in a single-layer, interrupted fashion using no. 4-0 or no. 5-0 polydioxanone monofilament absorbable suture. If nonabsorbable suture is used, all knots must rest outside of the anastomosis to prevent stone formation.
- Stenting across the anastomosis is not routinely undertaken, even in the case of a normal-sized duct.
- An end-to-side anastomosis provides for ease of exposure during the reconstruction. Electrocautery is used to create an enterotomy on the antimesenteric side of the Roux limb approximately 3 to 4 cm from the stapled end. The enterotomy is sized smaller than the transected CBD width, in anticipation of "enterotomy stretch" that occurs with suturing.
- The CBD is reopened, bile flow is again confirmed, and the duct cleared as necessary. The duct is trimmed as needed with Potts scissors, allowing for maximal diameter; sharp, crisp edges; and identification of good vascularity.

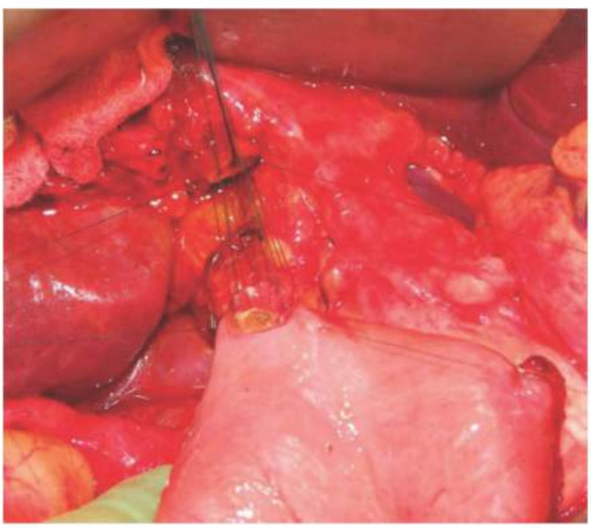

FIG 7 ● Creation of the choledochojejunostomy anastomosis. Corner sutures placed to permit lateral traction and orientation of the posterior and anterior rows. Posterior row of monofilament sutures are placed in such a way that the knots will lay within the lumen.

- The jejunum is placed near the CBD stump, positioned so as to limit redundancy and kinking of the jejunum. Lateral traction sutures are placed full thickness out-to-in on the jejunum and in-to-out on the bile duct, left untied, and placed on hemostats under gentle lateral traction.
- The posterior row sutures are placed approximately every 2 to 3 mm apart, taking full-thickness bites of the duct and jejunum, working from one lateral corner to the other. Be certain that the jejunal mucosa is incorporated into the stitch. Sutures are placed in-to-out on the jejunum and out-to-in on the duct, such that when tied the knot will be within the lumen (**FIG 7**). Gentle upward traction on the anterior wall of the bile duct provides nice exposure of the lumen to ensure proper suture placement through the posterior wall. The sutures are tagged and left untied to allow the Roux limb to be manipulated freely to maximize exposure.
- Great care is taken to maintain orientation of the suture so that it does not become twisted. Suture order must be preserved to prevent overlaping, and thus narrowing of the anastomosis when the posterior row is complete and the knots tied. Small hemostats should be used to tag each suture and place them in the proper orientation and order on a sponge forceps, thus making this task less cumbersome and more efficient (**FIG 8**).

FIG 8 ● Sutures placed during creation of the posterior and anterior rows are left untied, tagged with hemostats, and their orientation and order maintained by arranging them on a sponge forceps clamped to a laparotomy sponge. This is placed above the retractor system on the drapes and optimizes efficiency when tying the sutures.

- Once all of the posterior row sutures are placed, we begin tying each suture in order from one corner to the other, carefully laying the knots to ensure optimal intervals along the way. If an interval is determined to be too large (>3 to 4 mm), an additional suture is placed, tied, and then the remainder of the row sutures are tied (**FIG 9**). The corner sutures are left untied to allow mobility and maximum exposure of the entire back row while placing the anterior row of sutures. Suture tails are then cut short and the anterior row is addressed.
- The anterior row sutures are placed in an out-to-in fashion on the jejunum and an in-to-out fashion on the duct so that the knots will be on the outside when tied (**FIG 10**). Again, intervals are assessed and additional sutures placed as needed.
- Once complete, the anastomosis is inspected for evidence of a bile leak (**FIG 11**). Absence of tension on the anastomosis is confirmed. The surgical field is dried, ensuring good hemostasis and a clean, white surgical sponge is carefully packed around the anastomosis, and attention is turned to creating the jejunojejunal anastomosis.

FIG 10 ● The anterior row of sutures have been placed. Visual inspection confirms proper interval placement of the sutures. The sutures are ready to be tied to complete the choledochojejunostomy anastomosis.

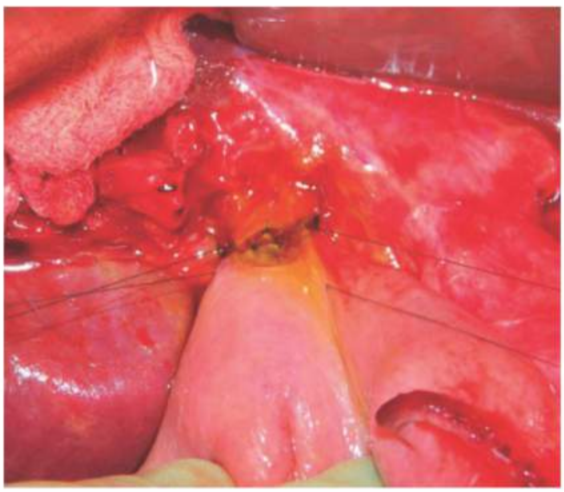

FIG 9 ● The choledochojejunostomy posterior row sutures have been tied and the row inspected. The previously placed lateral traction sutures are left untied in preparation for placement of the anterior row sutures. Gentle downward traction on the Roux limb enhances exposure as shown in the picture.

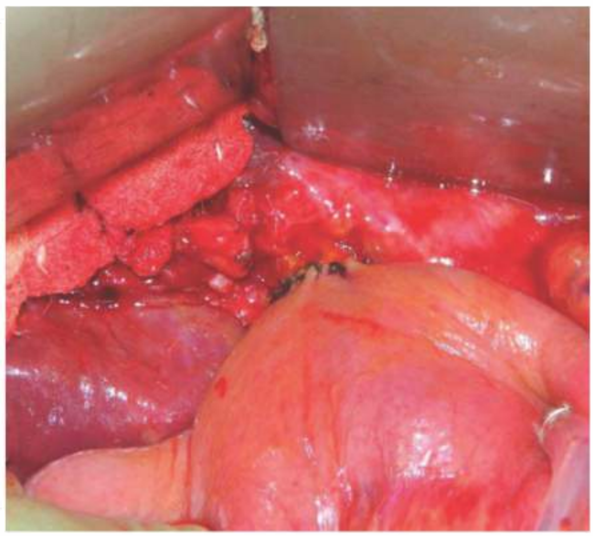

FIG 11 ● The anterior row sutures have been tied, and the choledochojejunostomy anastomosis is carefully inspected for any bile leak. A small, clean, white gauze (not pictured) is placed posterior to the anastomosis to aid in evaluation of a biliary leak.

JEJUNOJEJUNAL ANASTOMOSIS

- Intestinal continuity is reestablished by a Roux-en-Y anastomosis. The proximal biliopancreatic limb is anastomosed to the biliary-enteric Roux limb approximately 45 to 65 cm downstream from the choledochojejunostomy anastomosis to minimize enteric reflux. We prefer to create a side-to-side, functional end-to-end anastomosis using a linear stapling device, then closing the common enterotomy with a single row of interrupted no. 3-0 silk sutures using a modified Gambee technique.
- The small bowel mesenteric defect is closed at the Roux-en-Y anastomosis.
- If a retrocolic position for the biliary-enteric limb was used, any redundancy laying in the subhepatic bed is reduced without placing tension on the anastomosis. The mesocolic defect is closed, incorporating a seromuscular bite of the passing jejunum, with no. 3-0 silk sutures to prevent the possibility of limb migration and/or internal herniation. Every attempt should be made to ensure that this closure does not impinge upon the bowel.

PREPARING FOR CLOSURE

- Returning to the choledochojejunostomy, the previously placed sponge is carefully removed and inspected for any bile staining. If present, further inspection of the anastomosis is warranted and additional sutures are placed as needed.

CLOSURE

- We routinely place a single fluted surgical drain on closed suction posterior to the choledochojejunostomy anastomosis and down into Morrison's pouch, then out through a separate stab incision on the right side of the abdomen. The drain is appropriately secured with suture at the skin.
- The abdominal fascia is closed in two layers (posterior fascia and anterior fascia) with no. 1 absorbable synthetic monofilament.
- The skin is reapproximated with buried, deep dermal, interrupted, no. 3-0 absorbable braided sutures. The skin is closed with surgical glue.

PEARLS AND PITFALLS

Indications	■ A thorough history and physical (H & P) exam with good preoperative imaging is important in anticipating the extent of the procedure.
Dissection	■ Anticipate aberrant and accessory anatomy within the porta hepatis.
Excision	■ Send CBD margins for frozen section analysis when considering malignant disease.
Choledochojejunostomy	■ Meticulous suture technique is critical. There should be no concerns with the posterior row prior to proceeding with the anterior row. ■ Avoid the urge to place too many sutures. ■ Proper suture orientation is important as any crossing of suture knots will lead to ischemia of the interposed tissue. ■ Ensure there is no tension on the anastomosis.

POSTOPERATIVE CARE

- We typically remove the nasogastric tube (NGT) early (i.e., 1 to 2 days postoperative), unless ileus is anticipated (e.g., emergency surgery, active cholangitis, extensive enterolysis), and start a clear liquid diet.
- The patient is encouraged to begin ambulating on postoperative day (POD) 1. Appropriate postoperative thromboembolism prophylaxis is started on POD 1.
- Drain output is assessed and followed for the presence of bile. If present, the drain will be kept until bile output has cleared, as it almost always will do so on its own. If drain output is serous, then the drains can be pulled with little concern for volume of output. Drains are pulled after the patient is tolerating a diet and usually prior to discharge.
- Postoperative laboratory studies are followed on a daily basis to include a complete blood count, serum chemistry, and liver function tests.

OUTCOMES

- Long-term survival rates after choledochojejunostomy are dependent on the underlying indication for the procedure.

COMPLICATIONS

- Complications occur in up to 40% of cases[2] and include the following:
  - Wound infection
  - Biloma—can usually be managed with percutaneous drainage
  - Anastomotic leak (biliary and/or enteric)—may require operative drainage but often can be managed with the surgically placed drain or by radiologically placed percutaneous drains
  - Cholangitis—generally indicates reflux from ileus; it can be managed with NGT decompression and antibiotics; PTC may be used to decompress Roux limb specifically if NGT ineffective.
- Biliary stricture (can occur up to 10 or more years after surgery)—heralded by rising alkaline phosphatase; often can be treated with PTC and balloon dilation but may require surgical revision of the anastomosis

Chapter 9 Minimally Invasive Choledochojejunostomy

Janak Parikh C. Max Schmidt Eugene P. Ceppa

DEFINITION

- Hepaticojejunostomy is the operative formation of an anastomosis between the biliary tree and a Roux limb of the jejunum to manage biliary obstruction secondary to benign or malignant strictures, or to reconstruct continuity following resection of the extrahepatic biliary tree or pancreaticoduodenectomy.

DIFFERENTIAL DIAGNOSIS

- Benign
  - Traumatic or iatrogenic bile duct injury
  - Chronic pancreatitis
  - Choledochal cyst
  - Mirizzi's syndrome
- Malignant
  - Extrahepatic cholangiocarcinoma (palliative or after resection)
  - Periampullary tumors (palliative or after resection)
  - Portal lymphadenopathy (palliative)

PATIENT HISTORY AND PHYSICAL FINDINGS

- History—The following features may be obtained:
  - Weight loss (malignancy vs. malabsorption)
  - Fevers/chills (cholangitis)
  - Yellow eyes/skin (obstructive jaundice)
  - Tea-colored urine (obstructive jaundice)
  - Acholic stools (obstructive jaundice)
  - Right upper quadrant pain (distended gallbladder, may suggest a process distal to the cystic duct confluence)
- Physical examination
  - Temporal wasting (cachexia)
  - Scleral icterus
  - Jaundiced skin
  - Right upper quadrant tenderness
  - Courvoisier's sign—painless, palpable gallbladder with jaundice

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Ultrasonography—preferred initial evaluations as it is readily available and inexpensive. Findings may include the following:
  - Gallbladder
    - Stones
    - Cholecystitis
  - Biliary tree
    - Extrahepatic duct dilatation
    - Intrahepatic duct dilatation
- Cross-sectional imaging
  - Computed tomography abdomen/pelvis (CT A/P) with intravenous (IV) contrast—Triple-phase CT A/P is warranted in most cases of obstructive jaundice as part of determining the probable etiology and defining surgical anatomy. This includes the following:
    - Determine location of hepatic arteries and potential anomalous anatomy
    - Compression, invasion, or thrombosis of portal, splenic, and/or superior mesenteric veins
  - Magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) with IV contrast is preferred by some institutions. It is superior to ultrasound (US) and CT in identifying the location of biliary strictures.
- Cholangiography
  - Endoscopic retrograde cholangiopancreatography (ERCP) is the "gold standard" when biopsy or other therapeutic intent is warranted.
    - Provides superior diagnostic information by identifying level of obstruction/anatomy
    - Allows for sampling of tissues at the level of obstruction via brushings for cytology
    - Is therapeutic by placement of biliary endoprosthesis to decompress biliary tree
  - Percutaneous transhepatic cholangiography (PTC) is reserved for therapeutic intervention when ERCP is technically not feasible, that is, following gastric bypass or in the clinical setting of concomitant gastric outlet obstruction.
    - Second option—Palliation is less effective as the patient will have pain from the PTC site and will need to perform daily care to the catheter.

SURGICAL MANAGEMENT

Preoperative Planning

- Underlying cardiopulmonary disease must be evaluated when considering the laparoscopic approach; affected patients may not tolerate reduced venous return or clear increased concentrations of carbon dioxide resultant from the pneumoperitoneum.
- An extensive past abdominal surgical history or previous peritonitis may impact the ability to perform the hepaticojejunostomy laparoscopically due to extensive adhesions. Prior abdominal surgery may also impact the approach of initial peritoneal access and subsequent port placement (i.e., avoiding abdominal wall defects), or mandate modification of the formation or routing of the reconstructive Roux limb.
- Morbid obesity can preclude adequate laparoscopic visualization, but these patients have the greatest potential benefit of a minimally invasive approach due to the reduced wound morbidity. Obesity mandates several considerations:
  - Distinct, longer instrumentation may be required to reach the right upper quadrant and level mechanics, thus may impact fine motor movements limitations with suturing and intracorporeal knot tying.
  - Mobilization of the hepatic flexure and a Kocher maneuver are made more difficult when the transverse mesocolon

and omentum contain more fat and organs are larger in size overall.

- Large, friable livers as a result of fatty liver disease and are prone to lacerations (hemorrhage within the operative field significantly impairs image brightness).

Positioning

- The patient is positioned supine with both arms abducted on arm board extensions of the operating table.
- A nasogastric tube and Foley catheter are placed.
- Use a footboard.

LAPAROSCOPIC CHOLEDOCHOJEJUNOSTOMY

- Port placement and role of each in the procedure is depicted in **FIG 1**.
- To first create the Roux limb, elevate and retract the omentum and transverse colon to the upper abdomen. The ligament of Treitz is identified at the base of the transverse mesocolon. Reverse Trendelenburg positioning may facilitate visualization by dropping the small bowel into the lower abdomen.
- A point for division of the proximal jejunum is identified distal enough from the ligament of Treitz to facilitate the jejunojejunostomy and such that the mesentery will have adequate length to reach the right upper quadrant without tension on the blood supply. At this location, the small bowel is divided using a laparoscopic stapler with a 2.5-mm staple load after a window is created between the vasa rectae of the small bowel.
- Use bipolar energy device or a vascular staple load to divide the mesentery toward the base. Use care not to encroach on the arterial arcade on either side of the divided bowel. This maneuver will give additional length of the mesentery necessary to reach the bile duct without putting the anastomosis under undue tension. The bowel proximal to the staple line is the alimentary limb; an additional 40 to 60 cm of small bowel distal to the staple line is measured and referred to as the Roux limb.
- A side-to-side jejunojejunostomy is fashioned. Two 3-0 stay sutures are placed 6 to 10 cm apart. Small, adjacent enterotomies are created in each limb of the jejunum with the cautery. An articulating 60-mm long, 2.5-mm staple load is introduced into the bowel via the enterotomies. Care must be taken to ensure that the mesentery is outside the staple load. The anastomosis between the alimentary and Roux limbs is created with the stapler. The common enterostomy is oversewed with a 3-0 absorbable running suture. Alternatively, this common defect can be closed with an additional firing of the stapler. The jejunojejunostomy mesenteric defect is closed with a running 2-0 nonabsorbable suture to prevent future internal hernias. Avoid full-thickness bites across the bowel mesenteric edge that was previously sealed with an energy device; this can lead to unnecessary hemorrhage, ischemia, or hematoma near your anastomosis resulting in bleeding, perforation, or obstruction postoperatively. Solely suture the peritoneum superficially together.

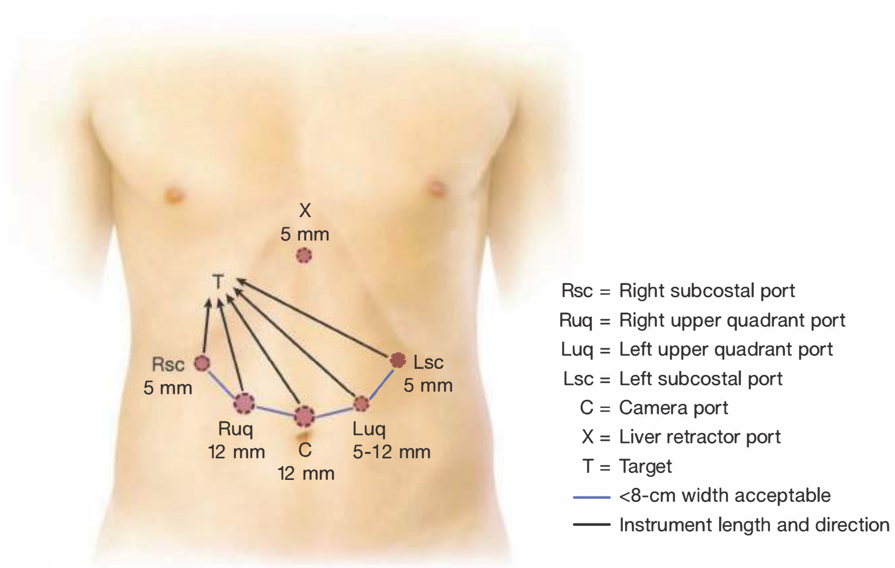

FIG 1 ● Laparoscopic access ports. The surgeon is positioned on the patient's right. The liver is retracted anterior with a fixed retractor. The first assistant on the patient's left facilitates the procedure by maintaining tension on the running suture at all times and assisting in the positioning of the Roux limb to facilitate accurate placement of sutures.

- Next, visualize the Roux limb mesenteric edge and travel down toward the root of the mesentery to ensure the mesentery is not twisted (this is worth double- or triple-checking as peripheral visualization is limited during laparoscopic surgery).
- Create a defect in the transverse mesocolon with the tissue-sealing device to the right of the right branch of the middle colic artery. Preserve the left space in case a future pancreatic Roux limb is needed.
- Mark the Roux limb staple line with a stitch or a Penrose drain/colored tourniquet to make passing the bowel through the mesenteric defect to the porta hepatis easier (optional).
- Attention is turned to the mobilization of the common bile duct within the hepatoduodenal ligament.
    - If cholecystectomy has not been previously performed, identify the cystic duct and dissect proximally toward the common hepatic–bile duct junction; if the gallbladder is surgically absent, start the dissection using a lateral to medial approach to the soft tissues of the hepatoduodenal ligament. Incise the peritoneum overlying the anterior aspect of the hepatoduodenal ligament to expose the bile duct and hepatic arterial supply. The bile duct will be lateral to the hepatic proper artery. Be mindful that the right hepatic artery travels anterior to the common hepatic duct in 10% of patients.
    - Mobilize the ligament further by incising the peritoneum laterally, extending the dissection down toward the inferior vena cava. Anterior retraction of the bile duct will facilitate exposure of the plane between the common bile duct and portal vein. This step is important to facilitate the next step, the blind passage of an instrument from the medial side, between the hepatic artery and the bile duct while staying anterior to the portal vein.
    - Encircle the bile duct with a vessel loop or Penrose drain; use metallic clips to secure the tails together.
    - Pass a right-angle instrument posterior to the bile duct and sharply divide the bile duct. Careful application of cautery or fine absorbable sutures can be used to obtain hemostasis at the 3 o'clock and 9 o'clock arterial supply at the cut edge of the proximal bile duct. The bile duct should bleed briskly; if it does not, then consider shortening the bile duct proximally to better perfused tissue.
    - If a biliary endoprosthesis or percutaneous biliary drain is across the bile duct, it should be removed at this time. If stenting the biliary-enteric anastomosis is desired, the ideal situation is to place a new 8- to 12-Fr biliary endoprosthesis across the anastomosis after the posterior row has been completed.
    - A laparoscopic bulldog clamp is commercially available and can be used to clamp the proximal cut edge of the bile duct; in some cases, this may allow for a slight dilatation of a smaller bile duct and minimize biliary soilage of the peritoneum.
- Biliary-enteric anastomosis
    - Most surgeons prefer the Trendelenburg position at the time of an intracorporeal hand-sewn choledochojejunostomy to take tension off of the anastomosis by way of the small bowel mesentery using gravity to bring the Roux limb closer. Reverse Trendelenburg position is useful in obese patients by using gravity to retract the hepatic flexure away from the porta hepatis. The Roux limb is usually supported with a grasper from one of the assistant port sites in either scenario.
    - For larger bile ducts (>5 mm in diameter), a running suture technique is appropriate. Tie two separate, 15- to 20-cm long, 4-0 absorbable sutures together to create a double-armed suture. For small bile ducts, interrupted 4-0 absorbable sutures are used for the posterior and anterior rows.
    - An enterotomy is made in the antimesenteric border of the Roux limb. Keep this enterotomy shorter than the diameter of the bile duct—it will stretch.
    - A stay suture is placed at 12 o'clock position on the bile duct for retraction of the anterior wall during creation of the posterior row (optional).
    - The "double-armed" suture that was created is introduced into the peritoneum; one arm is passed "outside-in" on the bowel and the other outside-in on the bile duct (starting at 3 o'clock position). Thus, both needles are "inside" and the knot is "outside" (**FIG 2A,B**).
    - The posterior row is created first by taking the suture inside the bile duct and going "inside-out" on the bowel, then outside-in on the bile duct, and so forth, advancing 2 to 3 mm with each passage of the suture across entire posterior row.
    - Upon completion of the posterior row, tension must be maintained on the posterior suture. A bulldog clamp or equivalent instrument is placed on the posterior row stitch to maintain this tension (**FIG 3A,B**).
    - The optionally placed 12 o'clock stay suture should be removed now to prevent confusion.
    - Stenting the biliary-enteric anastomosis would occur either now or midway through completing the anterior row.
    - Similarly, the anterior row is completed by taking the suture inside the bowel and going inside-out on the bile duct, then outside-in on the bowel, and then end-over-end across entire anterior row (**FIG 4A,B**).
    - The anastomosis is completed by tying the two sutures on the outside at the 9 o'clock position.
    - After completion of the anastomosis, the redundant Roux limb is pulled back through the mesocolon defect toward the jejunojejunostomy; it is important to minimize the risk of an afferent limb obstruction or biliary stasis in the Roux limb. The limb is secured directly to the peritoneum at the mesenteric defect with 3-0 nonabsorbable suture to prevent future herniation.
    - Surgical drainage of the anastomosis is by surgeon preference.

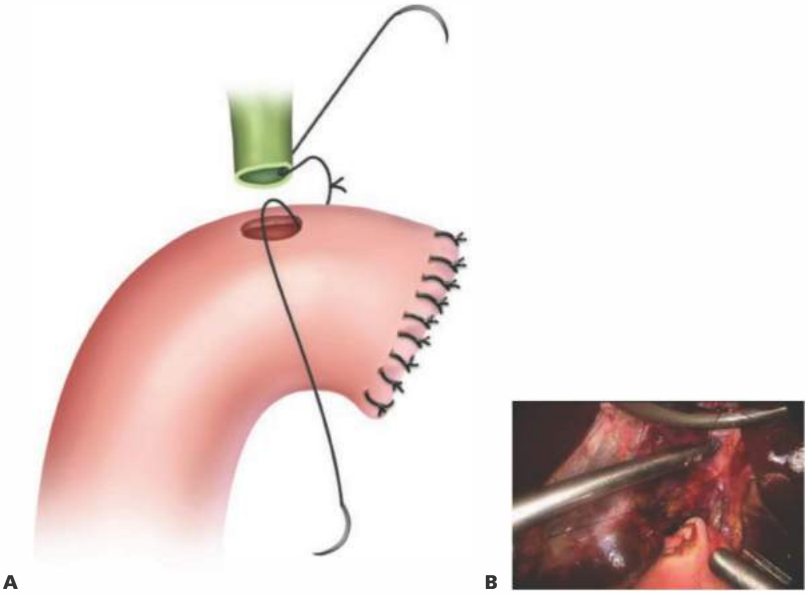

FIG 2 ● **A.** The initial suture is placed in the 3 o'clock position, such that the knot used to form the double-armed suture is external to the planned anastomosis. **B.** Intraoperative photograph of the 3 o'clock suture.

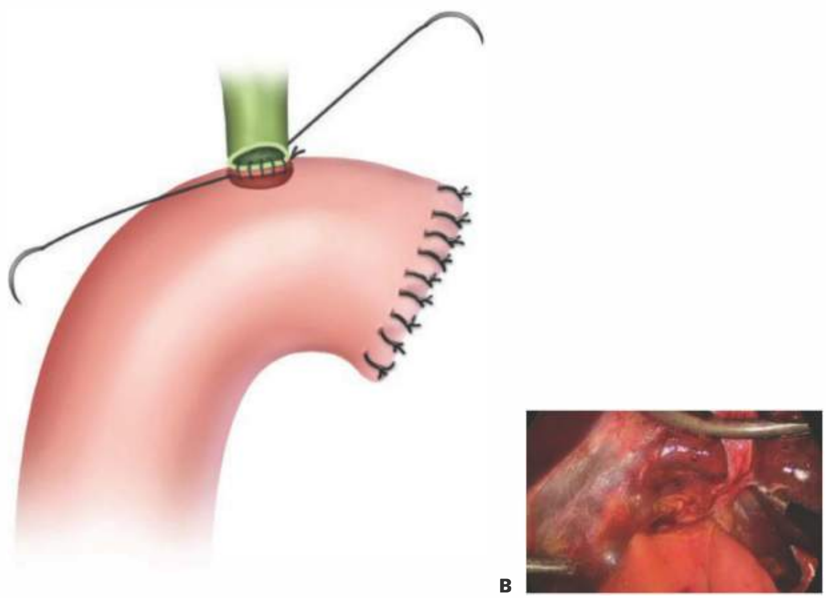

FIG 3 ● **A.** Artist's rendition of the posterior suture line. Note that the final suture will be on the jejunal side (outside the bowel) to facilitate tying this arm to the anterior suture row arm. **B.** Intraoperative photograph of the anastomosis at the completion of the posterior suture line.

FIG 4 ● **A.** Artist's rendition of the complete anastomosis prior to tying the two arms of suture. **B.** Intraoperative photograph of the anastomosis at the completion of the anterior suture line. This arm of the suture will finish on the outside of the bile duct.

ROBOTIC CHOLEDOCHOJEJUNOSTOMY

- Overall technique is similar to that of the laparoscopic choledochojejunostomy.

First Step

- Port placement for robotic choledochojejunostomy as seen in **FIG 5**.
  - Port placement is set further away from the target of dissection due to the long robotic instruments and inability of the robot to optimally articulate when the arms approach greater than or equal to 90-degree angle to the patient.
  - Additionally, the robotic ports should be placed wider than the laparoscopic ports. This helps avoid "conflict" or collisions between the robotic arms.
- Mobilization of the hepatic flexure, creation of the Roux limb, creation of the jejunojejunostomy, and introduction of the Roux limb through the transverse mesocolon are performed with conventional laparoscopy before docking the robot.
- The patient is placed in a steep reverse Trendelenburg position with the right side tilted slightly up.
- The robot is docked as follows:
  - Robot is positioned over the patient's right shoulder.
  - Place a foam pad over the patient's arm and face.
  - Position the robot correctly in terms of both maintaining it centered in its "sweet spot" (the arrow must point to the area within the blue stripe visible on the front of the robot) as well as creating sufficient distance between the robotic arms.
  - The function of the robotic arms is optimal when the arm number is facing directly out.
- The biliary enteric anastomosis is performed robotically as described previously.

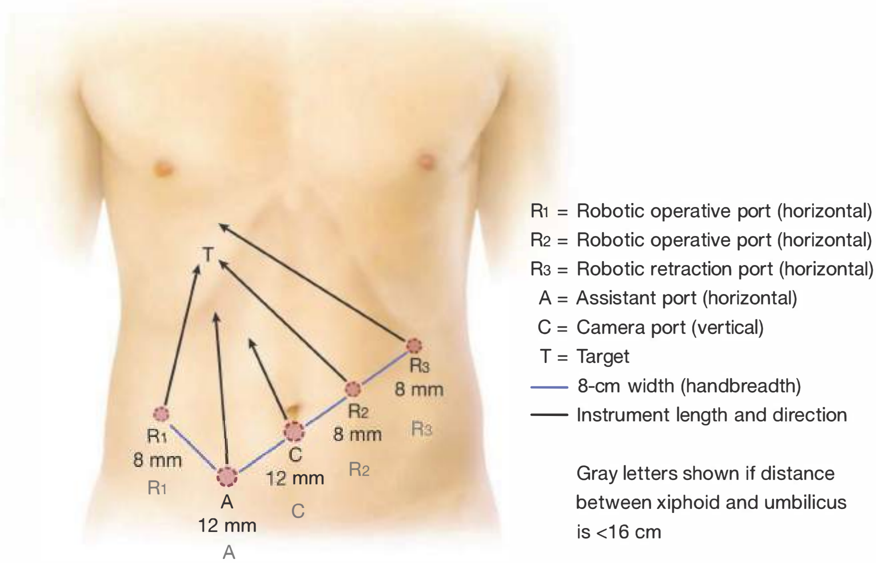

FIG 5 ● Robotic access ports. R1 serves as the surgeon's left hand and R2 serves as their right hand. R3 provides liver retraction. The assistant provides tension on the running suture or provides additional exposure via retraction of the jejunal limb.

POSTOPERATIVE CARE

- Depending on the extent of the resection, the return of bowel function will be variable but can be virtually immediate. The authors remove the nasogastric tube on postoperative day 1. Liquids are initiated on postoperative day 2.
- Monitor the patient for signs of biliary fistula; a lack of bile in an operatively placed drain does not ensure the absence of an evolving fistula.
  - Fevers
  - Tachycardia
  - Right upper quadrant pain
  - Leukocytosis
  - Persistent ileus
- CT with percutaneous drainage of any identified fluid collections is employed if fistula is suspected.

OUTCOMES

- Biliary-enteric reconstruction patency rate
  - Open: 70% to 90%
  - Minimally invasive: no data
- Follow-up
  - Four weeks postoperatively with laboratory studies (complete blood count [CBC], complete metabolic panel [CMP]). An elevation in the alkaline phosphatase is usually the earliest and most sensitive indicator of biliary obstruction or stricture.
  - Twelve weeks postoperatively with a right upper quadrant US to examine for dilated intrahepatic ducts or postoperative fluid collections, or sooner if liver function tests are abnormal.
  - Twenty-four weeks postoperatively with a technetium-99m Choletech scan in nuclear medicine to assess filling of the Roux limb with radiotracer (optional).
  - The risk of stricture persists for 10 years. The authors recommend obtaining liver injury tests every 3 months for the first year, and then semiannually until the fifth anniversary of the operation.

COMPLICATIONS

- Mortality: 1%
- Morbidity: 10% to 20%
  - Biliary fistula (early)
  - Biliary stricture (late)
  - Jejunojejunostomy leak or stricture (<1%)
  - Afferent limb obstruction (<1%)

Chapter 10 Choledochoduodenostomy

Katherine A. Morgan   David B. Adams

DEFINITION

- Choledochoduodenostomy (CDD) describes an anastomosis between the extrahepatic biliary tree and the duodenum undertaken to provide internal drainage of an obstructed distal common bile duct (CBD).

DIFFERENTIAL DIAGNOSIS

- Choledocholithiasis
- Autoimmune-induced biliary strictures
- Chronic pancreatitis
- Periampullary malignancy

PATIENT HISTORY AND PHYSICAL FINDINGS

- The primary indications for CDD are benign causes of biliary obstruction including chronic pancreatitis and distal biliary stricture related to choledocholithiasis. In the current era of endoscopic retrograde cholangiography, the frequency of operative biliary bypass has decreased; nonetheless, CDD remains an important part of the general surgeon's armamentarium.
- Patients with distal biliary obstruction will typically present with right upper quadrant abdominal pain and associated jaundice. If cholangitis is attendant, fever and chills (Charcot's triad) or, in more severe cases, hypotension and altered mental status (Reynolds' pentad) may be evident.
- Elevated serum hepatic chemistries are essential to the diagnosis of significant biliary obstruction. Total and direct bilirubin, alkaline phosphatase, and gamma-glutamyltransferase are elevated preferentially to the hepatic transaminases in cases of biliary obstruction as contrasted to intrinsic hepatic disease.
- Patients with chronic pancreatitis who present with biliary obstruction may have a reversible component to the inflammatory obstruction, and thus are often best managed initially with endoscopic stenting. In cases with persistent biliary obstruction due to constricting fibrosis in the pancreatic head, marked by elevated serum hepatic chemistries and a dilated CBD, surgical intervention is warranted. In patients with an accompanying inflammatory pseudotumor in the head of the pancreas or a concern for malignancy, pancreatic head resection may be indicated. When resection is not indicated, CDD is an excellent means of biliary bypass while minimizing perioperative morbidity and preserving pancreatic parenchyma.
- Patients with a terminal biliary stricture due to long-standing choledocholithiasis do well with CDD. Common indications include a dilated CBD (>1.5 cm); multiple CBD stones; and primary, recurrent, or recalcitrant choledocholithiasis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Right upper quadrant ultrasound is the frontline test for biliary obstruction, visualized as dilated intrahepatic and extrahepatic biliary ducts. It is highly sensitive, noninvasive, inexpensive, readily available, and requires no radiation.
- Contrast-enhanced computed tomography (CT) is a useful modality to evaluate abdominal pain. CT will demonstrate a dilated biliary tree and can help in the evaluation for causative-associated pathology including choledocholithiasis, chronic pancreatitis, and periampullary malignancy.
- Magnetic resonance cholangiopancreatography (MRCP) can give detailed information about biliopancreatic ductal anatomy and pathology (T2 weighted images) and soft tissue abnormalities related to pancreatitis or neoplasm (T1 weighted images). MRCP is an important tool for assessment of biliary obstruction because of the advanced ductal imaging capability.
- Endoscopic retrograde cholangiopancreatography (ERCP) is the primary initial therapeutic approach to biliary obstruction in the current era. ERCP can be both diagnostic and therapeutic in the management of biliary obstruction. It can be used to identify stones and apply a variety of maneuvers that facilitate stone clearance:
  - Sphincterotomy
  - Balloon cholangioplasty and sweeping
  - Basket retrieval
  - Lithotripsy
- Strictures can be dilated and stented endoscopically. Even with alternative strategies (metal stents, multiple plastic stents), endoscopic stenting lacks durability in the management of chronic, longer segment CBD strictures due to chronic pancreatitis and stone disease and CDD is often employed in these cases.
- Endoscopic ultrasound (EUS) can be helpful in the careful evaluation of the terminal biliary tree for the diagnosis or exclusion of malignant obstruction and the assessment for occult cholelithiasis. EUS has also been more recently used for an endoscopic-directed choledochoduodenal stent.
- Percutaneous transhepatic cholangiography (PTC) is undertaken to study the biliary tree and allow for biliary drainage in cases where endoscopic transampullary access is not possible. Maturation and dilation of the tract after PTC can allow for percutaneous instrumentation to be used under radiographic guidance to clear stones from the biliary tree.

SURGICAL MANAGEMENT

- CDD is indicated in patients with a benign terminal biliary stricture, with an associated dilated CBD (>1.5 cm diameter), most commonly due to chronic pancreatitis or choledocholithiasis. CDD has been effectively used in the management of malignant biliary obstruction.
- When planning a biliary bypass procedure, a neoplastic cause for biliary obstruction should be sought out and recognized, as a malignant (or potentially malignant) process may call for a divergent operative approach.
- When biliary bypass is indicated in unresectable periampullary malignancy, CDD may be selected as an alternative to hepaticojejunostomy.
- Classically, the CDD anastomosis is performed in a side-to-side fashion but may also be performed with an end

(bile duct) to side (duodenum) technique, particularly when using a laparoscopic approach. Both methods are presented.

Preoperative Planning

- CDD is best undertaken in an elective setting. Acute pancreatitis should be allowed to settle and cholangitis should be properly treated. Often, endoscopic stenting can be helpful to temporize patients and allow for medical optimization.
- Particular attention should be taken to the nutritional status of the patient, as patients with chronic inflammation are often malnourished. Enteral or parenteral supplementation may be appropriate to condition the patient for surgery.
- Hepatic function should also be assessed prior to surgery, as it may be compromised in patients with long-standing biliary obstruction. Vitamin K supplementation, in particular, may be useful.
- Patients with terminal biliary stenosis due to chronic pancreatitis may have associated duodenal stenosis, pancreatic ductal obstruction and dilation, or splanchnic venous obstruction, which may require operative management and should be confirmed with preoperative evaluation.
- Patients with terminal biliary stenosis and cavernous transformation of the portal vein may undergo CDD safely, although additional emotional and physical work is demanded in the conduct of the procedure.

CHOLEDOCHODUODENOSTOMY, SIDE-TO-SIDE

Incision and Exposure

- An upper midline incision or a right subcostal incision may be used for this operation (FIG 1). The abdomen is explored for unexpected findings including evidence for distant malignancy. Caudal mobilization of the hepatic flexure of the colon is undertaken to aid in adequate duodenal exposure.
- Use of self-retaining retractors facilitates exposure of the terminal bile duct and the first and second portions of the duodenum (FIG 2).
- An extensive Kocher maneuver is performed to optimally mobilize the duodenum. This mobilization is a critical step for the success of a tension-free anastomosis. The pancreatic head and terminal bile duct are palpated and examined to assess for extent of disease and unexpected findings.
- If the gallbladder remains in place, a cholecystectomy is performed (FIG 3).
- The porta hepatis is examined and the CBD clearly identified for the course of greater than 3 cm along its anterior wall. In cases with significant inflammation and fibrosis, the anatomy can be distorted. Palpation of the hepatic artery can be helpful in orientation, as can palpation of an intraductal biliary stent or aspiration of bile with a fine needle and syringe.
- Incision of the peritoneum at the cephalad aspect of the first portion of the duodenum can facilitate the establishment of a plane between the posterior wall of the

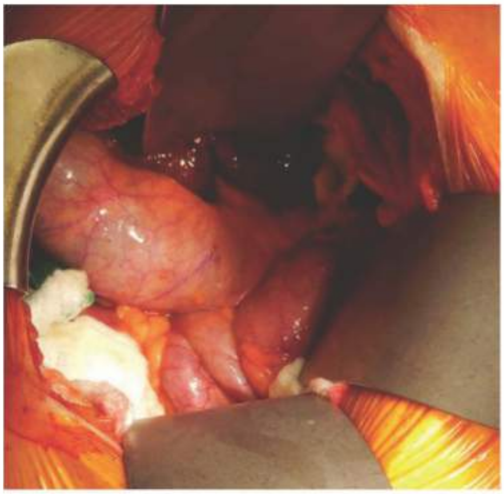

FIG 2 ● A fixed retractor facilitates exposure.

FIG 1 ● The authors favor a right subcostal incision.

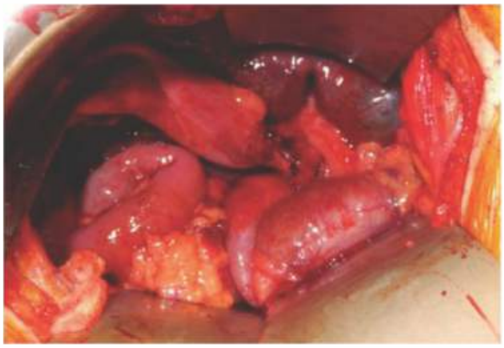

FIG 3 ● When present, retrograde dissection of the gallbladder facilitates identification of the cystic duct confluence and distal CBD.

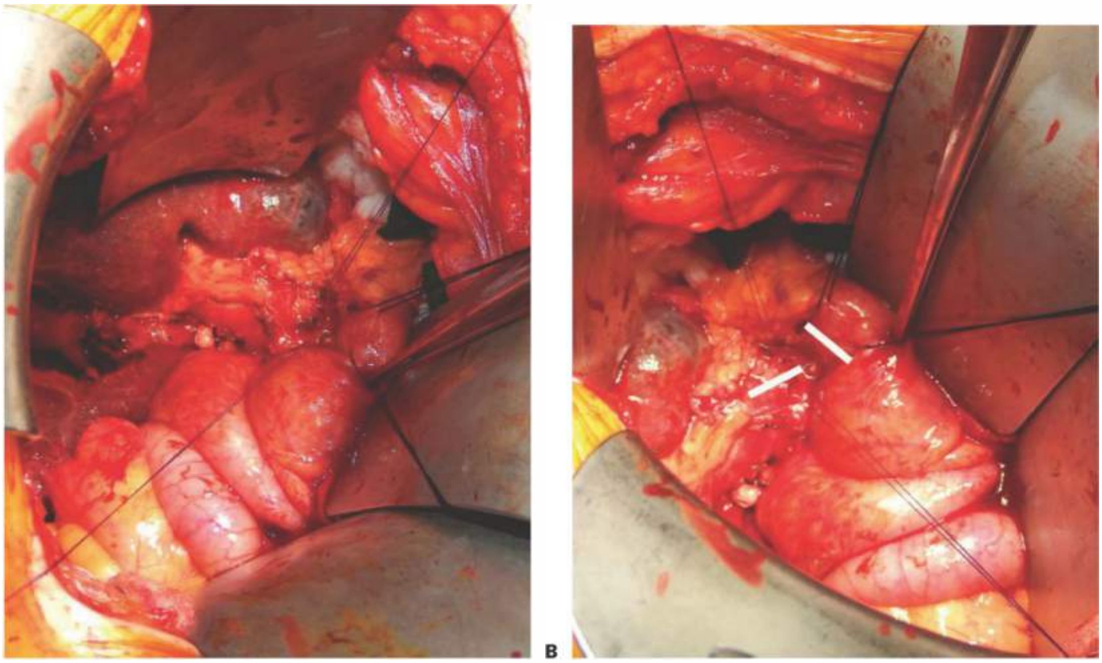

A B

FIG 4 ● **A.** After caudal mobilization of the duodenum, stay sutures are placed in the distal CBD (fine monofilament sutures) and the duodenum (larger braided sutures) to facilitate exposure. **B.** Additional view from the patient's right further demonstrates how this mobilization facilitates an anastomosis free of tension. Planned ductotomy and duodenotomy *(white lines)*.

duodenum and the anterior wall of the CBD, providing additional length and improving the proximity of the planned ductotomy and duodenotomy sites, thus reducing potential tension on the anastomosis (**FIG 4**).

Choledochoduodenal Anastomosis

- Identification of the CBD is confirmed by aspiration with a 21-gauge needle.
- An anterior ductotomy is made sharply, typically with a no. 11 blade at the site of the needle aspiration, large enough to permit entrance into the duct with the tip of a fine hemostat. An anterior longitudinal choledochotomy is then extended with scissors or electrocautery for 1.5 cm in length. The ductotomy is made on the distal CBD as close as safely possible to the duodenum. Arterial bleeding on the distal ductotomy means "far enough."
- The distal CBD and common hepatic duct should be irrigated with an 8-Fr catheter to clear the duct of stones and sludge. If ductal lithiasis is present, choledochoscopy should be undertaken to confirm clearance of the duct of stones. Residual stones may require balloon catheter or basket extraction.
- When cavernous transformation of the portal vein is present, the venous network surrounding the common duct will require a combination of suture ligation, coaptive electrocautery, and argon beam coagulation to achieve hemostasis.
- The mobility of duodenum is assessed to determine where an anastomosis will most suitably lie without tension. A duodenotomy is then made with electrocautery, with cutting current in the postbulbar duodenum. The angle of the duodenotomy will vary from patient to patient, depending on the underlying disorder and variation from normal anatomy. In pancreatitis, the mobility of the duodenum varies with the underlying peripancreatic fibrosis so the location of the duodenotomy will vary accordingly. The duodenotomy is usually an oblique incision, with the goal of a comfortable anastomosis without distortion of the duodenal flow. The duodenotomy should be cut at a length of about 1.0 cm as it will always stretch more than expected (**FIG 5**).
- If a preoperative prograde or retrograde stent has been placed, it may be prudent to leave it in place to serve as a postoperative stent, particularly in the difficult anastomosis in the presence of severe peripancreatic fibrosis, recognizing the risk of stent-induced postoperative biliary sepsis related to the sialomucin stent biofilm harboring gram-negative bacteria.
- A single layer of interrupted sutures with fine 4-0 or 5-0 monofilament absorbable suture is used for this anastomosis. Full-thickness corner sutures are placed through the duodenum and then the bile duct at either end of the anastomosis such that the tails are outside the lumen. They are marked with a hemostat and act for exposure and for conceptual planning (**FIG 6**).
- The posterior row of sutures is placed with the tails on the inside of the lumen, beginning with the middle suture to aid in spatial planning. This suture will be at the

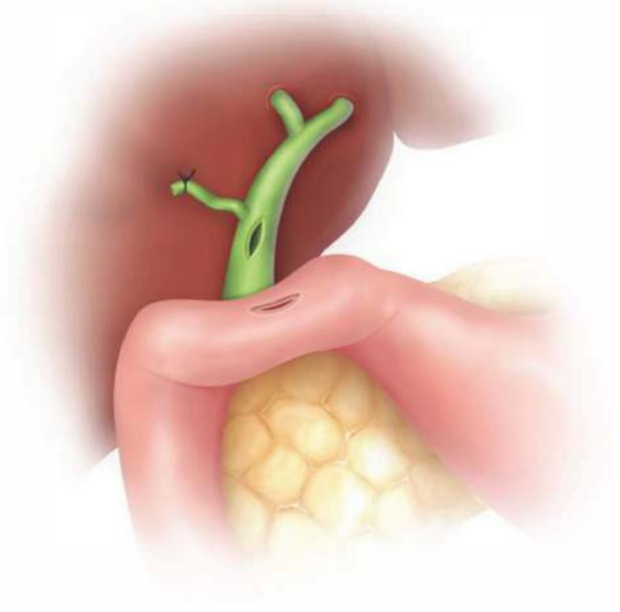

FIG 5 ● An anterior choledochotomy is performed in an oblique manner, at least 1.5 cm in length. An oblique duodenotomy is made in a configuration that will allow for a tension-free anastomosis without distortion of the duodenum, approximately 1.0 cm in length as it will stretch.

end of the choledochotomy and at the middle of the duodenotomy. The individual sutures are tagged and then tied down at the completion of the posterior row, except the corner stitches, which remain untied to aid in exposure (**FIG 7**).

- The anterior row of sutures is then placed, beginning with the middle suture, with the tails on the outside of the anastomotic lumen. All remaining sutures are then tied securely in place (**FIG 8**).
- When the anatomy is favorable, particularly with a thickened bile duct, a large anastomosis, and easy duodenal mobility, the anastomosis can be constructed with continuous sutures.
- A closed suction drain is placed near the anastomosis.

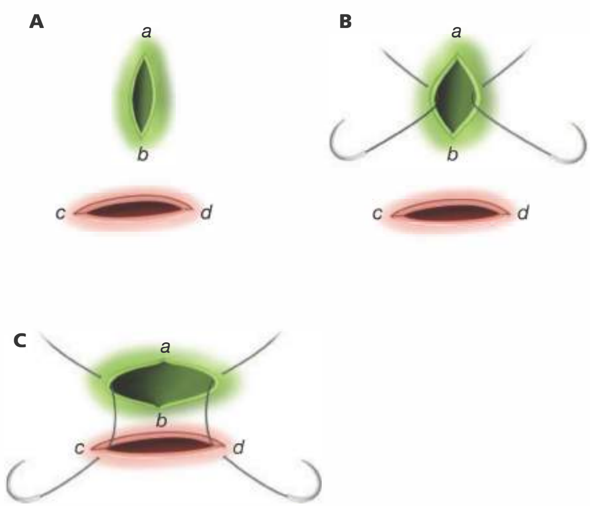

FIG 6 ● Schematic drawing of how the two ostomies are oriented for the anastomosis. **A.** Depiction of the ostomies as they lie perpendicular to one another. **B.** Stay sutures are placed on both sides of the midpoint of the choledochotomy (halfway between *a* and *b*). **C.** These stay sutures are then used to take full-thickness bites of the duodenum at the ends of the duodenotomy. This aligns the structures for placement of the posterior suture line.

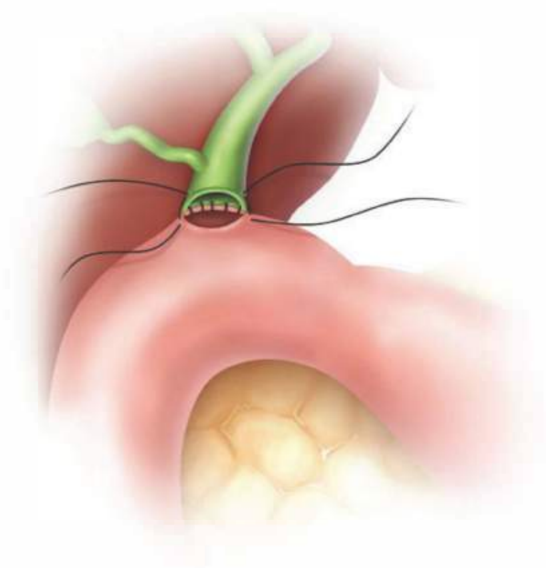

FIG 7 ● Anatomic depiction of the corner sutures that are placed with tails outside the lumen and tagged to aid for exposure and spatial planning. The back row of sutures is performed in an interrupted fashion, with tails on the inside.

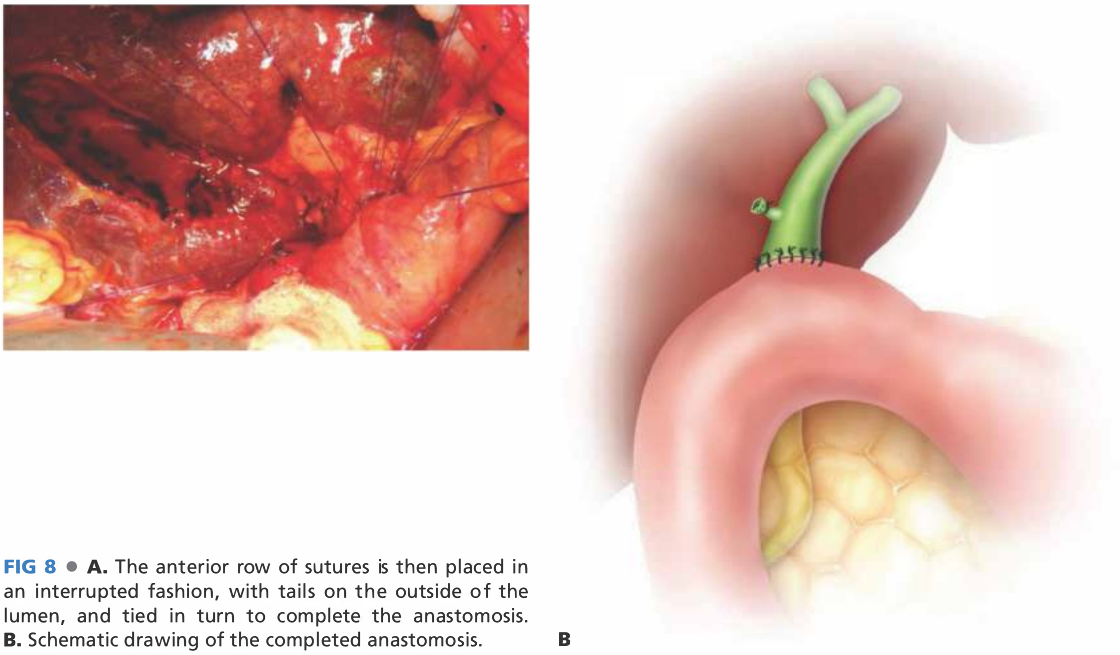

FIG 8 ● **A.** The anterior row of sutures is then placed in an interrupted fashion, with tails on the outside of the lumen, and tied in turn to complete the anastomosis. **B.** Schematic drawing of the completed anastomosis.

CHOLEDOCHODUODENOSTOMY, END-TO-SIDE

Incision and Exposure Including Portal Dissection

- The incision and exposure are similar to that for the side-to-side technique, including an extensive Kocher maneuver to mobilize the duodenum. In the end-to-side technique, however, circumferential dissection of the CBD is necessary. In cases with severe inflammation and fibrosis of the porta hepatis, a side-to-side technique may be prudent to avoid vascular injury. Medial to lateral dissection of the posterior CBD away from the hepatic artery and portal vein is the safest technique. Once the CBD has been encircled, it is divided as distally as possible, with attention to precise control of the radial blood supply of the duct, avoiding excessive use of cautery. The distal end of the divided bile duct is then oversewn in a running fashion using an absorbable suture.

Choledochoduodenal Anastomosis, End-to-Side

- A longitudinal incision is made in the second portion of the duodenum near where the divided bile duct is located. A single layer of fine (4-0) absorbable suture is also used for this anastomosis. Full-thickness corner sutures first through the bowel, then through the bile duct, and are placed at either end of the anastomosis for exposure and spatial planning.
- If an anastomosis with interrupted suture is planned, the conduct of the anastomosis is identical to that of the side-to-side technique. If an anastomosis with a running suture is planned, the corner sutures are tied and left long with needle in place. On one end, the needle is passed to the inside and run along the posterior wall inside the lumen and tied to the other corner's tail. The other suture is then run along the anterior wall and tied to the other corner's tail.
- A closed suction drain is placed near the anastomosis.

LAPAROSCOPIC CHOLEDOCHODUODENOSTOMY

Patient Positioning and Port Placement

- The patient is positioned supine and in reverse Trendelenburg with a left side down tilt.
- Laparoscopic port sites are placed in an arc above the level of the umbilicus with a right-sided bias. Port site placement similar to a laparoscopic cholecystectomy.

Initial Dissection

- The conduct of the operation is similar to that for the open technique, including mobilization of the hepatic flexure of the colon and an extensive Kocher maneuver to mobilize the duodenum. A laparoscopic liver retractor is necessary to expose the porta hepatis. Portal dissection is carried out with care using the hook electrocautery.

Choledochoduodenal Anastomosis

- When possible, an end-to-side technique is favored laparoscopically, as this anastomosis without tension is often technically easier to perform. In cases with severe inflammation and fibrosis of the porta hepatis, however, circumferential bile duct dissection may be treacherous and a side-to-side technique is favored.
- A fine absorbable suture is used for the anastomosis. The anastomosis is begun with corner sutures placed and tied without cutting the needle. The posterior row is run from medial to lateral and tied to the tail of the other corner suture. The anterior row is then similarly run, now lateral to medial and tied to the other corner's tail.
- A closed suction drain is placed near the anastomosis.

PEARLS AND PITFALLS

Indications	■ A thorough preoperative evaluation of the cause for biliary obstruction is important, specifically recognizing neoplasia if present to allow for proper operative decision making.
Preoperative planning	■ Inflammation associated with acute pancreatitis and infection and inflammation related to cholangitis on presentation should be properly treated and allowed to resolve prior to proceeding with this elective operation. ■ Patient nutritional status should be optimized prior to surgery to minimize morbidity.
Incision and exposure	■ An extensive Kocher maneuver should be performed to mobilize the duodenum and minimize tension potentially leading to anastomotic failure.
Choledochoduodenal anastomosis	■ The choledochotomy and duodenotomy should be configured in a way so as to minimize anastomotic tension and duodenal distortion. Careful intraoperative planning and an oblique bias to the incisions are useful. ■ The anastomosis should be greater than 1.5 cm in length to avoid stenosis resulting in cholangitis, hepatic abscess, stones, and potentially sump syndrome.

POSTOPERATIVE CARE

- Nasogastric decompression should be undertaken in the initial postoperative period.
- The closed suction drain is removed once diet is tolerated and there is no evidence of anastomotic leak.

OUTCOMES

- Outcomes following CDD are limited to small, retrospective, single institution case series, including both open and laparoscopic approaches. Postoperative morbidity following CDD is reported as 9.8% to 28%, with the most common complications being wound infection and anastomotic leak.
- A phenomenon known as "sump syndrome" has been described following CDD where food debris or stones accumulate in the terminal portion of the CBD, resulting in episodes of abdominal pain, fever, and cholangitis. The incidence of sump syndrome after CDD appears to be relatively uncommon, reported as 0% to 9% in case series, and presents in a delayed fashion, typically years after the procedure. Anastomotic stenosis has been implicated as the cause for sump syndrome as well as for the rare occurrence of recurrent stones, cholangitis, and hepatic abscess, and therefore, generous anastomotic girth is encouraged to prevent these complications.

COMPLICATIONS

- Intraoperative hemorrhage from portal vein or proper hepatic artery
- Anastomotic leak, duodenal fistula
- Anastomotic stricture
- Cholangitis
- Hepatic abscess
- Choledocholithiasis or intrahepatic ductal stones
- Sump syndrome

Chapter **11**

Resection of Hilar Cholangiocarcinoma

Ryan T. Groeschl   T. Clark Gamblin

DEFINITION

- Hilar cholangiocarcinoma (HC), also referred to as Klatskin's tumor, is an extrahepatic cancer of biliary epithelial origin near the confluence of the right and left hepatic ducts. The hepatic artery and portal vein are in close proximity to the bile duct, and vascular involvement is common. Given the limited effectiveness of other therapies, margin-negative resection is the optimal treatment. Although multimodal therapy combined with transplantation is also a potential approach to HC,[1] this chapter focuses on the resection technique for this biliary disease.

DIFFERENTIAL DIAGNOSIS

- Growth patterns for HC may be exophytic, infiltrative, polypoid, or any combination thereof (**FIG 1**). The differential diagnosis includes pathologies that may mimic any of these appearances.
  - Papilloma—composed of vascular connective tissue and covered with columnar epithelium; low-grade malignant potential
  - Adenoma—glandular tissue surrounded by fibrous stroma; low-grade malignant potential
  - Benign biliary stricture from recurrent pyogenic cholangitis, primary sclerosing cholangitis, choledocholithiasis, Mirizzi's syndrome, previous surgery, or trauma.

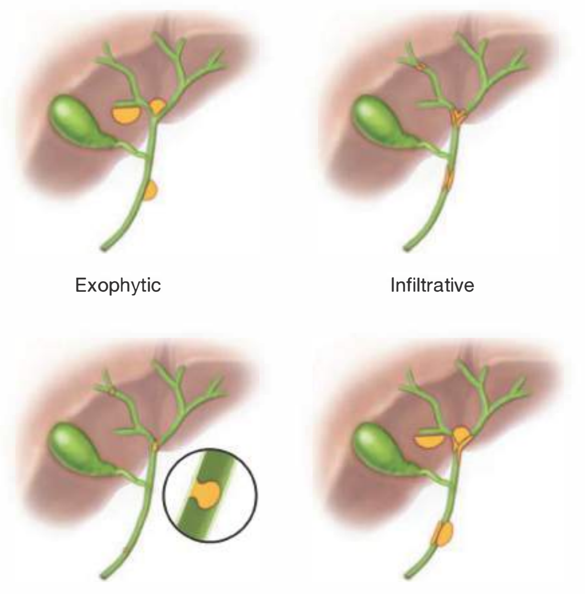

FIG 1 ● Various growth patterns of extrahepatic cholangiocarcinoma.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Successful hepatectomy must maintain an adequately healthy liver remnant. Initial assessment of the patient must not only focus on the malignancy itself but also on general liver function. Underlying liver dysfunction (due to chronic alcohol exposure, viral hepatitis, fatty liver disease, etc.) may alter operative planning and the minimum remnant required.
- History
  - Symptoms: jaundice, itching, unintentional weight loss, abdominal pain
  - Broader aspects of patient history: gallstones, cholangitis, primary sclerosing cholangitis, ulcerative colitis, previous surgery or trauma, viral hepatitis, cirrhosis, alcohol consumption, international travel, obesity, diabetes, hyperlipidemia, bruising, immune deficiency
- Physical exam
  - Jaundice or scleral icterus; muscle wasting may be present.
  - If disease occludes cystic duct, gallbladder may be palpable (Courvoisier's sign).
- Assess for stigmata of cirrhosis, portal vein thrombosis, or portal hypertension: ascites, encephalopathy, spider angiomata, skin telangiectasias, palmar erythema, bruising.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Transabdominal ultrasound
  - May identify duct dilation and large hilar tumors, but primarily functions as a screening tool
  - Doppler may identify narrowing or thrombosis of the hepatic artery or portal vein.
- Cross-sectional imaging: computed tomography and magnetic resonance
  - Good visualization of mass lesions and ductal dilation
  - Staging: may identify intraabdominal lymphadenopathy and/or metastases
  - Contrast enhancement allows assessment of vascular involvement and identification of anomalous hepatic inflow, which are critical to operative planning.
  - Signs of cirrhosis or portal hypertension may be present: irregular hepatic capsule, caudate hypertrophy, cavernous transformation, hypersplenism, ascites, recanalized umbilical vein.
- Cholangiography
  - Magnetic resonance cholangiopancreatography
    - Noninvasive; allows visualization and three-dimensional reconstruction of ductal anatomy
    - Does not provide opportunity to sample tissue
  - Endoscopic retrograde cholangiography
    - Allows visualization of ductal anatomy, provides opportunity for brushing or biopsy, and allows stenting in case of biliary obstruction
    - Invasive; risk of procedure-induced pancreatitis

- Cholangiography via percutaneous catheters
  - If percutaneous biliary drainage catheters have been placed, contrast can be used to delineate ductal anatomy and also allow brushings.
  - Ideally, such catheters are placed in the future remnant liver or bilaterally.
- Endoscopic ultrasound
  - Allows evaluation of the duct and regional lymph nodes, which may also be sampled with fine needle aspiration or core biopsy when available (19 gauge to 22 gauge)
  - Intraductal fiberoptic direct visualization (with biopsy) and intraductal ultrasonography are available at some centers.
- Positron emission tomography
  - Fluorodeoxyglucose (FDG) avidity is typically limited to mass lesions greater than 1 cm but provides poor quality for identifying cancers with infiltrative growth; hence, limited use beyond standard cross-sectional imaging for assessing primary tumor.
  - May identify occult metastatic disease
- Laboratory evaluation
  - Cholestasis may be indicated by elevated bilirubin, alkaline phosphatase, and gamma-glutamyltransferase levels.
  - Albumin and prothrombin time evaluate synthetic function.
  - Aspartate and alanine aminotransferase levels are often normal.
  - Low platelet levels may reflect hypersplenism due to portal hypertension.
  - Elevations in carbohydrate antigen 19-9 (CA 19-9) or carcinoembryonic antigen may be elevated in patients with HC.
    - CA 19-9 may be spuriously elevated in the setting of jaundice.
    - When workup reveals tumor marker elevation, these levels may be followed after resection to assess for disease recurrence.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients with jaundice should be drained either endoscopically or percutaneously to optimize liver remnant function.
- Operations for HC involve the dissection of critical structures, biliary and vascular reconstruction, and adaptation to intraoperative findings. Expertise in hepatobiliary anatomy and surgical technique is essential. In particular, familiarity with common patterns of anomalous ductal and arterial hilar anatomy (**FIG 2**) will prevent injury to unintended structures. Features of unresectability are shown in Table 1.
- When a diminutive liver remnant is anticipated, preoperative angioembolization of the contralateral (tumor-supplying) portal vein should be pursued in an attempt to hypertrophy the potential remnant.
- The Bismuth-Corlette classification is used to describe the extent of right and left duct involvement (**FIG 3**). Careful review of cholangiography and cross-sectional imaging will identify resectable patients and aid in operative planning.

Table 1: Liver-Specific Criteria for Unresectable Klatskin Tumors

Tumor extension to bilateral secondary branches of hilar structures
Portal vein
Hepatic artery
Bile duct
In patients with normal background liver
Future remnant liver <25%
Inability to preserve two adjacent segments
In cirrhotic patients
If resection is considered, preservation of a large remnant is essential to prevent postoperative liver failure.
These patients can be considered for transplantation in the context of an established multimodal treatment protocol or clinical trial.

- Right hepatectomy or trisectionectomy is generally indicated for types II and IIIa tumors.
- Left hepatectomy, and especially left trisectionectomy, is uncommonly performed and often carries a higher complication rate. This type of resection is usually reserved for type IIIb tumors, or those cases where the future left-sided remnant would be inadequate for type II tumors.
- Type IV tumors are unresectable unless a full sectoral branch is uninvolved and free of tumor.
- Type I HC may occasionally be amenable to local biliary resection alone; however, R0 rate and thus survival have been directly linked to the use of hepatic resection.[2]
- Apparent invasion of the portal vein or vena cava does not preclude resection. Large tumors can narrow adjacent vessels on imaging; however, this may be mass effect and not necessarily represent invasion.
- Contraindications to resection include distant metastatic disease and bilobar liver involvement.
- Although enthusiasm has grown for laparoscopic liver surgery, the dissection and reconstruction required for resection of HC currently requires laparotomy in most cases. However, a preliminary laparoscopy (performed immediately before planned resection) will identify occult disease in at least half of unresectable patients, who are then spared laparotomy.[3]
- Intraoperative ultrasound should be used liberally throughout the operation to assess extent of disease, location of ducts, and location/patency of vessels.

Positioning

- Supine position with arms perpendicular to body axis (**FIG 4**)
- Sterile skin preparation extends cranially beyond the nipple line, caudally to the groins, and laterally to the posterior axillary lines (particularly on the right side).
- If the need for portal vein reconstruction with autologous internal jugular vein is suspected, a sterile field is also prepared at the neck.
- If preoperative biliary catheters were placed, they are prepped into the field.
- Both groins are prepped if venovenous bypass is an anticipated strategy.

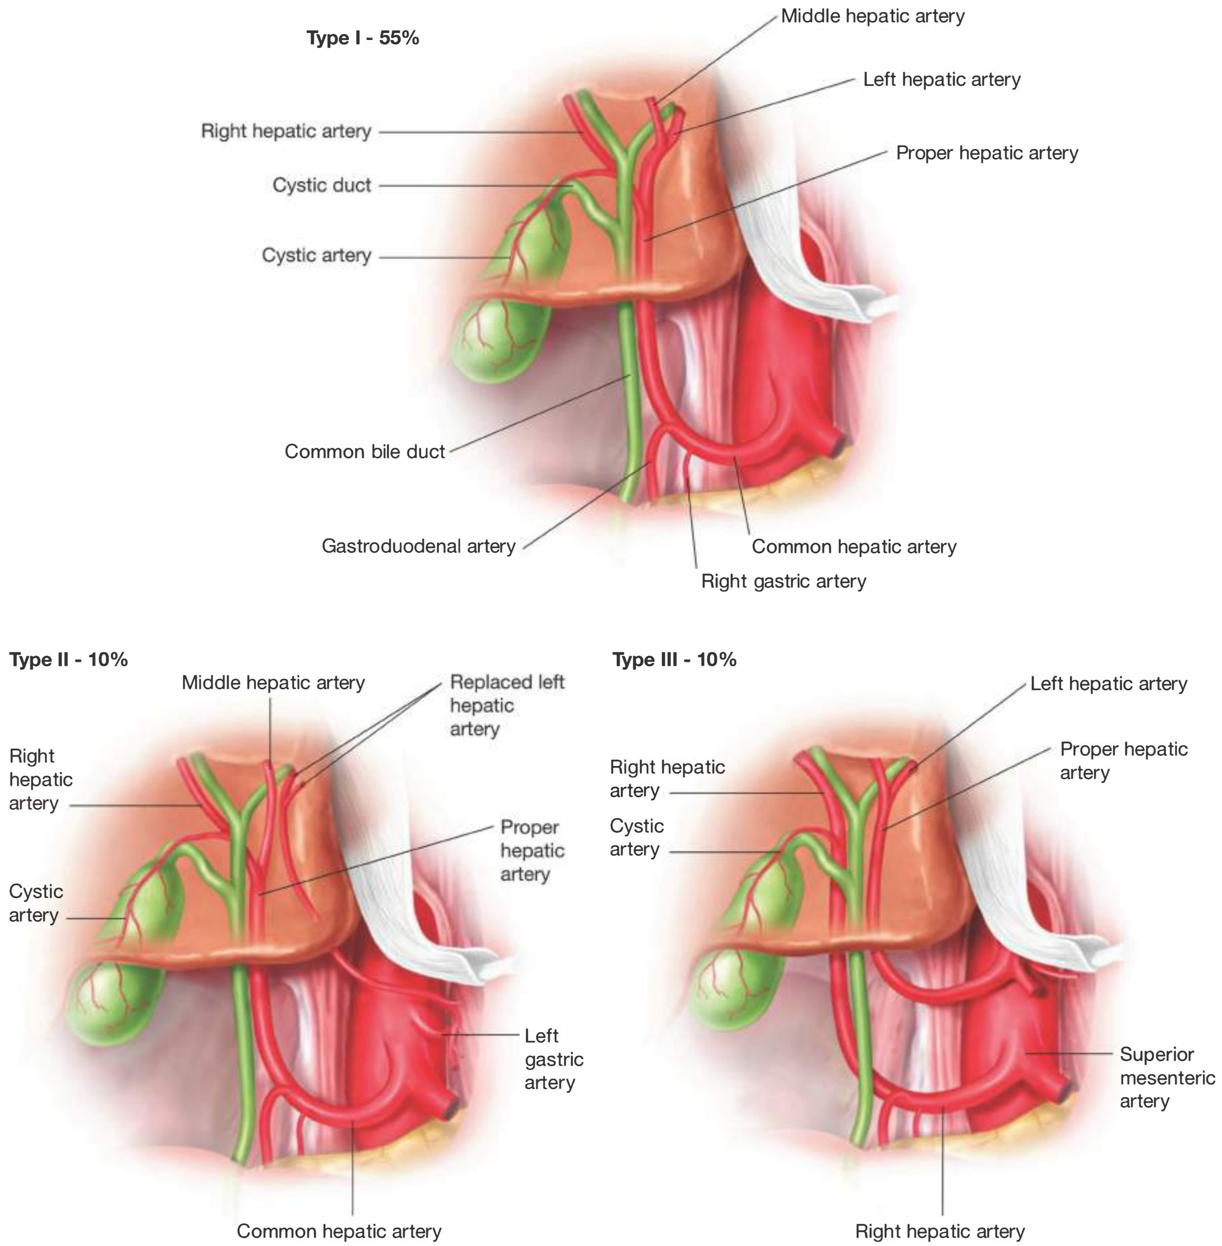

FIG 2 ● Common variations of hilar arterial anatomy. Although the usual course of the right hepatic artery is from the common hepatic artery and crossing laterally posterior to the bile duct confluence, a replaced (or accessory) right artery may originate from the superior mesenteric artery. A replaced (or accessory) left artery may be found in the gastrocolic ligament originating from the left gastric artery.

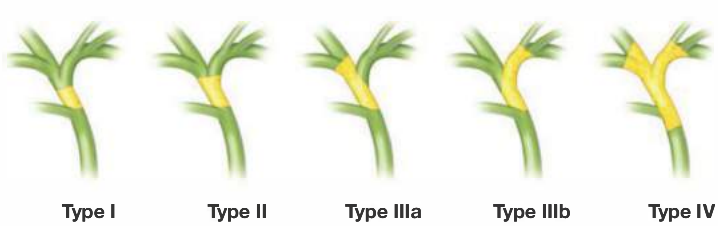

FIG 3 ● Bismuth-Corlette classification of Klatskin tumors.

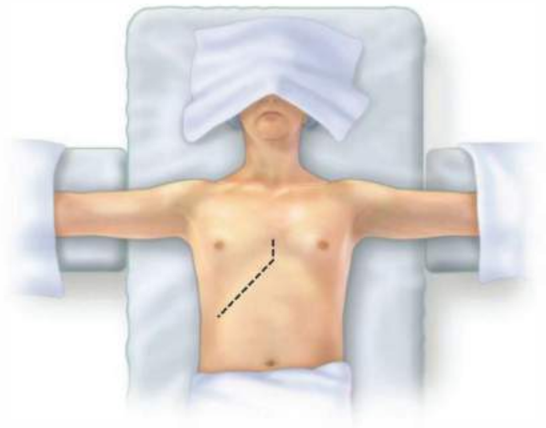

FIG 4 ● Proper positioning of the patient in the supine position with arms perpendicular to the body axis. The right subcostal incision with subxiphoid extension is also shown.

PRELIMINARY LAPAROSCOPY

- Using the Hasson method, a 10- to 12-mm periumbilical port is placed. A 10-mm 30-degree laparoscope is used to inspect the abdomen for evidence of metastases: peritoneal cavity, liver surface, porta hepatis, gastrohepatic ligament.
- If necessary, an additional 5-mm port is placed under direct visualization in the subxiphoid midline (to be included in the potential laparotomy incision).
- Potential metastases should be biopsied for immediate pathologic analysis.
- If distant metastatic disease or bilobar liver disease is noted, the operation is terminated.
- If there are no signs of unresectability, proceed to laparotomy.

LAPAROTOMY

Incision and Abdominal Inspection

- The abdomen is entered with a right subcostal incision with subxiphoid extension (FIG 4).
- The ligamentum teres hepatis (round ligament) is divided and falciform ligament taken down from the anterior abdominal wall.
- The abdomen is inspected thoroughly to confirm absence of distant disease. The liver is inspected with bimanual palpation and intraoperative ultrasonography.
- Along with control of the hilar vessels, circumferential control of the supra- and infrahepatic vena cava with a tape can be used selectively, which allows for nearly complete vascular control of the liver should venovenous bypass be necessary.

Paraaortic Node Assessment and Biliary Dissection

- The omentum is freed from the transverse colon, allowing access to the omental bursa.
- The hepatic flexure of the colon is mobilized and rotated medially until the duodenum and vena cava are identified.
- A Kocher maneuver is performed, retracting the duodenum to the left until the aortocaval groove is exposed.
- Firm or enlarged paraaortic nodes are sampled for immediate pathologic examination.
  - If nodes are grossly positive, the operation is terminated.
  - If nodes show microscopic disease, all exposed paraaortic fibrofatty and nodal tissue is resected.
  - If nodes are negative, no further paraaortic dissection.
- The gallbladder is dissected from the liver and left attached to the specimen via the cystic duct.
- Segment 4b is lifted to expose the hilar plate. Connective tissue investing the bile duct, hepatic artery, and portal vein in this area is additionally covered by a tissue confluence from Glisson's capsule on the liver surface. Fine scissor dissection here will expose hilar structures and clear fascial and lymphatic tissue from the field (FIG 5). A "no-touch" approach is recommended for handling the tumor and hilar vessels. Instead, manual manipulation should target periadventitial and other noncritical connective tissues.
  - The hepatic artery is identified proximally. Its bifurcation typically is caudal to the bile duct and portal vein confluences. The right hepatic artery most often courses posterior to the proximal common bile duct. Careful examination of high-quality cross-sectional imaging should allow the surgeon to anticipate the course of the artery and protect it.
  - Replaced or accessory arteries may originate from the left gastric artery through the gastrohepatic ligament (lesser omentum) on the left or from the superior mesenteric artery posterior to the common bile duct on the right.
  - Although the middle hepatic artery most often arises from the left hepatic artery and crosses anterior to the left duct, its origin and orientation are highly variable.

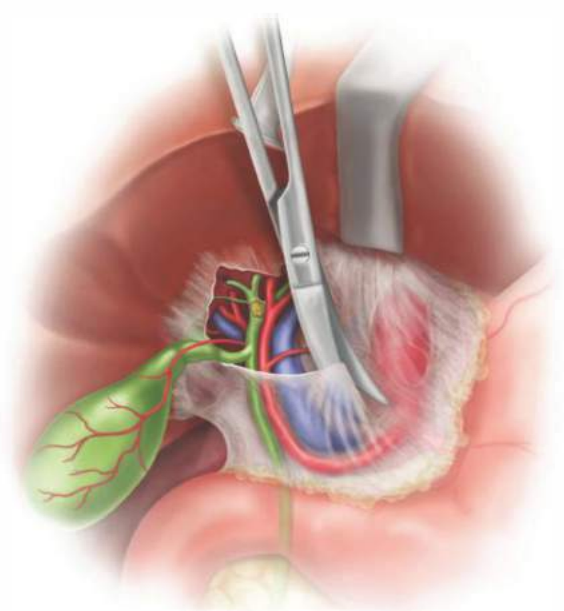

FIG 5 ● Dissection of the hilar plate begins with proximal identification of the bile duct and hepatic artery, which lie anterior to the portal vein. The gallbladder has been removed from the base of the liver and is used for retraction. A no-touch technique should be observed when dissecting near the tumor.

- The proximal extent of tumor is determined by caudal retraction of the bile duct and gallbladder. This step is critical as it will determine whether right or left hepatectomy is undertaken. Some liver parenchyma may need to be transected to adequately assess either duct. Dividing connective tissue between the base of segment 4 and the bile duct confluence (tumor) will often facilitate lowering the hilar plate.
  - To adequately inspect the left hepatic duct, the narrow bridge of liver parenchyma under the umbilical fissure can be divided. The left duct has a longer extrahepatic course and lies perpendicular to the common duct before entering the liver parenchyma at the base of the umbilical fissure. The length of the extrahepatic portion of the left duct is the primary reason that a right liver resection is most often performed in pursuit of an R0 resection.
  - The extrahepatic right hepatic duct is typically shorter and rapidly ascends laterally into the parenchyma. In nearly one-fourth of patients, a right segmental duct will cross Cantlie's line to join the main left hepatic duct. Due to its short length and orientation, the right duct is prone to inadvertent injury. Intraoperative cholangiogram serves as a valuable tool to clarify the anatomy.
  - If gross disease extends to all four hepatic sectional ducts, the tumor is unresectable and further operative exploration is not warranted.
- The right gastric artery is ligated and divided at its origin from the common hepatic artery.
- The posterior superior pancreaticoduodenal artery (PSPD) crosses the common bile duct near the superior aspect of the pancreatic head. The common bile duct will be ligated and transected in this area:
  - If no tumor involvement nearby, the PSPD may be left in situ.
  - If adherent to tumor, the PSPD should be ligated and resected en bloc with tumor specimen.
  - If tumor extends into pancreatic head but the PSPD is not involved, then the PSPD is divided and retracted to allow dissection of tumor inferiorly into pancreatic parenchyma. In rare cases of HC, a pancreaticoduodenectomy may be necessary for margin-negative resection.
- The distal common bile duct is transected just above the pancreas and a distal margin sent for immediate pathologic assessment.
  - The distal peripancreatic stump is oversewn with running 5-0 Prolene.
  - If biliary drainage catheters are in place, they are retracted into the hepatic parenchyma, allowing for the proximal duct to be tied off and retracted superiorly.
- Caudate resection is recommended.[4,5] Exploration commences by exposing the inferior vena cava (IVC) posterior to the liver. The most inferior hepatic veins are ligated and divided to allow posterior exposure of the caudate.
  - Veins less than 5 mm in diameter can be divided with standard suture ligation or clips.
  - Commonly, there will be at least one vein greater than 5 mm in diameter behind the caudate. Such veins should be controlled with a Satinsky clamp on the vena cava, tie ligated at the caudate aspect, divided, and the caval stump oversewn with running 5-0 Prolene suture (**FIG 6**).
  - Figure-of-eight stay sutures placed in the caudate are a useful means of retracting the caudate off the vena cava (**FIG 7**).
  - The left aspect of the hepatocaval ligament may have to be divided to allow visualization.
- Portal vein involvement is assessed by retracting the bile duct anterior and cranial.

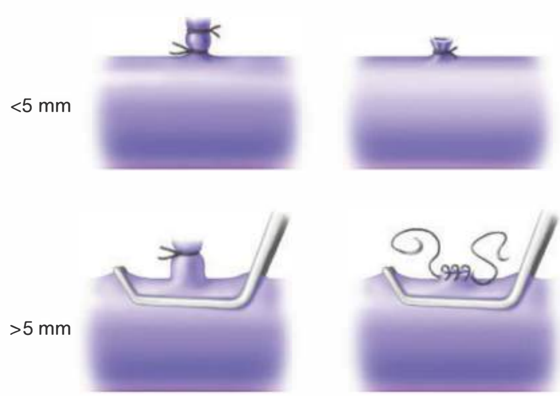

FIG 6 ● Technique of dividing short hepatic veins from segment 1, 4, 5, or 8.

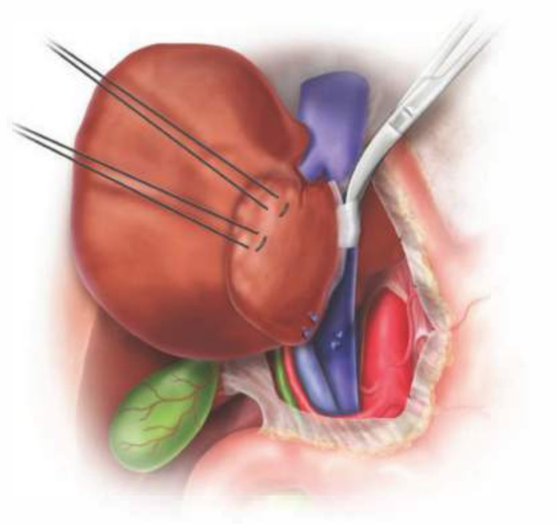

FIG 7 ● To assist with caudate retraction, figure-of-eight stay sutures can be placed in the caudate parenchyma and gently retracted.

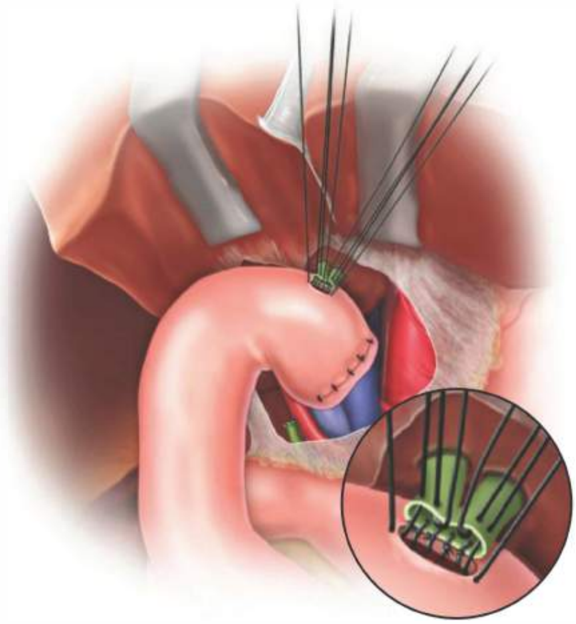

FIG 8 ● Hepaticojejunostomy.

- Caudate preservation is only possible if sufficient biliary outflow can be spared. Although variability exists, the caudate will typically have at least two ducts, which most often drain to the main left duct, the main right duct, or the right posterior sectional branch.
- If caudate resection is performed, then small portal vein branches (posterior aspect of both right and left main portal veins) must be ligated and divided.
- Caudate mobilization is assisted by approaching from both the right side and left side of the vena cava.

Hepatectomy

- As previously described, the choice of hepatectomy is directly related to the extent of ductal, portal venous, and hepatic arterial involvement.
  - Right hepatectomy is described in Part 3, Chapter 23.
  - Left hepatectomy is described in Part 3, Chapter 25.
  - Right trisegmentectomy is described in Part 3, Chapter 30.
  - Left trisegmentectomy is described in Part 3, Chapter 31.
- Portal vein considerations are unique during hepatectomy for HC, however, and described here.
- En bloc hepatic arterial resection and reconstruction is rarely needed, as this extent of tumor is generally deemed unresectable.

Biliary Resection and Reconstruction

- The duct is cut sharply without cautery artifact. Periductal bleeding is controlled with digital pressure.
- Frozen section pathologic analysis guides the extent of biliary resection into the remnant liver. Stay sutures (5-0 Prolene) in the duct allow further retraction and dissection if a more proximal margin is necessary.
- A Roux-en-Y jejunal limb is brought through the colonic mesentery to the right of the middle colonic vessels (retrocolic), with sufficient mobilization to allow for tension-free hepaticojejunostomy.
- An enterotomy is created on the antimesenteric border of the Roux limb, size-matched to the target hepatic duct. When practical, multiple adjacent ductal branches can be incorporated en masse to the anastomosis (**FIG 8**).
- Interrupted, double-armed 5-0 Prolene sutures are initially placed in the anterior wall of the duct and gently retracted with shods to facilitate exposure.
- Anastomosis begins along the posterior wall, where a single layer of 5-0 Prolene sutures incorporate the full-thickness wall of both duct and Roux limb. Knots are tied once all posterior sutures are successfully placed.
- If already present, percutaneous transhepatic stents are advanced and left in place across the bilioenteric anastomosis.
- As an alternative, a 4- to 6-Fr transanastomotic tube can be placed through the antimesenteric wall of the Roux limb with the Witzel technique, placed proximally into the remnant biliary tree, brought out through the abdominal wall, and connected to a drainage bag. This allows access to the biliary tree without placing retrograde biliary catheters through the liver (**FIG 9**).
- The previously shod-retracted anterior ductal 5-0 Prolene sutures are incorporated into the bowel wall and tied to complete the anastomosis.
- The final hilar margin should be marked with clips (or gold fiducial markers) to guide subsequent needs for external beam radiation.
- Closed suction drains are placed adjacent to the bilioenteric anastomosis and under the right diaphragm before abdominal closure.

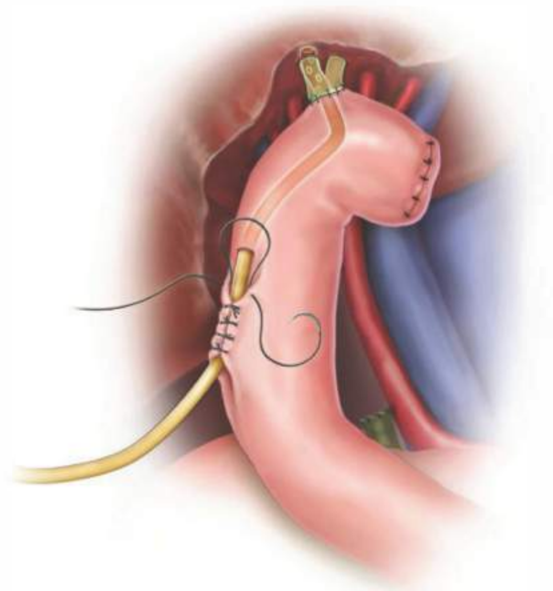

FIG 9 ● Alternative placement of transanastomotic tube.

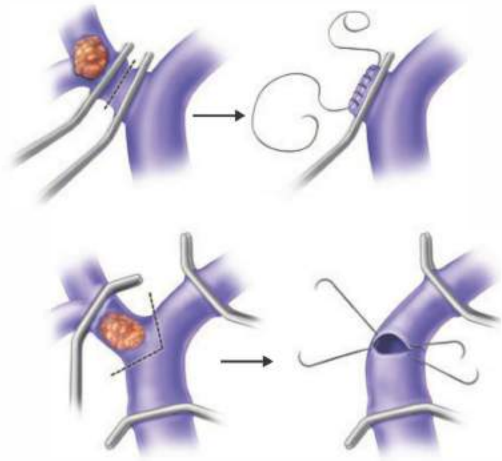

FIG 10 ● Various approaches to portal vein resection. When complete tumor resection encroaches on the portal vein confluence, closure should be performed in a transverse fashion, as longitudinal suture lines may cause stenosis of the remaining vessel.

Division of Portal Vein

- If the portal vein is free of tumor, then the portal vein is divided in standard fashion as for routine hepatectomy.
- If the right or left portal vein transection plane encroaches into the confluence due to tumor involvement (**FIG 10**)
  - Clamp the main and contralateral portal vein branch separately and transect the vein as necessary to achieve tumor-free margins.
  - Close the portal defect in a transverse orientation with running 6-0 Prolene. Longitudinal closure results in unnecessary narrowing and skewing of the remaining portal vein.
- If tumor involves the portal confluence, vein resection and reconstruction is performed later in the operation (after liver parenchyma has been fully transected and left hepatic duct dissected).
- Portal vein resections of up to 3 cm can be repaired primarily.
  - Clamp the main and contralateral portal vein, and excise the portal vein en bloc with tumor. Heparin is administered systemically prior to clamping the main portal vein and is reversed at the completion of the operation.
  - After ensuring proper mobilization of remaining vein, running 6-0 Prolene suture is used to approximate ends.
- Portal vein resections greater than 3 cm in length typically require interposition autograft (the authors prefer either left renal vein or internal jugular vein).

PEARLS AND PITFALLS

Indications	■ Multidetector cross-sectional imaging should accurately stage most patients and will often reveal anomalous hilar vascular anatomy. Careful preoperative review of these images is essential.
Skeletonizing the hepatoduodenal ligament	■ Observe a no-touch technique when mobilizing the tumor, ducts, and arteries. ■ Grasping adjacent connective tissue (such as periadventitium or neural plexus) will avoid iatrogenic injury and tumor capsule violation.
Variable anatomy	■ Complexity of ductal and vascular dissection increases with the presence of tumor bulk and infiltration in the hilum. ■ Review of imaging and knowledge of common anatomic variants will expedite a safe operation.
Caudate resection	■ Should be routinely performed and can be approached from either side ■ The caudate and right posterior section should be divided by parenchymal transection toward the right caval edge.

POSTOPERATIVE CARE

- Standard thromboprophylaxis should be given immediately.
- Early ambulation and pulmonary toilet are mandatory.
- Early ultrasound is a vital tool for any suspected insult to the remnant liver.
- High-volume ascites may signify postoperative hepatic failure and is an early sign of portal thrombosis.
- Bilious drain output may indicate a disconnected biliary duct in the remnant or an anastomotic leak. This should be evaluated with cholangiogram and cross-sectional imaging.
- Closed suction drains are typically removed after biliary tree catheters are clamped, provided there is no substantial bile leak or ascites. This typically occurs prior to discharge.

OUTCOMES

- After curative intent resection for HC, 5-year survival is 25% to 30%.[6]
- Rate of R0 resection is typically 64% to 71%.
- Postoperative morbidity and mortality rates range up to 50% and 10%, respectively.
- Bile leaks may occur in up to 20% of resected patients.
- Left liver resection (particularly left trisectionectomy) is associated with greater morbidity and a higher rate of positive margins.

COMPLICATIONS

- Bile leak
- Bilioenteric anastomotic stricture
- Torsion of liver remnant
- Thrombosis of portal vein, hepatic vein, hepatic artery, or vena cava
- Cholangitis or abscess
- Liver failure

Chapter 12

Intrahepatic Biliary-Enteric Anastomosis

Reid B. Adams Victor Zaydfudim

DEFINITION

- Intrahepatic biliary-enteric anastomosis is defined as biliary reconstruction at the level of the hepatic hilum (biliary confluence) or more proximal bile ducts.
- Intrahepatic biliary-enteric anastomoses are indicated for definitive treatment of hilar biliary strictures; rarely, they may be indicated for palliation of malignant hilar obstruction.

DIFFERENTIAL DIAGNOSIS

- Biliary strictures at the hepatic hilum can be due to benign or malignant processes. Common malignant etiologies include hilar cholangiocarcinoma and gallbladder carcinoma; benign strictures typically are a result of prior biliary tract surgery or intervention.
- Uncommon benign etiologies include inflammatory or autoimmune diseases such as primary sclerosing cholangitis or IgG4 immune-mediated sclerosis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most common presentation is jaundice. Associated symptoms may include pruritus, cholangitis, or less commonly, pain. If the patient has had biliary surgery, they may present with an acute abdomen or sepsis due to a biloma or biliary fistula.
- In the absence of prior biliary surgery, stone disease should be suspected.
- If a history of prior biliary surgery or instrumentation is present, a benign stricture should be suspected. Postoperative strictures present within the first 6 months in approximately 70% of patients. However, benign strictures can present years after biliary surgery.
- In the absence of stone disease and prior biliary surgery, a malignant stricture should be suspected.
- A complete history and physical examination is required to ensure the patient does not have evidence of infection or symptoms suggestive of metastatic disease. This assessment also should assess whether the patient is a candidate for major surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A fundamental knowledge of biliary anatomy and the adjacent vascular structures is critical for success, both in deciding whether operative intervention is indicated, and if so, the type of procedure and an approach to ensure it is safe and effective. Biliary anomalies are frequent and should be expected; imaging studies should clearly define these structures and their relationship to each other. Hepatic vasculobiliary anatomic details are reviewed in Part 3, Chapter 15, Surgical Anatomy.
- The aim of the diagnostic evaluation is to define the anatomy for restoration of biliary-enteric continuity in patients with benign strictures or plan appropriate palliative care in patients with malignant disease not amenable to curative resection. Magnetic resonance cholangiopancreatography (MRCP) is the initial diagnostic study of choice in patients with obstructive jaundice thought to be due to stone disease. Otherwise, magnetic resonance imaging (MRI) with intravenous contrast and MRCP is the initial study of choice for patients with obstructive jaundice due to a stricture (**FIG 1**). Ideally, it should be performed prior to any biliary interventions such as endoscopic retrograde cholangiography (ERC) or percutaneous transhepatic cholangiography (PTC). However, most patients come for referral with prior invasive studies or biliary stents in place; these can make image interpretation challenging and/or lead to cholangitis in obstructed segments.
- MRI/MRCP gives a detailed view of the biliary tract and the level or type of obstruction when a stricture is the cause (**FIG 2**). The vascular phases allow assessment of hepatic artery and portal vein involvement in the case of malignant processes and whether the hepatic arteries are intact and patent in cases of benign strictures related to prior biliary surgery. Finally, it allows for the assessment of direct hepatic involvement or metastatic disease.
- When contrast for MRI cannot be given or the vascular anatomy is not adequately assessed, B-mode and Doppler ultrasonography (US) is highly accurate in assessing vascular patency and/or involvement.[1,2] It is important to note whether lobar atrophy is present, as this dictates treatment options.
- ERC and PTC are supplementary techniques for defining the anatomy of the biliary tract and the extent of a stricture

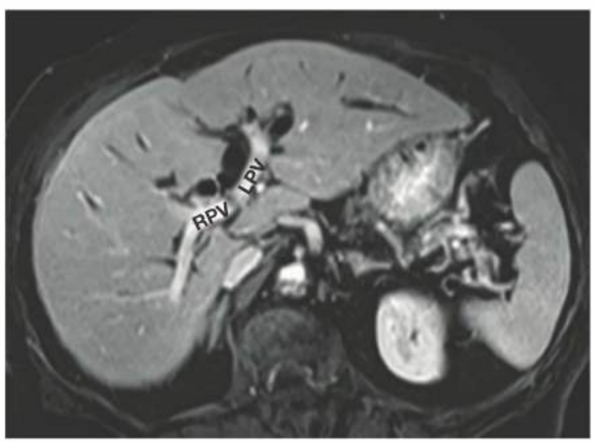

FIG 1 • MRI during the portal venous phase showing the right portal vein *(RPV)* and left portal vein *(LPV)*. The dilated left hepatic duct (LHD) lies anterior and superior to the LPV.

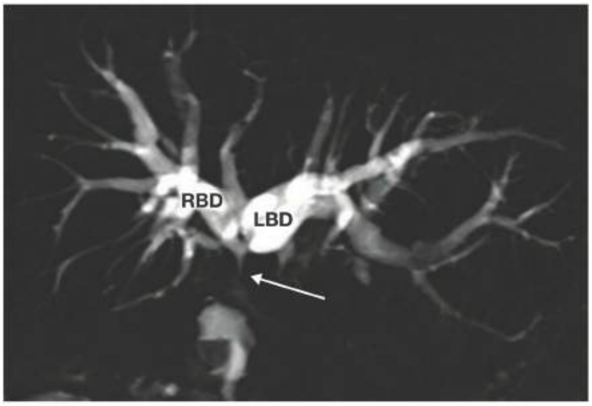

FIG 2 ● This MRCP shows a dilated right biliary duct *(RBD)* and left biliary duct *(LBD)*, leading to a type II hilar stricture at the proximal most common hepatic duct *(white arrow)*.

when these are not clear from the MRCP. Either or both may be used to obtain a tissue diagnosis in unresectable patients or for stent placement to treat symptoms and/or for preoperative preparation. There is considerable debate as to which technique is optimal for treating hilar biliary strictures and this discussion is beyond the scope of this chapter.

- To effectively relieve jaundice, approximately 30% of the functioning liver volume must be drained.[3] The functioning and proposed drained volumes can be estimated using calculated liver volumes from preoperative cross-sectional imaging (computed tomography [CT] or MRI).[4] Conversely, drainage of an atrophied hepatic lobe or segment is not effective.

SURGICAL MANAGEMENT

- Issues associated with repair of benign strictures are discussed separately from malignant strictures.
- Intrahepatic biliary-enteric anastomoses are complex procedures that require experienced, multidisciplinary, hepatobiliary team care. If this is not available at your institution, the patient should be referred to an appropriate institution for definitive repair.
- All procedures are done with 2.5× magnification using loupes. This allows for meticulous surgical technique and allows precise dissection and reconstruction.
- It is important to establish a standardize approach for biliary-enteric anastomoses. Use this each time and the high intrahepatic anastomosis will be easier to perform.

Preoperative Planning

Benign Stricture

- The goal for benign strictures is definitive restoration of biliary-enteric continuity. The type of stricture will dictate the nature of the biliary-enteric anastomosis (**FIG 3**).[5] Types E1 to E3 strictures are amenable to a Hepp-Couinaud approach.[6] E4 and E5 strictures require a modified Hepp-Couinaud approach and generally two separate anastomoses to reconstruct the right and left ducts separately.[7]
- Prior to undertaking surgery, sepsis and biliary fistulae must be resolved and all the biliary segments drained. Biliary drainage usually requires a PTC for hilar (high) strictures or injuries.
- In the clinical setting of sepsis, operative repair should not be undertaken until a minimum of 6 to 12 weeks have passed. This waiting period allows for resolution of active inflammation and evolution of any ischemic injury. Both of these are critical issues, as repair prior to resolution of these processes will decrease the success of the repair.
- Prior to operative repair, each isolated segment of the biliary system ideally should have a PTC placed. Just prior to surgical repair, the PTC drain(s) is exchanged such that the tip is guided into the distal most part of the intubated duct(s) to intraoperatively facilitate localization.

Malignant Stricture

- For this group, the preoperative evaluation focuses on whether the patient is a candidate for potentially curative resection. If so, they are approached as outlined in Part 3, Chapter 11.
- With unresectable disease, current percutaneous and endoscopic techniques (drainage with plastic or expandable metallic stents and intraductal photodynamic therapy or radiofrequency ablation) provide excellent palliation; thus, there is little to no role for a planned palliative intrahepatic biliary-enteric bypass.
- Consequently, intrahepatic biliary-enteric anastomosis generally is reserved for patients with biliary obstruction found to be unresectable at the time of exploration and who are expected to survive more than 6 months. Otherwise, the morbidity and mortality associated with bypass is not justified. For instance, patients with unresectable gallbladder carcinoma have a median survival of 20 weeks. Thus, stenting is a better choice for palliation. On the other hand, the median survival for unresectable hilar cholangiocarcinoma is 52 weeks and a bypass may be reasonable under these circumstances.[8] Even this circumstance is questionable, as there appears to be no survival advantage between surgical and

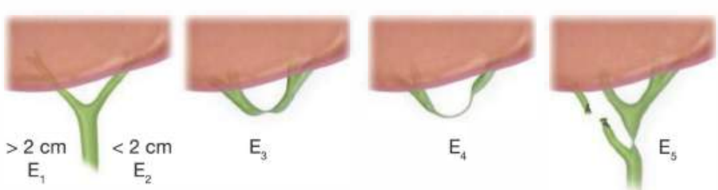

FIG 3 ● Strasberg classification of biliary strictures.

nonsurgical drainage approaches and the morbidity and mortality for surgical approaches are significant in comparison.[9]

- Other intrahepatic biliary-enteric anastomotic approaches are not included in this discussion as they are primarily of historical interest. These include the Longmire approach, mucosal graft operation, and right duct approaches. Current alternatives provide better palliation with lower risks.
- This discussion, therefore, is limited to the segment 3 bypass (round ligament or ligamentum teres approach) as the primary practical option for these patients. Although a right sectorial duct bypass can be done, the circumstances where it might be applicable are quite limited and the results relatively poor.[8] As such, it has little practical value and the best palliation for these patients is stenting and possibly tumor ablation to prevent liver failure and cholangitis.
- Patients eligible for a segment 3 bypass are limited to those with unresectable Bismuth types I, II, or IIIa strictures without atrophy of the left hepatic lobe; to be effective, at least 30% of the functioning liver volume must be drained. Types IIIb and IV lesions are not effectively drained by a segment 3 approach. Importantly, there is no role for this bypass if the right ductal system has been contaminated by prior right duct intubation, as these patients will require continued right duct drainage to prevent cholangitis.

FIG 4 ● Operative positioning is supine with arms extended. Position the percutaneous transhepatic catheters *(black arrows)*, leaving them intact during the procedure. Sterilely prep those portions left in the field and cover them with an adherent drape.

Positioning

- The patient is placed in the supine position with both arms extended (**FIG 4**).
- The percutaneous drains are aseptically prepped but positioned out of the field as much as possible (i.e., under additional sterile draping) and ideally left to drain. The catheters will need freedom of movement from within the abdominal cavity during the procedure, thus, extreme care must be taken to ensure that this is feasible without undue risk of inadvertent dislodgement of the drains.

HILAR HEPATICOJEJUNOSTOMY (HEPP-COUINAUD APPROACH)

Preparation

- This approach takes advantage of the extrahepatic course of the left hepatic duct as it runs along the base of segment 4 for approximately 2 to 3 cm from the biliary confluence to the umbilical fissure (**FIG 5**). It is the anterior–superior most structure in the hilum, and this position facilitates its exposure and the anastomosis while minimizing injury to the portal vein and hepatic artery (**FIGS 6** and **7**).

Incision

- A right subcostal incision allows access to the hepatic hilum. Often, a midline extension facilitates full exposure (**FIG 8**).

Exposure

- Identify, doubly clamp, and divide the falciform ligament. Ligate each end and leave a long tie on the superior side to use as a handle. Divide the falciform ligament superiorly to the superior edge (diaphragm) of the liver. When the patient has extensive adhesions, the ligamentum teres is an invaluable guide to locating

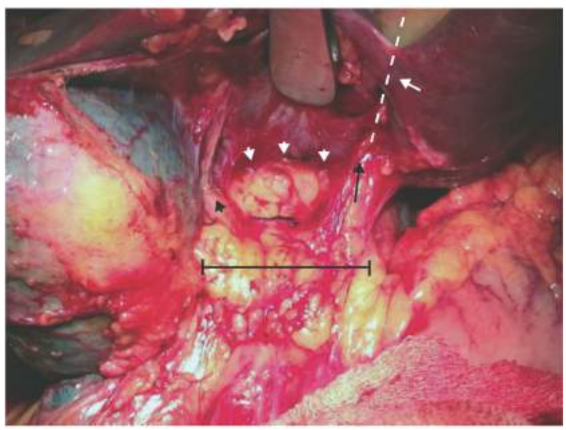

FIG 5 ● The left hepatic duct runs in the hilar plate. Find it just posterior to the base of segment 4 *(white arrowheads)* at its junction with the hepatoduodenal ligament *(black line)*. The base of the gallbladder fossa is shown *(black arrowhead)* as well as the base of the umbilical fissure *(black arrow)*. The left hepatic duct runs approximately 1 to 2 cm to the patient's left of the base of the gallbladder fossa to the base of the umbilical fissure. The umbilical fissure *(dotted white line)* runs between segment 4 and the segments 2 and 3 of the left lobe. A bridge of liver tissue *(white arrow)* between segment 4 and segment 3 frequently covers a portion of the umbilical fissure.

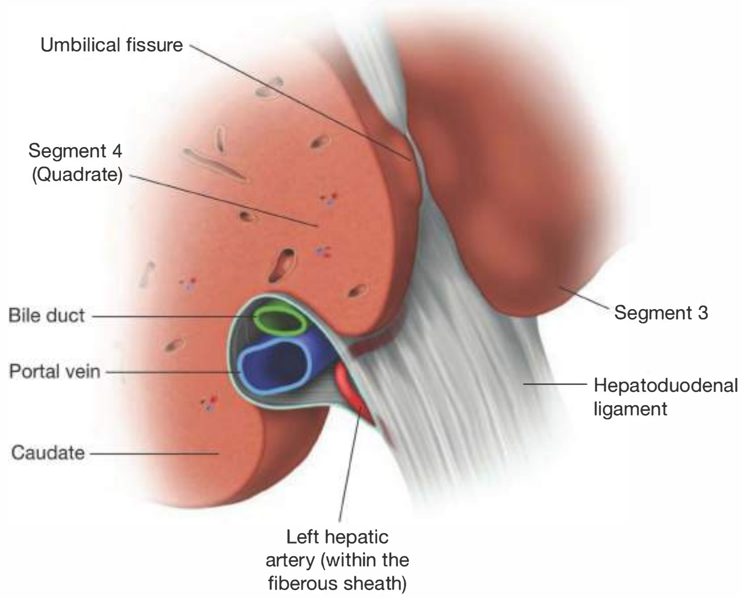

FIG 6 ● This oblique sagittal section shows the relationship of the left hepatic duct and portal vein in the hilar plate (superior most portion of the hepatoduodenal ligament) and the plate's relationship to segment 4 (quadrate lobe). The base of segment 4 covers the anterior–superior most portion of the hilar plate. At this location, the left hepatic duct lies anterior–superior to the left portal vein. The left hepatic artery usually is not present at this site as it runs along the left lateral edge of the hepatoduodenal ligament and joins these structures at the base of the umbilical fissure. As segment 4 lies over the anterior hilar plate, this necessitates incising Glisson's capsule at this site to push segment 4 superiorly and anteriorly, thereby exposing the hilar plate and the left hepatic duct.

the umbilical fissure. During dissection, follow it posteriorly to locate the umbilical fissure; this assists in identifying the anterior surface of the hepatoduodenal ligament.

- Take down adhesions to the inferior surface of the liver and the anterior surface of the hepatoduodenal ligament to expose the gallbladder fossa and the base of segment 4 (**FIG 9**). It is easiest to work from the right edge of the liver back toward the hilum when taking down adhesions. There often is a free space at the right edge of the liver that allows access posteriorly around the lateral edge of the adhesions.
- Place a clamp behind the usually present liver bridge joining segments 4 and 2 or 3, and divide it with electrocautery. This exposes the umbilical fissure and facilitates exposure of the left hepatic duct (**FIG 10**).
- Carry the dissection to the base (posterior aspect) of segment 4 and its junction with the hepatoduodenal ligament (**FIG 5**). Retract the base of segment 4 superiorly and anteriorly with a malleable retractor if necessary for exposure.

FIG 7 ● Coronal MRI showing the relationship between the left hepatic duct *(bent white line)* and the left portal vein *(asterisk)*. The duct lies anterior–superior to the left portal vein at the base of segment 4. The left hepatic artery *(white arrowhead)* runs along the left side of the hepatoduodenal ligament and joins the duct and vein at the base of the umbilical fissure *(black arrow)*.

FIG 8 ● A right subcostal incision *(solid line)* often allows sufficient exposure to the hepatic hilum. If not, a midline extension to the xiphoid facilitates access to the hilum and superior liver. The right subcostal incision typically is two fingerbreadths (~4 cm) below the right costal margin *(white arrows/dotted line)*. This image shows the two PTC tubes secured off the field except at the level of the xiphoid process (solid "V").

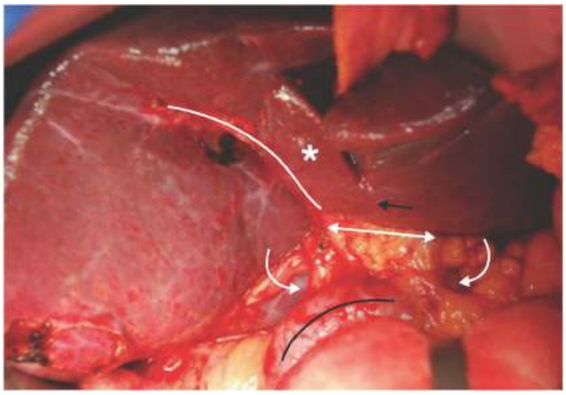

FIG 9 ● Incise adhesions to expose the inferior surface of the liver and anterior surface of the hepatoduodenal ligament *(white double-headed arrow)*. This exposes the gallbladder fossa *(curved white line)*. The base of segment 4 is not apparent in this image, as an exophytic lobe of segment 4 *(asterisk)* covers it. The bridge of liver tissue connecting segment 4 with segment 3 *(black arrow)* limits access to the base of segment 4. The foramen of Winslow (*curved arrow*, patient's right) allows access posterior to the hepatoduodenal ligament. Opening the gastrohepatic ligament to the left of the hepatoduodenal ligament (*curved arrow*, patient's left) connects with the space posterior to the ligament and superior to the duodenum *(curved black line)*.

- Caution is warranted if the patient has right hepatic lobe atrophy and left lobe hypertrophy. The hepatoduodenal ligament anatomy often is distorted with the bile duct complex and hepatic arteries rotated to the right and posteriorly. Consequently, the main portal vein often is the anterior-most structure in the ligament in this situation.

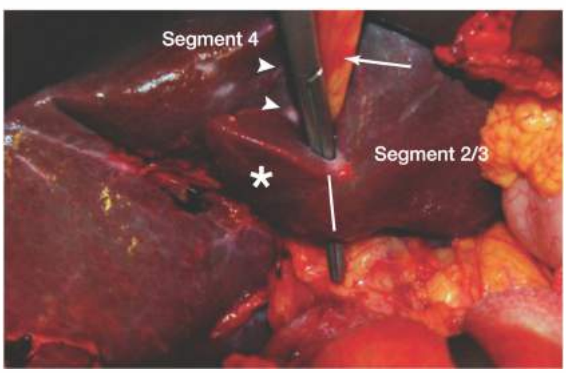

FIG 10 ● To open the bridge of liver connecting segment 4 and segment 2 or 3 *(white line)*, place a clamp between it and the ligamentum teres *(white arrow)*. This can be divided with electrocautery because there are rarely vessels of any size within this structure. This opens the umbilical fissure exposing portal structures for segment 4 *(white arrowheads)*. This patient has an exophytic portion of segment 4 *(asterisk)*. A small portal pedicle connected this exophytic lobe. It was divided and the lobe removed to facilitate exposure to the base of segment 4.

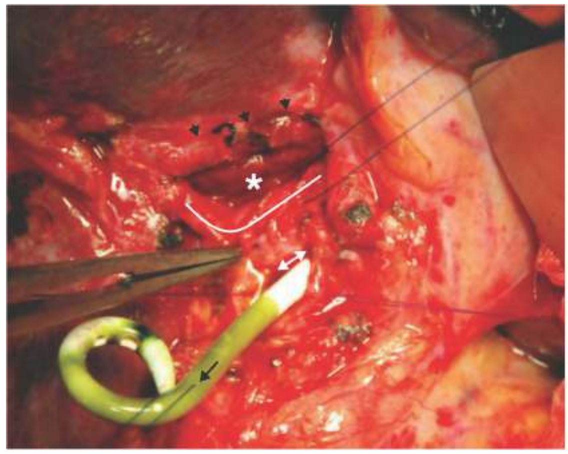

FIG 11 ● At its junction with the hepatoduodenal ligament, incise Glisson's capsule *(black arrowheads)* to expose the hepatic parenchyma *(asterisk)* superior to the hilar plate *(curved white line)*. The anterior surface of the left hepatic duct *(white double-headed arrow)* is incised longitudinally, exposing the PTC tube within the duct. Pull the PTC from within the duct and place a nylon suture through the straight portion of the tube *(black arrow)* to manipulate the tube during the procedure.

Lower the Hilar Plate

- Incise Glisson's capsule at its junction with the hepatoduodenal ligament at the base of segment 4. This leads to entry into the hepatic parenchyma adjacent to the hilar plate (**FIG 11**). Venous bleeding will occur; it is easily controlled with pressure. Once the base of segment 4 is released, it is retracted further superiorly and anteriorly, exposing the hilar plate and providing access to the left hepatic duct (**FIG 11**). This is the Hepp-Couinaud approach or "lowering the hilar plate" to expose the left and right hepatic ducts.[6]

Locate the Left Hepatic Duct

- Palpate the stent in the left duct to locate it within the fibrous sheath of the hepatic plate. Intraoperative ultrasound can help locate the stent within the duct. Likewise, aspiration of bile using a 25-gauge needle and syringe can assist in locating the duct and verifying its position.

Incise the Hepatic Ducts

- Once located, make a longitudinal incision in the anterior surface of the duct until the lumen is entered (**FIG 11**). The lumen will be evident from the stent within it. The stent serves as a guide, delineating the lumen and course of the duct. Use a blunt probe to explore the left and right hepatic ducts and identify the confluence of the two.
- Grasp the stent and pull it out of the duct. Place a monofilament suture through the straight portion of the stent above the curved end (**FIG 11**). Cut the stent just distal to the suture, thus removing the self-retaining end of the stent. The suture through the stent serves as a "handle" to move the stent in and out of the opened duct. Allow

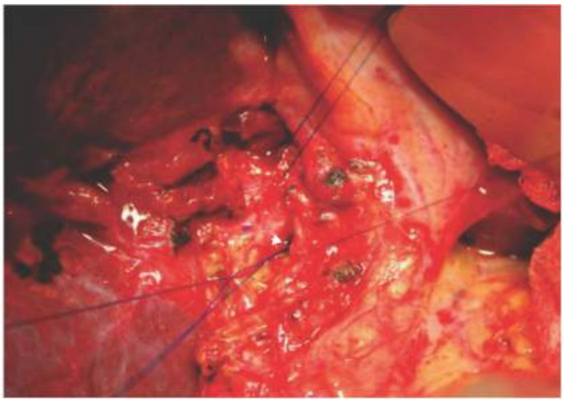

FIG 12 ● Cut the PTC tube distal to the nylon suture, allowing it to retract above the site of the anastomosis. The left duct orifice is shown *(white arrowhead)*.

it to retract above the distal left duct (**FIG 12**). Removing the distal end of the stent facilitates probing and opening of the duct. Having the stent out of the opened duct makes suture placement easier during the anastomosis.

- With a right-angle instrument, the stent, or a probe within the duct as a guide, use a knife to sharply open the duct a minimum of 1 cm for the anastomosis; open it longer if the patient's anatomy allows. Alternatively, angled (e.g., Potts) scissors can be used to open the duct. The duct is opened toward the patient's left to the base of the umbilical fissure or just to the right of the segment 4 (middle) hepatic artery, which often lies along the right edge of the umbilical fissure. This artery runs anterior to the left hepatic duct; take care to avoid injury to it. Reverse the direction of the incision and open the duct to the patient's right to the base of the gallbladder fossa. This will open the distal right hepatic duct (**FIG 13**). The goal is exposure of viable duct and healthy mucosa for the anastomosis.

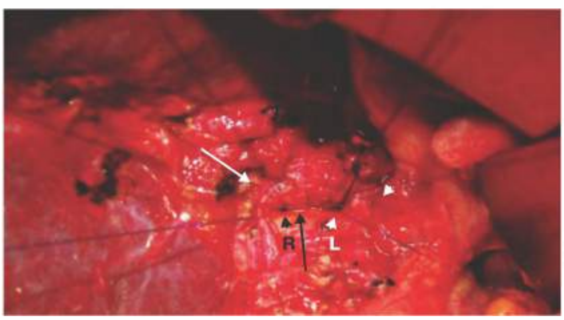

FIG 13 ● Incising the duct toward the base of the umbilical fissure *(white arrowhead)* exposes a portion of the left hepatic duct (between *black arrow* and *white arrowhead*, *L*) along the base of segment 4. Incising the duct toward the base of the gallbladder fossa *(white arrow)* opens the very short extrahepatic portion of the right hepatic duct exposing its orifice (*black arrowhead*, *R*). The septum between the right and left ducts *(black arrow)* is shown illustrating the longer extrahepatic course of the left hepatic duct. The left duct orifice is shown (*white arrowhead*, *L*).

Roux-en-Y Jejunal Limb Construction

- Identify the ligament of Treitz. Further distally, find the first jejunal arcade by transilluminating the small bowel mesentery. Divide the bowel at this site with a linear stapler.
- Divide the mesentery between clamps to develop a pedicle of sufficient length to reach the right upper quadrant.
- Approximately 55 to 60 cm distal to the end of the Roux limb, construct a side-to-side enteroenterostomy with the linear stapler. Close the resulting enterotomy with running absorbable sutures. Oversew this suture line with interrupted absorbable sutures in a Lembert fashion.
- Close the mesenteric defect with running absorbable suture.
- Bring the Roux limb into the right upper quadrant through the transverse mesocolon in the avascular space to the right of the middle colic vessels. This results in a retrocolic Roux limb that passes anterior to the second portion of the duodenum.
- Imbricate the Roux limb staple line with interrupted absorbable sutures in a Lembert fashion (**FIG 14**). This prevents dense adhesions to the staple line in the event reoperation is necessary.

Hepaticojejunostomy

- Make an antimesenteric jejunotomy near the end of the Roux limb that is approximately two-thirds the length of the longest diameter of the ductal opening.
- Using 6-0 monofilament absorbable sutures, tack the jejunal mucosa to the serosa around the circumference of the jejunotomy (**FIG 14**). We believe this step is critical to ensure the jejunal mucosa is in apposition with the bile duct mucosa upon completion of the anastomosis. Furthermore, this technique is much easier than trying to find the mucosa during each stitch of the anastomosis, especially if the duct is small or it is difficult to see well in the depth of the field. This technique is particularly helpful to ensure the mucosa is incorporated in the anterior layer when placing the anterior row of sutures in the bowel after the posterior layer has been tied.

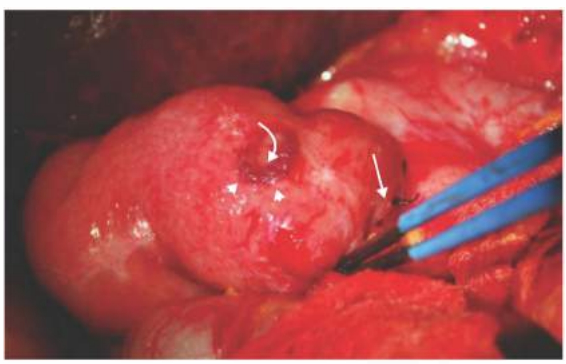

FIG 14 ● Imbricate the staple line *(white arrow)* of the Roux limb in a Lembert fashion. Tack the jejunal mucosa to the edge of the serosa *(white arrowheads)* at the jejunotomy (*curved white arrow* indicating the lumen) to ensure a mucosal-to-mucosal anastomosis with the bile duct.

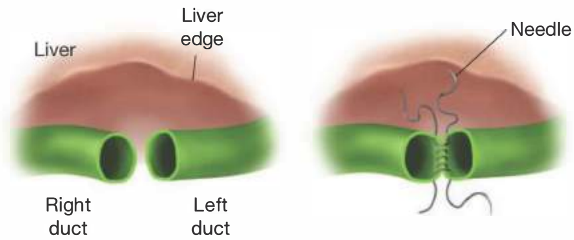

FIG 15 ● When two separate duct openings are in close approximation, a single lumen is constructed as this facilitates a single biliary-enteric anastomosis. Use fine (5-0 or 6-0) absorbable suture to approximate the adjacent bile duct walls to form a common septum. The corner sutures are tied on the outside and the remaining sutures are tied in the interior.

- If two separate ducts are present and they are close enough to be joined into a single anastomosis, this is desirable. Interrupted absorbable monofilament sutures are used to approximate the ducts (**FIG 15**).
- Typically, 5-0 or 6-0 (depending on duct size, thickness/friability of the tissue) interrupted monofilament absorbable sutures on a small needle are used for the anastomosis. Place the corner sutures in the bile duct first (9 o'clock and 3 o'clock positions) such that the knot will be tied on the outside of the anastomosis. Place the anterior row sutures through the bile duct next such that the knot will be tied on the outside of the anastomosis (**FIG 16**). Place sutures approximately 4 to 5 mm apart. Leave the needle on and secure each suture with a fine clamp, placing it on moderate tension. It is essential to establish a system to keep the sutures organized (**FIG 17**). Placing the anterior row first and keeping it under tension opens the duct to facilitate the remaining portions of the anastomosis and ensure precise suture placement.

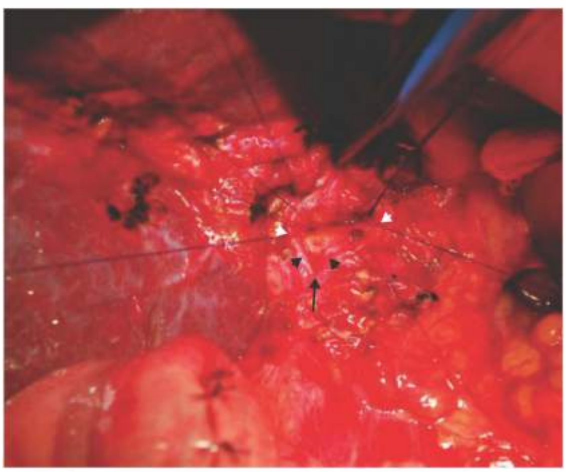

FIG 16 ● Place the corner sutures initially in the bile duct *(white arrowheads)* so they will be tied on the exterior. Place the remaining anterior sutures such that they will be tied on the exterior. Place the first suture to bisect the distance between the corners. Then place the remaining sutures to bisect each half until the sutures are 4 to 5 mm apart. The scarred and obstructed proximal common hepatic duct *(black arrow)* is seen at its junction *(black arrowheads)* with the left and right hepatic ducts.

- In the event two anastomoses are required, treat them as one and place all the anterior sutures first. Trying to perform each anastomosis separately makes construction of the second one very difficult. When two anastomoses are required, place the anterior sutures into the first duct in a similar fashion to that described previously. Once they are laid out under tension, place a white towel over these sutures and clamps. Place the anterior row sutures in the second duct. Using this method, the two sets of sutures will not get confused when it is time to complete the anterior row sutures.
- Keep the bowel and bile duct apart while placing the posterior row sutures. It is easier to precisely place each suture using this technique. Start by placing the corner sutures through each corner of the jejunotomy, then place a clamp on the suture and put it under tension (**FIG 18**). To start the posterior row, place a suture through the posterior wall of the jejunotomy and then the posterior duct halfway between each corner stitch, thereby bisecting the distance between the two. This places the posterior row sutures so the knots will be tied on the inside of the anastomosis. Place this suture and each subsequent one on a clamp and organize the sutures as done for the anterior row to prevent tangling. Complete the right half of the posterior row by placing sutures to sequentially bisect the remaining distance between the right corner and middle sutures until there are no gaps of more than 4 to 5 mm. Complete the left half of the posterior row in a similar fashion.
- Slide the bowel to the bile duct while keeping each of the sutures taut. Tie the corner suture furthest from the

FIG 17 ● After each anterior suture is placed in the bile duct, attach a fine clamp and organize each suture to prevent tangling. Placing each suture under moderate tension and arranging them on white towels as shown facilitates this. The white towels make the sutures easier to see on the field.

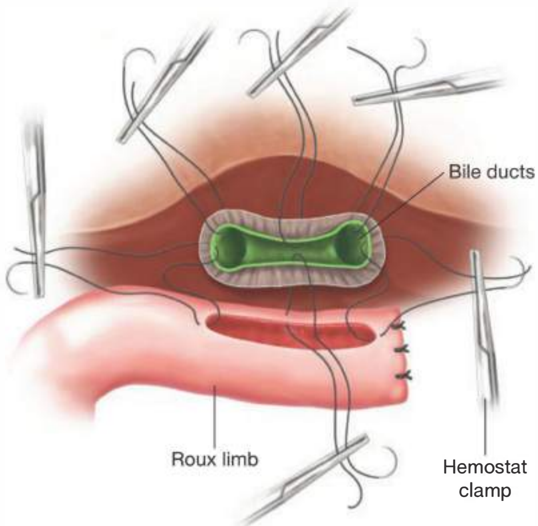

FIG 18 ● Place the posterior suture row by placing each corner suture in the corresponding corner of the jejunotomy. Place each of these under tension as shown in **FIG 17**. Keep the bowel and bile duct separated by 5 to 10 cm while placing the remaining posterior sutures. Place the remaining sutures so they will be tied on the interior. The first suture is placed to bisect the distance between the corner sutures. Next, the right half sutures are placed, again by bisecting the distance between the corner and the middle suture. This is done until the distance is 4 to 5 mm between the sutures. Finish the posterior row by placing the left half sutures.

surgeon first. Sequentially tie each next suture, working from the tied corner to the other corner suture. The assistant can use forceps to hold the anterior lip of the bowel inferiorly, opening the anastomosis and allowing the surgeon to observe each suture as it is tied, thus ensuring apposition of the bowel and bile duct mucosa (**FIG 19**).

- Once the posterior row sutures are tied, place a right-angle clamp into the lumen of the jejunotomy and gently open the clamp. This ensures that none of the anterior mucosa is trapped in the posterior sutures while tying them. This prevents webs or strictures in the anastomosis as a result of trapped mucosa.
- If the intraductal stent is protruding into the anastomosis, pull the retaining suture down and cut the stent so the end will rest proximal to the anastomosis. If it is already in good position above the anastomosis, cut the retaining suture. We never stent our anastomoses. There are two primary reasons why stents are not left traversing the anastomosis. First, if the anastomosis is done as described, a stent in the anastomosis provides no technical advantage in assuring a precise anastomosis. Second, one only has to observe the intense inflammation, tissue injury, and thickening associated with biliary stents to be concerned that a stent placed across an anastomosis will cause similar changes and lead to a postoperative stricture. Finally, there is no evidence that stenting a surgically constructed anastomosis improves outcomes.
- Complete the anastomosis by placing the anterior row sutures through the bowel, tying the knots on the outside (**FIG 20**). Place the suture closest to each corner first, then the adjacent suture next, working toward the center of the anastomosis. It is easier to see each suture placed in this fashion rather than working from one corner to the other.

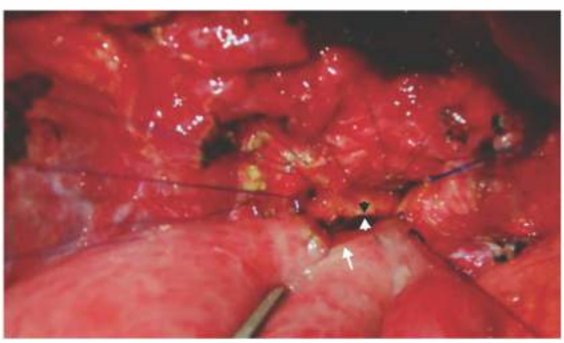

FIG 19 ● Tie the posterior row sutures by pushing the bowel into apposition with the bile duct. Start by tying the corner furthest from the surgeon, tying each next suture in succession. Forceps retracting the anterior edge of the jejunotomy *(white arrow)* allow examination of the posterior wall of the anastomosis to ensure a mucosal-to-mucosal anastomosis (opposing *black* and *white arrowhead*).

Final Steps

- Upon completion of the anastomosis, use sutures to tack the Roux limb to the cystic plate or other fibrous tissue to prevent tension on the anastomosis.
- Tack the Roux limb to the transverse mesocolon with interrupted absorbable sutures to prevent it from herniating into the right upper quadrant.
- Place a 19-Fr round Blake drain through a separate incision and place the end in the subhepatic space.
- If the PTC tubes were manipulated and the fibrous sheath around them was disrupted, place a silk purse string in the liver and tie it around the tube at the exit site to prevent bile leakage.
- After closing the incision, suture the PTC to the skin to prevent dislodgement. Although the anastomosis is not stented by the PTC, it is left in place postoperatively to gravity drainage until the patient is ready for discharge. Just prior to discharge, a cholangiogram is completed. If no leak or stricture is seen, the tube is removed.

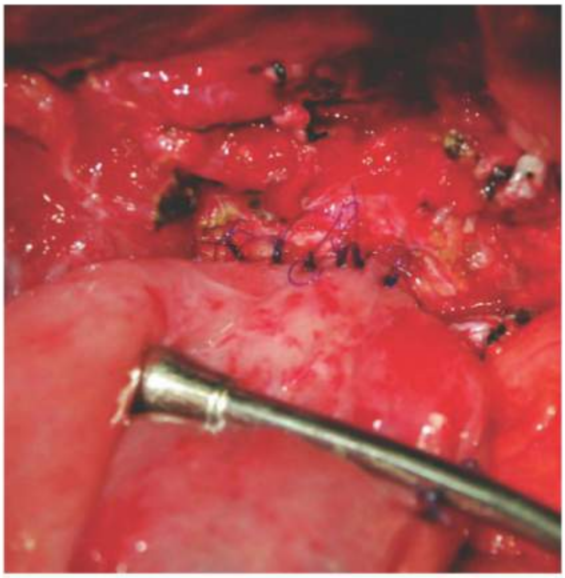

FIG 20 ● Complete the anastomosis by placing the anterior row sutures through the bowel and tying them on the exterior of the anastomosis.

SEGMENT 3 HEPATICOJEJUNOSTOMY (LIGAMENTUM TERES OR ROUND LIGAMENT APPROACH)

Preparation

- This approach takes advantage of the position of the segment 3 duct, which lies cranial to the left portal vein (**FIG 21**) at the anterior–inferior aspect of the umbilical fissure (**FIG 22**). The ligamentum teres (remnant of the umbilical vein, which joined the terminal left portal vein in utero) runs in the dorsal portion of the falciform ligament as it passes into the umbilical fissure. Advantage is taken of the relationship between the ligamentum teres and the left portal vein to facilitate identification of the segment 3 bile duct.

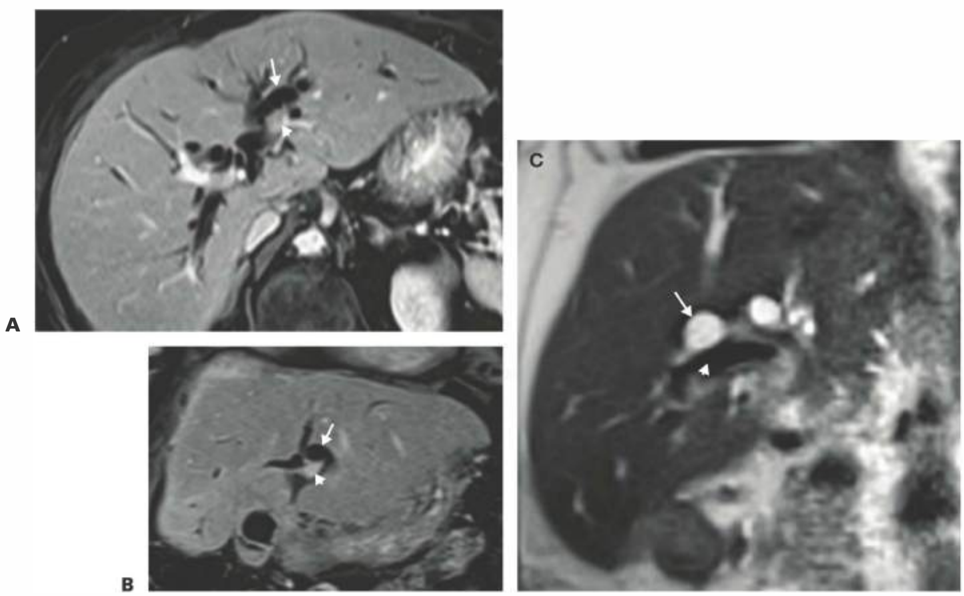

FIG 21 ● The segment 3 duct *(white arrowhead)* is located cranial to the left portal vein *(white arrow)* within the umbilical fissure. **A.** Axial contrast-enhanced portal phase MRI. **B.** Coronal contrast-enhanced portal vein phase MRI. **C.** Sagittal T2 weighted MRI.

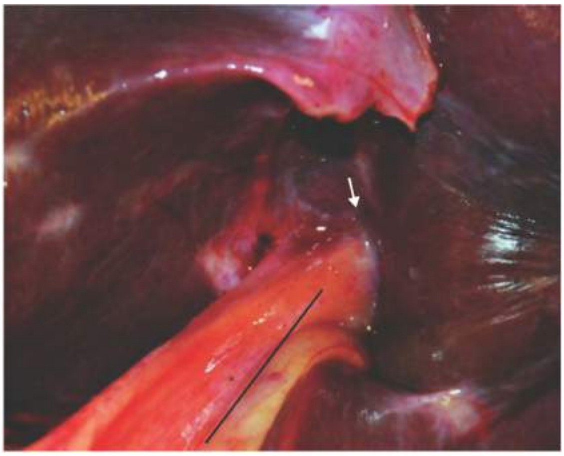

FIG 22 ● The ligamentum teres *(black line)* runs in the dorsal portion of the falciform ligament and its junction with segment 3 *(white arrow)* helps locate the approximate position of the segment 3 duct.

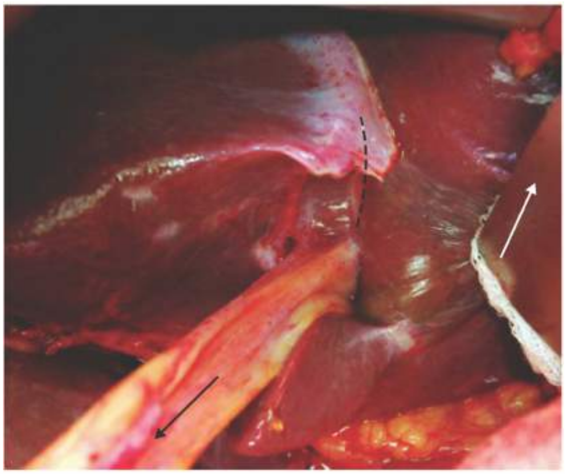

FIG 23 ● Retracting the ligamentum teres *(black arrow)* inferiorly and to the right while retracting the lateral segment of the liver *(white arrow)* superiorly and anteriorly opens the umbilical fissure and facilitates exposure to the segment 3 portal pedicle. The liver is divided just to the left of the falciform ligament *(dotted black line)* to access the segment 3 duct.

- Contraindications to the segment 3 approach include an isolated right ductal system that is infected or has been instrumented by an endoscopically or percutaneously placed drain, atrophy of the left hepatic lobe, metastatic disease, or tumor involvement of the secondary bile ducts of the left lobe or posterior to the base of the umbilical fissure.

Locate the Segment 3 Duct

- The initial steps including positioning, incision, exposure, and construction of the Roux limb are the same as described in the prior section. Likewise, constructing the hepaticojejunostomy follows the principles outlined earlier.
- Retraction of the ligamentum teres inferiorly and to the right while retracting the adjacent liver superiorly and anteriorly facilitates exposure to the segment 3 duct (**FIG 23**).
- Divide the liver just to the left of the falciform ligament starting superior to the umbilical fissure and incise the liver inferiorly and posteriorly toward the junction of the left portion of the ligamentum teres with segment 3 of the liver (**FIG 23**). If necessary, remove a small wedge of hepatic parenchyma to expose the segment 3 duct (**FIG 24**). This approach avoids dividing the portal vein

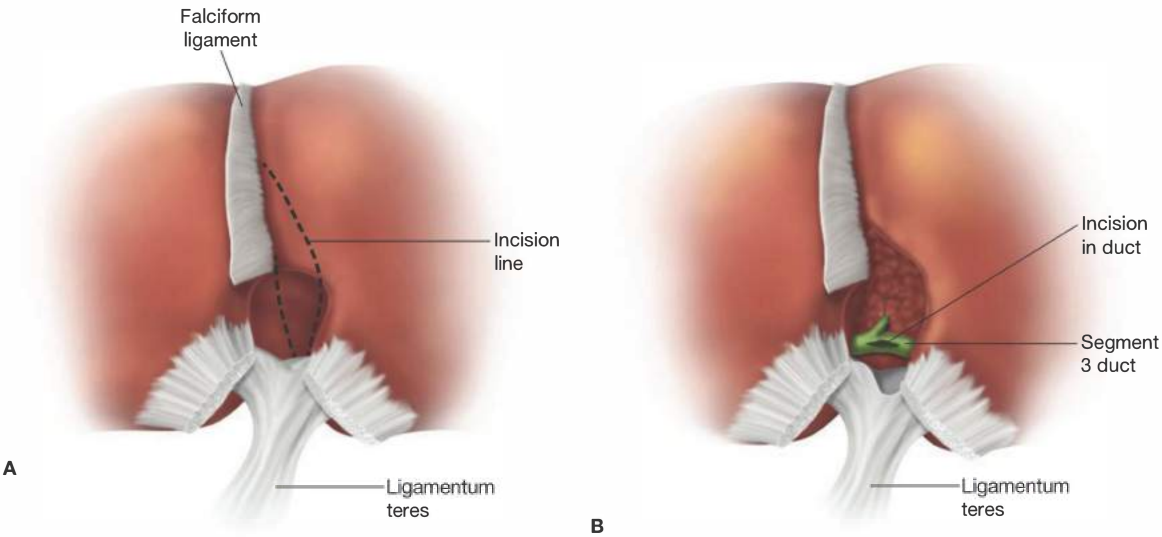

FIG 24 ● **A.** Removing a wedge of liver just to the left of the falciform ligament will expose the segment 3 duct. **B.** Once the segment 3 duct is exposed, place stay sutures superior and inferior to the proposed ductotomy and longitudinally incise the duct. Once the lumen is identified, probe the duct in each direction and open the duct for a minimum of 1 cm for the anastomosis.

branches to segment 3. Avoid dissection of more than the anterior surface of the duct to avoid devascularization of the duct.

- Intraoperative ultrasound can help locate the duct. Likewise, aspiration of bile using a 25-gauge needle and syringe can assist in locating the duct and verifying its position.

Incise the Hepatic Ducts, Biliary-Enteric Anastomosis, and Final Steps

- Once located, place fine stay sutures in the anterior duct wall, elevate them, and make a longitudinal incision in the exposed surface of the duct until the lumen is entered (**FIG 24**). Use a blunt probe to explore the duct.
- With a right-angle instrument inside the duct, use a knife to sharply open the duct a minimum of 1 cm for the anastomosis; open it longer if the patient's anatomy allows. Alternatively, angled (e.g., Potts) scissors can be used to open the duct. Reverse the direction of the incision and open the duct to the patient's right to the extent feasible.
- The biliary-enteric anastomosis to the Roux limb is constructed as described in the previous section. Place the anterior row sutures first followed by the posterior row.
- The final steps are similar to those described previously.

PEARLS AND PITFALLS

Indications	■ Biliary-enteric anastomosis may be necessary for benign or malignant disease. ■ The stricture etiology (benign or malignant) dictates the anastomotic location and options.
Preoperative evaluation	■ MRCP/MRI is the initial imaging study of choice. ■ Endoscopic/percutaneous cholangiography is a supplementary study for defining biliary anatomy. Biliary stenting often is necessary for preoperative preparation.
Benign	■ Allow 6 to 12 weeks following resolution of sepsis and/or control of biliary fistulae before proceeding with repair. ■ Ensure all ducts are accounted for and each isolated biliary segment has a PTC within it.
Malignant	■ Nearly all patients with unresectable disease can be effectively palliated without a biliary-enteric anastomosis. ■ A segment 3 bypass is reasonable for patients with malignant hilar obstructions that do not extend to the secondary radicles of the left hepatic duct.
Identifying the hilar bile duct	■ At the base of segment 4 and its junction with the hepatoduodenal ligament, incise Glisson's capsule at this junction to "lower" the hilar plate. ■ The left hepatic duct lies anterior and superior in the hilar plate.
Segment 3	■ Identify the duct at the superior–posterior portion of the segment 3 portal triad by ultrasound or aspirating bile. ■ The duct lies cranial to the left portal vein in the anterior–inferior portion of the umbilical fissure. ■ Incise the liver just to the left of the falciform ligament and carry this inferiorly to the superior portion of the ligamentum teres. Remove a small wedge of liver if necessary. ■ Incise the duct longitudinally.
Constructing the biliary-enteric anastomosis	■ Tack the mucosa to the serosa at the jejunotomy site. ■ Cut the PTC tube(s) above the level of the anastomosis. ■ Place each corner suture first in the bile duct and then the anterior row so the sutures will be tied on the exterior. ■ Place a clamp in the intestinal portion of the anastomosis and open to ensure the anterior mucosa is not trapped.
Final steps	■ Tack the Roux limb to the hilar plate and transverse mesocolon. ■ Secure any PTC tube to the liver to prevent a bile leak. ■ If present, perform a cholangiogram through the PTC prior to discharge. If no leak or stricture, remove the PTC.

POSTOPERATIVE CARE

- If a preexisting PTC is left in place following biliary reconstruction, leave it to gravity drainage. Just prior to discharge, perform a cholangiogram. If there is no leak and the anastomosis is patent, remove the PTC prior to discharge.
- If no bile is present in the Blake drain, remove it prior to discharge. Otherwise, leave it until the leak has ceased.
- Long-term follow-up is necessary to assess for early and late anastomotic stricture. This includes symptom assessment for pruritus, jaundice, or cholangitis and serial serum liver studies (LFTs). Liver tests typically are done every 4 months in the first year, every 6 months in years 2 and 3, and if stable, annually for life.

OUTCOMES

- Approximately 80% to 90% long-term excellent results are reported for hilar hepaticojejunostomy. The more complex the injury (E4, E5), the lower the success rate.
- Approximately 70% of anastomotic strictures occur in the first 3 years following surgery and 80% within the first 5 years. Follow-up longer than 5 years is important as late strictures may develop in up to 5% of patients even after

more than 12 years.[10] A recent study confirmed improved results in recent patient cohorts undergoing biliary-enteric anastomosis.[11]

- Modest serum liver test elevations are seen following biliary-enteric anastomosis in patients with excellent results. Caution is warranted when interpreting these tests and trends over time are more useful than individual data points.[12] Rising values, particularly in the alkaline phosphatase, should lead to investigation for an anastomotic stricture.

COMPLICATIONS

- Bile leak, fistula, or biloma
- Cholangitis
- Anastomotic stricture
- Infection—organ space or wound abscess

Chapter 13

Operative Management of Choledochal Cyst

Charles S. Cox, Jr. Robert Hetz

DEFINITION

- Choledochal cyst represents a spectrum of cystic abnormalities of the extrahepatic biliary tree. It is not an isolated defect of the choledochus, rather, it also includes a constellation of abnormalities of the pancreaticobiliary system/junction.
- The classification of the cystic structural abnormalities (types I to V) as originally described by Alonso-Lej[1] and modified by Todani[2] is typically used (**FIG 1**).
    - Type I is the predominant type of cyst (90% to 95% of cases) and is a fusiform, solitary dilation of the common bile duct (CBD) and hepatic duct. Type I is further subdivided into a, b, and c subtypes.
    - Type II is a cystic diverticulum of the CBD.
    - Type III (subtypes 1 and 2) is called a choledochocele and is a cystic dilation of the duct at the junction with the duodenum (intraduodenal subtype 1), with the CBD and pancreatic duct entering the intraduodenal choledochocele separately and draining into the duodenum via a stenotic/inflamed opening; and rarely, the intrapancreatic subtype 2, the choledochocele, is a diverticulum off the CBD at the level of the ampulla of Vater.
    - Type IV is a combined dilation of the intra- and extrahepatic biliary tree and is the second most common type of cyst.
    - Type V is also known as Caroli's disease and is single or multiple intrahepatic cyst(s).

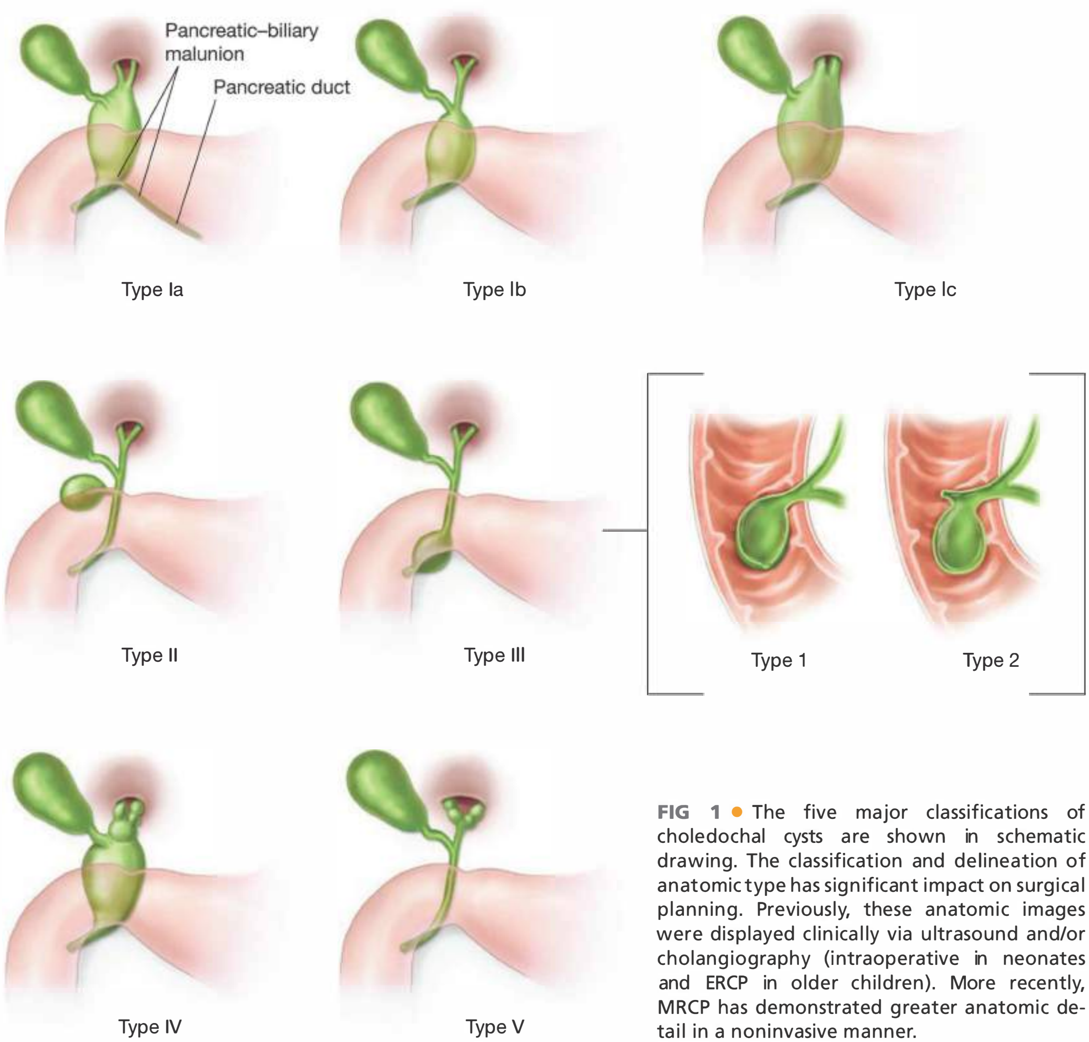

FIG 1 • The five major classifications of choledochal cysts are shown in schematic drawing. The classification and delineation of anatomic type has significant impact on surgical planning. Previously, these anatomic images were displayed clinically via ultrasound and/or cholangiography (intraoperative in neonates and ERCP in older children). More recently, MRCP has demonstrated greater anatomic detail in a noninvasive manner.

- In terms of anatomy of the distal CBD, symptomatic infants often have a stenotic opening, and older patients have a patent communication. The types II, III, and V are all very rare, representing only a few percent of the total number of cysts.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of choledochal cyst is age-dependent.
- In infants, the differential of most concern is cystic variants of biliary atresia; other abdominal cysts, including renal, are in the infant differential.
- For older children, cystic lesions of the pancreas, hepatic tumors, rhabdomyosarcoma of the biliary tree, and cystic neuroblastoma are considerations. Most of these are distinguished on more advanced imaging, once the issue is raised with ultrasound.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with choledochal cysts are usually characterized as either infantile (now includes fetal or in utero diagnoses) or noninfantile forms.
- Infantile (in utero): The infantile patient with an in utero diagnosis is an increasing cohort of patients; the cystic mass adjacent to the liver is usually noted on prenatal ultrasound in midgestation. There have been reports of cystic lesions visualized as early as 15 weeks, but most are in the 20 to 24 weeks of gestation range. The antenatal abnormality should be confirmed by ultrasound postnatally. The issue that arises is timing of surgical intervention, as even the infantile forms are often asymptomatic for months.
- Infantile forms that are not in utero diagnoses are by definition symptomatic—abdominal pain/mass, jaundice-mixed hyperbilirubinemia, acholic stools, and/or signs and symptoms of pancreatitis or cholangitis. In general terms, the infantile forms do not present with an abdominal mass or other signs of inflammation, rather, these patients are increasingly identified in utero with prenatal ultrasound and/or on postnatal ultrasound as part of the initial evaluation for mixed hyperbilirubinemia. Other presentations include failure to thrive and vomiting with mixed hyperbilirubinemia.
- Noninfantile forms: Symptoms and signs of the noninfantile forms of choledochal cyst are classically described as right upper quadrant pain, jaundice (direct hyperbilirubinemia), and a mass. Pain and jaundice are the major symptoms, and it is rare that a right upper quadrant mass is palpable. The triad is present in fewer than 10% of patients. A bigger issue is the cause for delayed diagnosis/referral. The principal cause is either misdiagnosis of mixed hyperbilirubinemia as hepatitis and an incomplete evaluation of an episode of pancreatitis or hyperamylasemia with abdominal pain. Rarely, children can present with cyst rupture; there is no correlation between cyst size and risk of rupture.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Ultrasound is the initial imaging study of choice. Ultrasound is the least invasive and most cost-effective method of investigating the biliary tree after an episode of pancreatitis or abnormal elevations in liver enzymes in association with abdominal pain (with or without jaundice). This modality will suffice in the setting of calculus disease, but additional imaging with greater resolution is required when dilation of the biliary tree is identified.
- Endoscopic retrograde cholangiopancreatography (ERCP) versus magnetic resonance cholangiopancreatography (MRCP) (**FIGS 2** and **3**): Both types of imaging of the biliary tree can be useful. ERCP was more frequently used in older children to obtain direct contrast injection into the extrahepatic biliary tree under fluoroscopic guidance. It provides excellent detail of the structural anatomy of the cyst but very

FIG 2 ● ERCP in an older child demonstrating a type I cyst with fusiform morphology and moderately dilated right and left hepatic ducts.

FIG 3 ● MRCP in an older child demonstrating a type I cyst. This image demonstrates a greater detail in the anatomic relationship of the pancreatic duct. This also shows how there is a relative continuum between types I and IV cysts.

FIG 4 ● Intraoperative cholangiogram demonstrating a type IV cyst with multiple proximal ductal cysts that have areas of narrowing between the dilated regions (as opposed to the type I cyst).

little input into the relationship to structures other than the pancreatic duct. ERCP has the advantage over MRCP in that it can also be therapeutic in the setting of obstructive jaundice. MRCP provides a similar level of detailed imaging of the ductal relationships with 3-D reconstruction of the anatomy of adjacent structures as well. MRCP also has the advantage of being noninvasive and thus is associated with less risk. **FIG 4** shows an intraoperative cholangiogram of a type IV cyst that can be an adjunct to the other imaging modalities.

- Computed tomography (CT): CT imaging is most commonly used when investigating abdominal pain of an undetermined etiology and when the findings suggest a choledochal cyst. With the more advanced CT imaging and 3-D reconstruction /multiplanar imaging now available, MRCP or ERCP is rarely required if a CT has been obtained.

SURGICAL MANAGEMENT

- The technique described in the following text represents the principal management of types I and IV cysts, which represents over 95% of choledochal cyst cases. Timing of intervention: The debate surrounding immediate (first 2 weeks of life) versus delayed (6 weeks to 3 months of age) surgical intervention hinges on whether there is a risk for progressive liver dysfunction developing in the interim time of waiting. There are no solid data to support either approach. The rationale for not waiting indefinitely is due to the fact that it can be somewhat difficult to distinguish the cystic variant of biliary atresia from a choledochal cyst in infancy. Missing the window to surgically correct a patient with biliary atresia is a potentially devastating complication that is avoidable. A reasonable intermediate approach is to follow the asymptomatic, anicteric patient serially with serum biochemical studies and ultrasound with a planned operation at 6 weeks of age to earlier if worsening. Symptomatic patients or patients with a mixed hyperbilirubinemia undergo early operation if other comorbidities are manageable. Older patients can undergo operation when physiologically stable. If these patients present with cholangitis/pancreatitis, they can typically be managed akin to an adult with gallstone pancreatitis. Once the acute inflammatory response has subsided, an operation is performed during that admission, as early recurrent pancreatitis is the norm.

Preoperative Planning

- We advise the use of an epidural catheter for perioperative pain management, and this is placed after the induction of anesthesia. Two peripheral intravenous lines, radial arterial line, Foley catheter, and nasogastric tubes are routinely inserted under aseptic conditions. Any coagulopathy is corrected preoperatively (unusual), and 20 mL/kg body weight of packed red blood cell (PRBC) are crossmatched and available for the procedure. Preoperative cefoxitin (40 mg/kg body weight) is used as antibiotic prophylaxis and redosed at 4 hours if needed.

Positioning

- The patient is placed supine on the operating room table such that fluoroscopic cholangiography can be performed if needed. A small towel "bump" is placed under the right flank. The right arm is on an armboard at 90 degrees (**FIG 5**).

FIG 5 ● The patient is placed supine on the operating table with the abdomen available for fluoroscopic imaging. A small towel bump is placed under the right flank. The right arm is at 90 degrees and is the site for a radial arterial catheter for blood pressure monitoring/sampling.

- The rationale for total cyst excision is to minimize the risk of malignant degeneration in the future. Roux-en-Y cyst jejunostomy is favored over cyst duodenostomy because of poor long-term results associated with the latter, namely recurrent cholangitis and anastomotic stenosis leading to insidious biliary cirrhosis. We exclusively use an open laparotomy with total cyst excision for types I and IV lesions (over 95% of cases) with Roux-en-Y hepaticojejunostomy.
- The use of minimally invasive approaches has been described and is technically feasible. There are no long-term data on this approach; laparoscopic portoenterostomy for biliary atresia has been abandoned not due to technical issues but rather due to exacerbation of hepatic insufficiency that is thought to be due to either technical dissection of the portal plate or more recently, a reduction of hepatic/portal blood flow for the time of operation.[3]

INCISION AND EXPOSURE

- A standard right subcostal incision is made to enter the abdomen. For larger cysts, the incision is extended to a partial chevron to gain adequate exposure. A self-retaining retractor (Bookwalter or Thompson) is used. The right colon and hepatic flexure are mobilized from lateral to medial, taking down the peritoneal reflection to expose the porta hepatis and duodenum.
- Next, the duodenum is fully mobilized (Kocher maneuver). Be prepared for the potential severe acute and/or chronic inflammation including saponification of these tissue planes, making dissection tedious, bloody, and potentially hazardous. If the anatomy is difficult to discern, an intraoperative cholangiogram can be very helpful. This can be performed in the usual manner at the cystic duct using Omnipaque 300 and fluoroscopy. A 5-Fr infant feeding tube is used to cannulate the cystic duct, and real-time fluoroscopy can identify the anatomy and help resolve any anatomic questions.

GALLBLADDER AND ARTERIAL DISSECTION

- Mobilization of gallbladder—"top-down approach": Once the self-retaining retractor is in place and the anatomic field is identified in general terms, the gallbladder is mobilized from the fundus down to the cystic duct/cyst junction. The cystic duct and gallbladder are dilated. The cystic artery is identified and traced back to the right hepatic artery (RHA) or its origin. The gallbladder is then available for traction and can be rotated medially to facilitate exposure and identification of the portal vein (PV), posteriorly. **FIGS 6** and **7** demonstrate the dissection

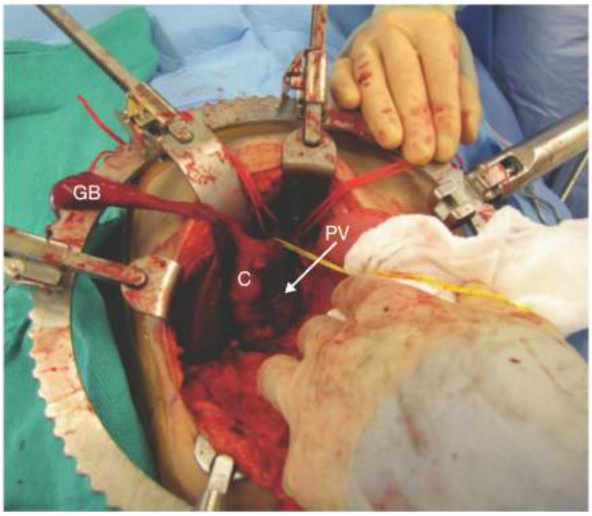

FIG 6 ● This intraoperative photograph (type I cyst MRCP in **FIG 3**) demonstrates the circumferential dissection of the cyst (yellow vessel loop, *C*), with the RHA and LHA looped *(red)*. The gallbladder *(GB)* has been completely mobilized and the duodenum Kocherized. The cyst is partially dissected posteriorly from the portal vein *(PV)*.

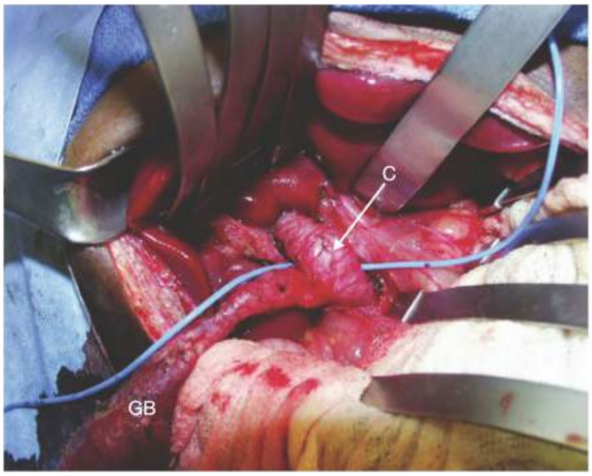

FIG 7 ● This intraoperative photograph of another type I cyst *(C)* demonstrates using the same operative approach of gallbladder *(GB)* mobilization and circumferential dissection of the cyst cephalad to the cystic duct confluence (blue vessel loop). The duodenum is completely Kocherized and under the retractor/laparotomy pad. There is minimal inflammation in this case.

of the gallbladder and circumferential dissection of the cyst in separate patients.

- RHA identification and further dissection of hepatic artery and left hepatic artery (LHA): Once the RHA is identified, the hepatic arterial anatomy can be dissected off of the cyst. The ease of this dissection is dependent on the degree of pericystic inflammation. Vessel loops can be placed around the hepatic arteries, and then, the dissection can proceed directly on the cyst wall anterior and lateral to the artery.

CIRCUMFERENTIAL DISSECTION OF CYST

- Typical approach: The goal of the dissection is a radical excision of the complete cyst from the level of the confluence of the hepatic ducts to the junction with the pancreatic ducts distally. To achieve this, the arterial anatomy is isolated anteriorly as described in the previous text, and then the back wall of the cyst is dissected free from the PV. Identify the PV just before it bifurcates, and circumferentially dissect on the undersurface of the cyst until the cyst is encircled with an umbilical tape or vessel loop. Dividing the cyst at the confluence of the right and left ducts allows anterior traction on the cyst and provides exposure of the anterior aspect of the PV as the dissection is carried distally toward the superior mesenteric vein (SMV). Once the cyst is off of the PV and divided proximally, then the biliary tree is retracted anteriorly as dissection directly on the cyst wall toward the junction with the pancreatic duct.
- Alternative approach: In the setting of extensive pericystic inflammation that obscures the anatomy and precludes safe circumferential dissection, Lilly[4] described an alternative approach of intramural dissection that leaves the posterior wall in place, akin to abdominal aortic aneurysm repair. The cyst is opened transversely, and the plane within the cyst wall that allows separation of the mucosa from the thinner exterior cyst wall is developed. There are numerous perforating small vessels that can be controlled with cautery. This dissection proceeds superiorly and inferiorly, leaving the back wall in place and adherent to the PV. This approach allows removal of all of the potentially malignant mucosa and prevents the potential catastrophic complication of injury to the PV.

CYST EXCISION

- Level of distal resection: As the cyst is circumferentially dissected down toward the pancreas, it invariably tapers down to a narrow neck. Preoperative imaging provides guidance as to the site of the confluence with the pancreatic duct; it can be quite high in cases of pancreatic–biliary malunion. This dissection typically dives into the head of the pancreas and it is critical to stay directly on the cyst wall for the dissection and not inadvertently violate the pancreatic duct—a catastrophic error that invariably leads to pancreatic fistula. **FIG 8** demonstrates the upward traction on the divided extrahepatic biliary tree and dissection down to the distal end of the cyst. Once the distal extent of the cyst is determined, it is divided at this level and oversewn with monofilament suture (3-0 or 4-0 Prolene), using care to preserve the pancreatic duct.

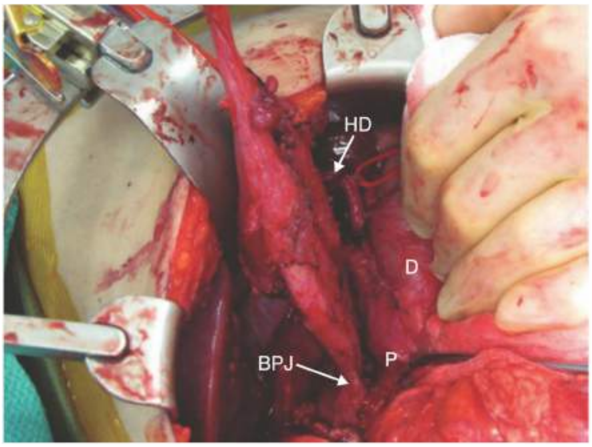

FIG 8 ● This intraoperative photograph demonstrates the extrahepatic biliary tree retracted anteriorly, after the proximal cyst has been divided at the junction of the confluence of the hepatic ducts *(HD)*, and the gallbladder is used as the point of traction. The duodenum *(D)* is fully Kocherized, exposing the posterior aspect of the pancreas *(P)*, and the red vessel loop is on the LHA. Stay sutures are on the transected duct. The cyst is tapering down to the junction with the pancreatic duct in an intrapancreatic position *(BPJ)*. The transition to an intramural dissection is noted on the anterior wall of the cyst halfway down the dissection.

BILIARY-ENTERIC RECONSTRUCTION

- Typical approach: retrocolic Roux-en-Y hepaticojejunostomy—The standard approach is to create a 40-cm Roux limb that originates 10 cm from the duodenojejunal junction. This is illustrated in the drawings in **FIG 9** and the initial anastomosis is shown in photographs in **FIG 10**.
- Numerous techniques are commonly used for the jejunojejunostomy. Most pediatric surgeons prefer an end (proximal jejunum) to side (distal jejunum), two-layered, hand-sewn anastomosis in older children. The inner row of sutures is placed using 4-0 Vicryl and hemi-Connell technique and the outer row thrown using Lembert technique and using 3-0 silk. In infants/small children, a single-layer anastomosis of interrupted 5-0 or 4-0 Vicryl is most often employed.
- The end of the Roux limb is closed in two layers and then brought through a defect created in the transverse mesocolon, just to the right of the middle colic vessels. The antimesenteric side of the Roux limb is used for the anastomosis to the confluence of the hepatic ducts.

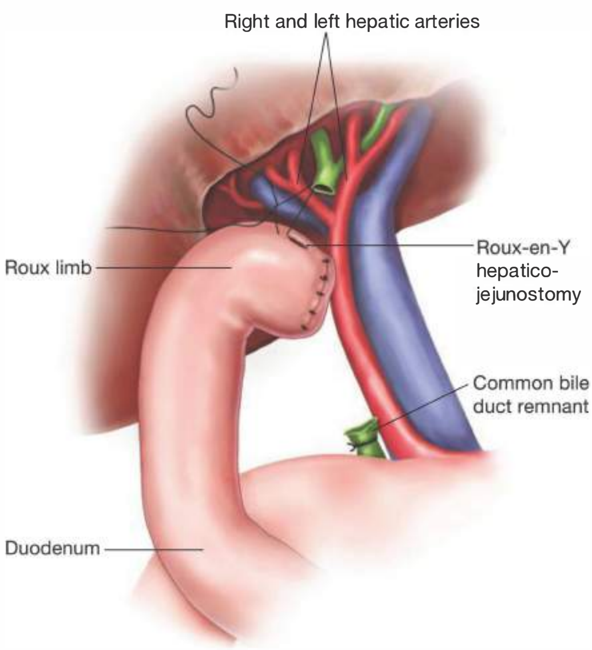

FIG 9 ● This drawing is a schematic diagram of the Roux-en-Y hepaticojejunostomy. The side jejunotomy is matched to the size of the hepatic duct, leaving a small distance of "j" configuration to the limb. This is not left more than a few centimeters to prevent sumping of bile, as this will grow with the child.

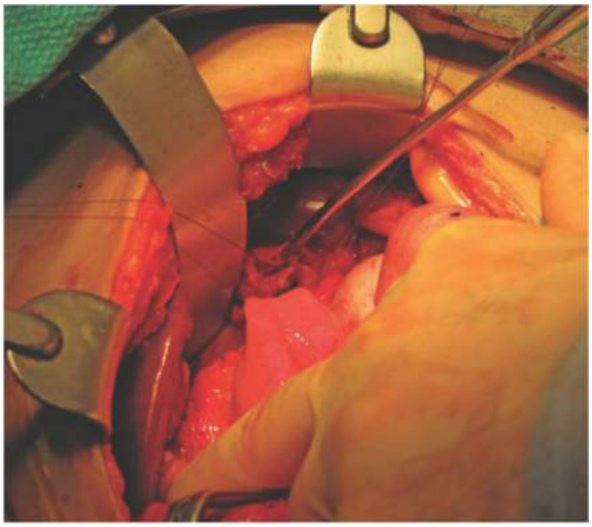

FIG 10 ● This is an intraoperative photograph of the Roux limb on stay sutures at 3 o'clock and 9 o'clock positions and the suction tip in the hepatic duct confluence. The duct was irrigated with saline to ensure no debris/stones were in the proximal ducts. After the sutures were laid in the back wall of the anastomosis, it was "parachuted" down, and then the anterior row was completed.

Interrupted 4-0 or 5-0 polydioxanone (PDS) or equivalent monofilament, absorbable sutures are placed to create a single-layer anastomosis. This should be tension free and care should be taken to ensure that the limb is not kinked or twisted in the final anatomic configuration. **FIG 11** demonstrates a completed anastomosis. The limb is secured to the mesocolic defect with interrupted sutures and the mesenteric defect of the jejunal anastomosis is closed as well.

- In cases that are complicated due to multiple previous bouts of pancreatitis and/or cholangitis, most surgeons prefer to leave a drain; in straightforward cases (usually the infantile forms), most omit the drain. Admittedly, there are no data to support either approach.
- Alternative approach: hepaticoduodenostomy—The group at Children's Hospital of Philadelphia has presented an alternative to the Roux-en-Y reconstruction, using a direct hepaticoduodenostomy.[5] The rationale for this approach is that there is a more physiologic end point for bile drainage and a simpler reconstruction. In their hands, the operations were shorter by approximately 1 hour, and there were fewer complications requiring reintervention. The long-term follow-up is not yet available. Of note, these patients were selected and not randomized patients with hepatico-duodenostomy being used in those patients in whom there would not be a tension at the anastomosis.
- Other approaches: There have been a number of other reconstructive options forwarded by others, such as valved Roux-limb conduits to the duodenum or use of the appendix as a pedicled graft.[6] These approaches are unnecessarily complex and in the case of the appendix, have worse long-term outcomes.

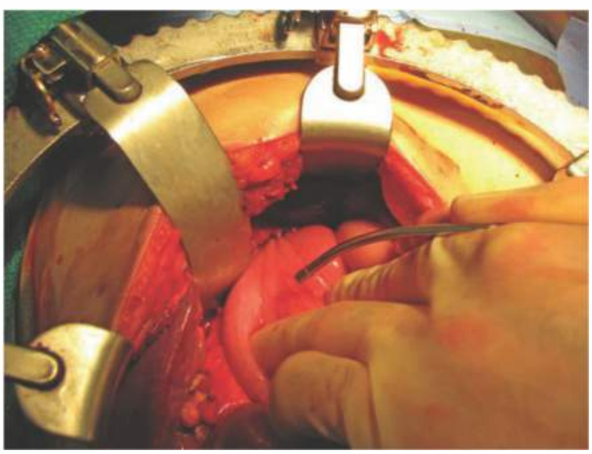

FIG 11 ● The completed hepaticojejunostomy is in the proper anatomic orientation.

LAPAROSCOPIC APPROACH

- The laparoscopic approach to choledochal cyst excision and reconstruction has been described by numerous authors. Monitor positioning and port placement are shown in **FIG 12**.
- The laparoscopic technique is much more amenable to the patient who has not experienced multiple bouts of cholangitis/pancreatitis.
- Unlike the open procedure, the gallbladder is divided at the cystic duct and then it is used to retract cephalad to expose the cyst/porta hepatis; the gallbladder is removed at the conclusion of the procedure.
- The procedure is otherwise performed in the sequence of events as described in the previous text. The hepatic flexure is mobilized to facilitate a Kocher maneuver. The cyst dissection is as described for the open approach starting with cephalad, superior exposure of the cyst and subsequent dissection of the vessels from proximal to distal.
- The jejunojejunostomy can be performed via an extended umbilical incision in infants to allow an extracorporeal jejunojejunal anastomosis.
- Early results are similar between open and laparoscopic cases.

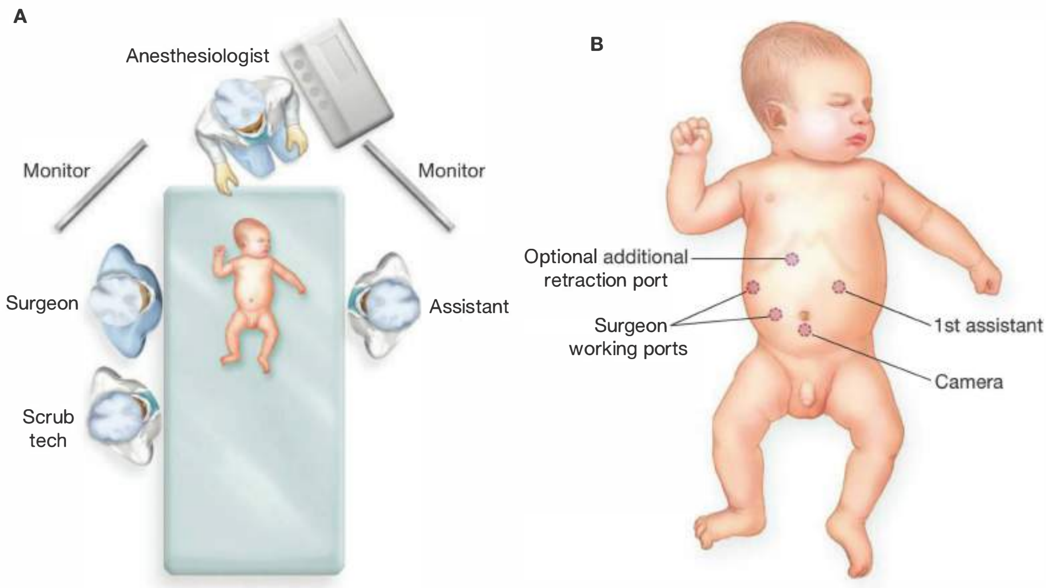

FIG 12 ● Laparoscopic approach: display arrangement and port placement. **A.** The surgeon is positioned on the patient's right side with a monitor over the patient's left shoulder. **B.** A 5-mm umbilical port and 30-degree camera are employed. Two subsequent ports are placed in the right midabdomen as shown. Another left-sided port is placed in the midclavicular line above the umbilicus; this is the right-handed working port of the assistant. An optional retraction port is in the right upper quadrant, below the costal margin in the midaxillary line.

OTHER CYST TYPES (II, III, V)

- Type II: The type II cyst is a diverticulum of the CBD. This configuration, especially with a long, narrow neck, is most amenable to a minimally invasive approach.[7] Most surgeons recommend removal of the gallbladder at the same operation.
- Type III: The type III cysts or choledochoceles are more complex procedures that are best addressed by transduodenal resection and sphincteroplasty. Once the duodenum is fully Kocherized, it is opened transversely along the antimesenteric border. The intraduodenal, stenotic ampulla is cannulated and opened. An intraoperative cholangiogram is useful, at times, and usually best done through the openings of the bile duct and pancreatic duct via the duodenum. Excision and then reapproximation of the duct to duodenal mucosa with 5-0 or 6-0 Vicryl is standard. This can be done over a calibrating stent of a 5- to 7-Fr catheter. The intrapancreatic lesions should be managed with internal drainage, and conceivably, this could not be accomplished and require a pancreaticoduodenectomy. The gallbladder is traditionally removed at the same operation.
- Type V: Caroli's disease is characterized by unilateral or bilateral cystic dilation of the intrahepatic biliary tree. This is surgically treated by lobectomy if there is disease isolated to a single anatomic lobe. Palliation is often done by interventional radiology by dilation of multiple strictures and stone retrieval. Liver transplantation may be required to effectively treat this problem.

PEARLS AND PITFALLS

Timing of operation	■ Delaying operation in the infantile form can potentially allow biliary cirrhosis to progress due to either stasis or biliary atresia misdiagnosis. Operation by 6 weeks of age should mitigate this risk and allow any other comorbidities to be addressed. ■ Operating during acute pancreatitis in the noninfantile form can increase the difficulty of dissection and lead to increased complications such as vascular injury and anastomotic leak.
Cyst excision	■ Too distal of a dissection with a high union of the pancreatic duct to the CBD/cyst can result in pancreatic duct injury or ligation. Appreciation of preoperative imaging with the pancreaticobiliary malunion (PBM) in mind can avoid this complication.
Biliary-enteric reconstruction	■ Ensure proper anatomic orientation of the Roux limb. Disorientation can create a loop of proximal jejunum–hepatic duct anastomosis or kinking of a properly corrected Roux limb.

POSTOPERATIVE CARE

- The postoperative care of the patient who undergoes resection of a choledochal cyst is similar to many patients undergoing major hepato-pancreato-biliary operations. As stated in the preoperative management, we use nasogastric decompression early in the perioperative period (usually 48 hours) and epidural analgesia with a combination of narcotic/local anesthetics. The postoperative pain management is augmented with scheduled intravenous Toradol and/or acetaminophen. No prophylactic, postoperative antibiotics are given. With return of bowel function, diet is slowly advanced. Serum chemistries (bilirubin, amylase/lipase) are followed in the first few days to ensure progressive decline.
- If present, the drain posterior to the hepaticojejunostomy is monitored for the character and volume of the output. Once the patient is tolerating a diet, and the drain effluent is serous, then the drain is removed prior to discharge.
- Some surgeons maintain these patients on suppressive antibiotics against cholangitis as with biliary atresia.
- Postoperative follow-up is at 2 weeks as part of routine care. Long-term follow-up is every 3 months for year 1, then annually in asymptomatic patients. This includes monitoring of serum liver enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT], γ-glutamyltransferase [GGT]), bilirubin, and amylase/lipase. Patients with elevations in their chemistries or clinical symptoms will undergo either a screening ultrasound with a focus on intrahepatic dilation or possibly a hepatobiliary iminodiacetic acid (HIDA) scan to evaluate functional bile excretion into the Roux limb. If there is a question about the Roux limb, a CT scan of the abdomen may be helpful. The long-term issue is related to anastomotic stricture and/or late stone formation as the etiology of the obstructive symptoms.

OUTCOMES

- The long-term outcomes for the surgical resection of choledochal cyst with Roux-en-Y hepaticojejunostomy are excellent (symptom free and overall survival over 90%).

The historical issue of malignancy and high rates of cholangitis/stones (90%) due to retained cysts has largely been eliminated due to the approach of complete excision and reconstruction, although there are rare cases after cyst excision. These cases probably represent incomplete excision of proximal or distal margins of the cyst. In broad terms, 2% to 10% of patients develop intrahepatic stones as follow-up goes out to 20 years. Stone formation can be associated with cholangitis, stricture, or both.

COMPLICATIONS

- Hemorrhage: PV or branches of the hepatic artery
  - Hepatic artery anastomotic leak pancreatitis
  - Late stricture
    - Cholangitis
    - Recurrent stones
  - Adhesive bowel obstruction

Chapter 14

Operative Treatment of Biliary Atresia

Charles S. Cox, Jr. *Robert Hetz*

DEFINITION

- Biliary atresia is an inflammatory process of unknown etiology that results in obliteration of the extrahepatic bile ducts in newborn infants. The incidence of biliary atresia is quoted as 1 per 10,000 live births, which in most U.S. referral centers should translate into approximately 4 to 5 cases per year.
- The Japanese Society of Pediatric Surgeons has classified the anatomic configurations of biliary atresia (**FIG 1**). The most common pattern is obliteration of the ducts from the porta to the common bile duct (CBD) (type I).
- Other variants not shown include fibrotic ducts and porta with a patent gallbladder and distal CBD.

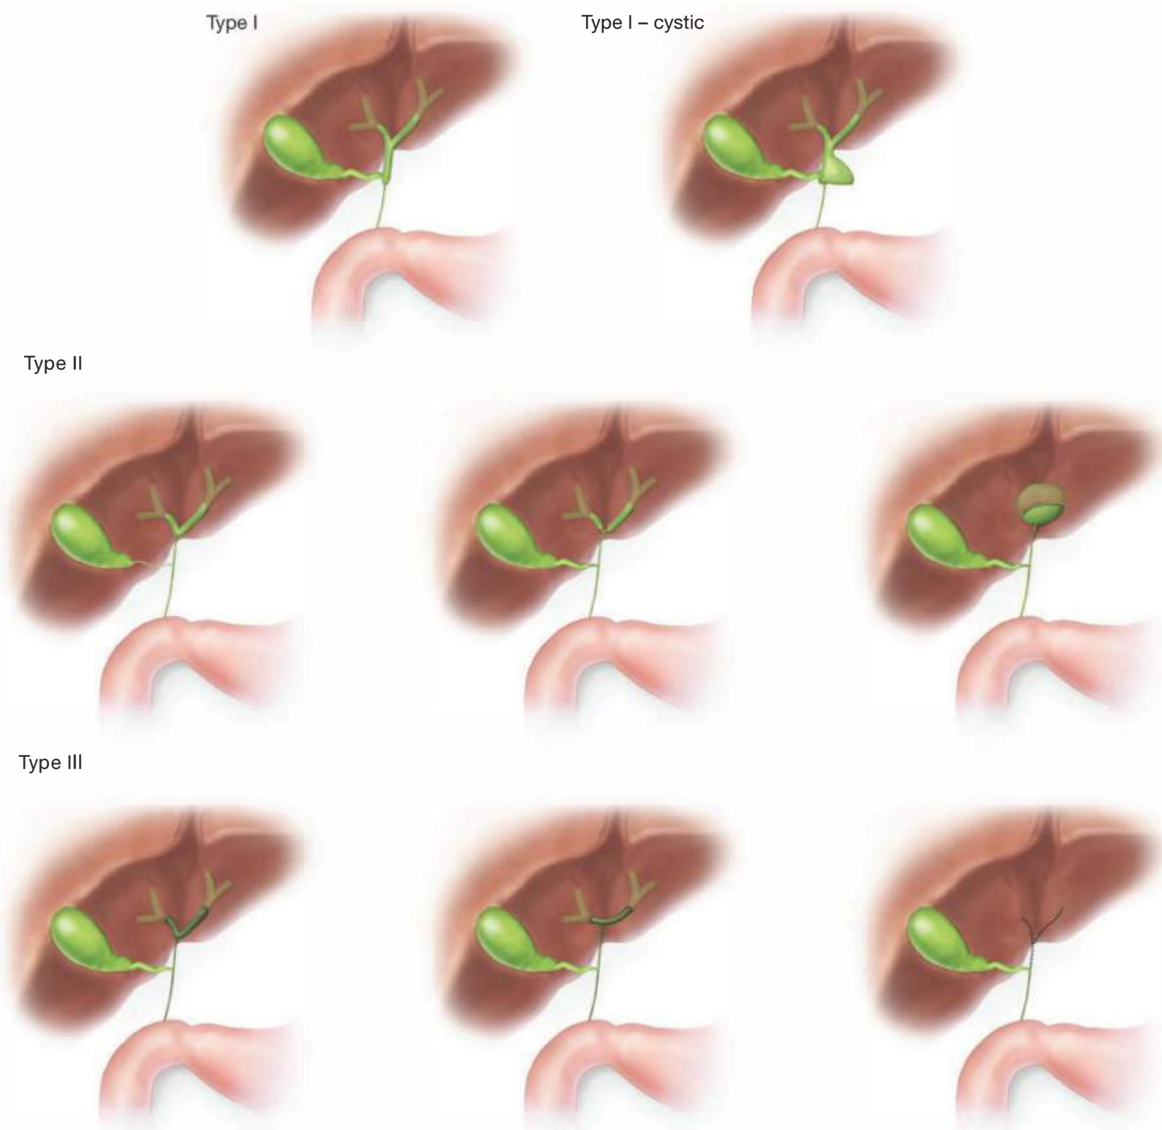

FIG 1 ● Classification of biliary atresia. Type I is associated with atresia at the level of the CBD; in type II, the atresia is at the level of the hepatic duct; in type III, atresia occurs at the porta hepatis.

- The "surgically correctable" form of biliary atresia is rare (10% of cases). In this situation, there is patency of a proximal segment of hepatic and/or common duct.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of a mixed hyperbilirubinemia in an infant includes the following:
  - Biliary atresia
  - Neonatal hepatitis
  - α1-Antitrypsin deficiency
  - Other metabolic deficiencies
  - Alagille's syndrome (biliary hypoplasia, pulmonary stenosis, vertebral anomalies, and elfin facies)
  - Choledochal cyst

PATIENT HISTORY AND PHYSICAL FINDINGS

- Infants are usually referred at approximately 6 to 8 weeks of age, placing a premium on rapid evaluation, diagnosis, and scheduling of operation. They typically present for evaluation of a mixed hyperbilirubinemia and the primary physical findings are jaundice and hepatomegaly. They also have acholic stools and dark urine.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Laboratory: The hallmark of the laboratory evaluation is a mixed hyperbilirubinemia. Investigations will be focused on excluding neonatal hepatitis, metabolic diseases, and α1-antitrypsin deficiency.
- Nuclear medicine: Technetium-based hepatobiliary scans are often used in the evaluation of infants with a mixed hyperbilirubinemia. Pretest preparation with phenobarbital for 3 to 5 days is useful. Visualization of the tracer in the duodenum/small intestine excludes biliary atresia. Slow uptake is indicative of a global hepatocyte dysfunction.
- Ultrasound: Imaging is usually supportive of the diagnosis of biliary atresia but is not definitively diagnostic. Usually, there is a thickened, contracted gallbladder and difficulty visualizing the extrahepatic biliary tree.
- Percutaneous liver biopsy: Recently, percutaneous needle biopsy has become one of the most definitive diagnostic tests in the evaluation of biliary atresia. The histologic appearance is that of any bile duct obstruction: portal tract edema and fibrosis, bile duct proliferation, and stasis. Mimics of biliary atresia are giant cell hepatitis, as it has some similar findings, most notably multinucleated giant cell infiltrates that can also occur with biliary atresia. Similar findings occur with Alagille's syndrome, which is characterized by biliary hypoplasia but associated with a characteristic elfin facies, pulmonary stenosis, and vertebral anomalies.

SURGICAL MANAGEMENT

- An important issue in the surgical management of patients with biliary atresia is the timing of the operation. In general terms, earlier is better. Results are better if the operation is performed before the infant reaches 6 weeks of age. Portoenterostomy may be reasonable up to 120 days of age, recognizing that the prognosis declines rapidly with delayed intervention.

Preoperative Planning

- Ensure that there is no coagulopathy. If present, must be treated with vitamin K (phytomenadione, 1 mg per day intramuscularly) and/or fresh frozen plasma replacement. Typically, a central vascular catheter or arterial line is not necessary. Epidural catheter anesthesia is a useful adjunct to intra- and postoperative pain management. A second- or third-generation cephalosporin should be administered prior to incision and continued until transition to oral cholangitis prophylaxis can be achieved.

Positioning

- The patient is placed in the supine position. A small towel roll is positioned transversely under the patient at the level of the lower chest/abdomen.

TECHNIQUES

- The authors recommend proceeding directly to an open exploration and cholangiogram. If positive, a classic Kasai portoenterostomy biliary drainage procedure is performed. The use of a laparoscopic approach has been associated with significantly worse outcomes.[1,2]

INCISION

- Initially, a small right-sided subcostal incision is made to perform the cholangiogram and then extended to facilitate the procedure once confirmation of the diagnosis has occurred. (**FIG 2**).

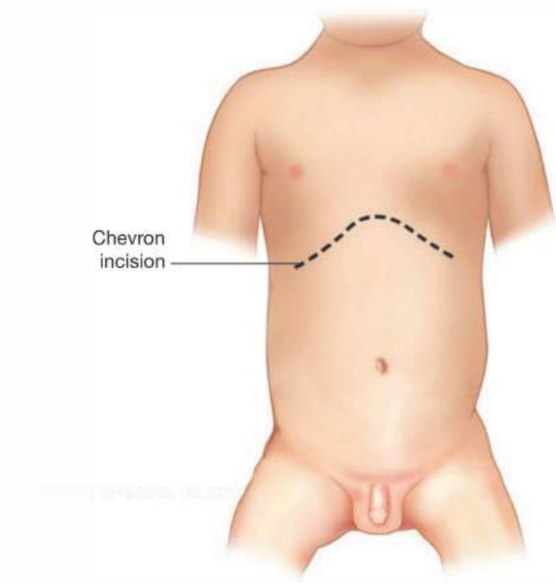

FIG 2 ● Incision. A modified hemi-chevron incision is used. Some centers use a more limited right subcostal incision, but to fully mobilize the liver requires a larger incision.

CHOLANGIOGRAM

- The gallbladder is identified; it is usually small and contracted with clear or milky bile in the lumen. A purse-string suture of 5-0 silk on a TF needle (or equivalent) is used and a cholecystotomy is made of a size to admit a 5-Fr infant feeding tube (**FIG 3**). Nondiluted Omnipaque 300 is injected under fluoroscopic visualization. If there is no visualization of the intrahepatic biliary tree, the distal porta hepatis should be occluded to promote visualization of the proximal hepatic ducts. If there is nonvisualization of the intrahepatic biliary tree, this typically confirms the diagnosis of biliary atresia.

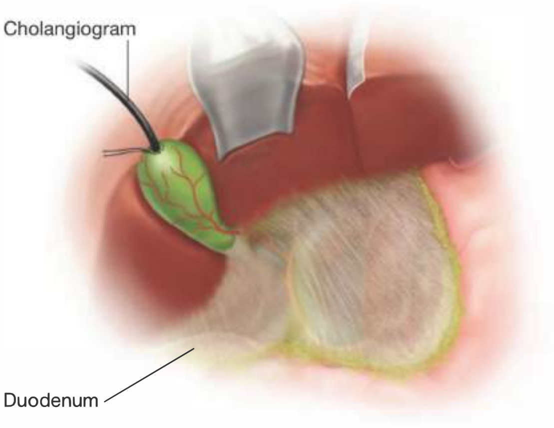

FIG 3 ● Intraoperative cholangiogram. A 5-Fr infant feeding tube is used to cannulate the dome of the gallbladder via a purse-string suture. Omnipaque 300 is used as a full-strength contrast agent to visualize the extrahepatic biliary tree. Aspiration of clear bile usually is indicative of biliary atresia. It can be difficult to be certain that the cannula is truly within the lumen of the gallbladder.

LIVER BIOPSY

- With more liberal use of percutaneous biopsy, there is little need for a redundant biopsy at the time of portoenterostomy. However, a classic biopsy that provides a larger sample is often informative regarding degree of liver injury and is essential when a percutaneous biopsy has not been obtained. This is performed as depicted in **FIG 4**. Using a 2-0 chromic suture on an SH or equivalent needle, two mattress-type sutures are placed in a "V" configuration from which the wedge biopsy will be

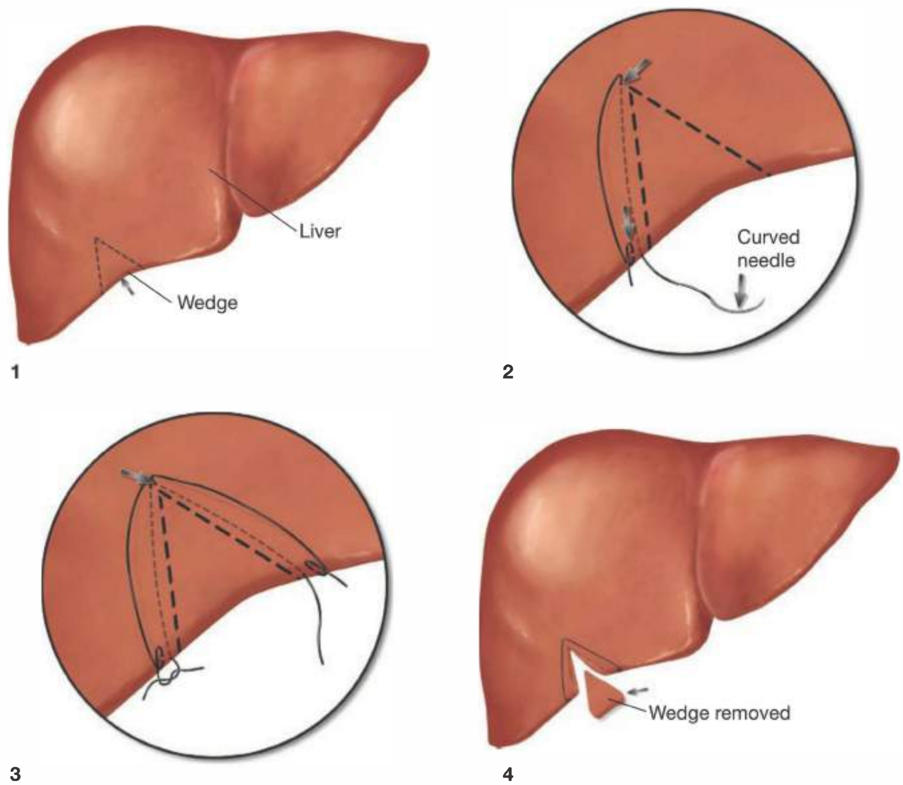

FIG 4 ● Liver biopsy. A V-shaped incision is made between two mattress sutures of 2-0 chromic that are then tied together over a Gelfoam bolster for hemostasis.

obtained. A no. 15 blade knife is used to excise a wedge of liver, and the bed is coagulated with the cautery. The tails of the chromic suture are left long and used to reapproximate the edges of the liver over a Gelfoam bolster that renders the field hemostatic. This should be done immediately after the cholangiogram to optimally ensure the site is hemostatic at the conclusion of the procedure and to prevent inadvertent omission of the biopsy following the main portion of the procedure—the portoenterostomy.

HEPATIC MOBILIZATION

- To fully expose the porta hepatis, a full mobilization of the liver is performed. Both triangular ligaments and the falciform ligament are divided, and the liver is rotated up into the wound. This is far more effective in infants and children than in adults. Laparotomy pads are placed behind the liver to maintain the exposure. However, care must be taken to not allow excessive tension to be placed on the portal vascular structures. An assistant's hand can further splay open the porta during critical elements of the dissection. Some authors have advocated against this maneuver arguing that it increases retrohepatic scarring in case of future transplantation. The authors are of the opinion that the value of optimum exposure to provide the greatest precision of the portal dissection and anastomosis outweighs the additional dissection that will be required should liver transplant ultimately be required (**FIG 5**).

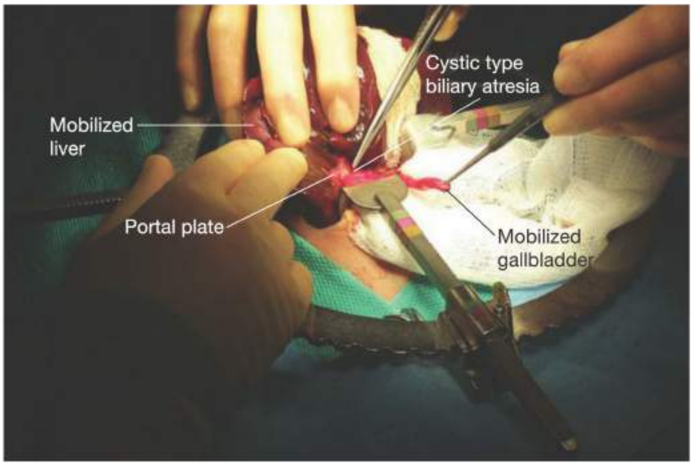

FIG 5 ● Intraoperative photographs of the hepatic and gallbladder mobilization. The left and right triangular ligaments and the ligamentum teres are all divided up to the hepatic venous hilum. This allows complete mobilization of the liver up into the incision, thus providing excellent exposure of the porta hepatis. The gallbladder is mobilized after the cholangiogram and used for a traction "guide" to the atretic extrahepatic biliary tree. The veil of peritoneum overlying the portal structures is divided with cautery and the vascular structures are identified and separated from the atretic bile ducts.

PORTAL DISSECTION

- Identification of vascular structures: The gallbladder is mobilized in a retrograde fashion using electrocautery until the cystic artery is identified. This is then traced back to the right hepatic artery. Further antegrade dissection beginning near the celiac artery trifurcation first identifies the common hepatic artery and then origin of the left and right hepatic arteries. Aberrant arterial anatomy must be considered. Expect disproportionately enlarged lymph nodes in the region. The left and right hepatic arteries should be isolated with vessel loops or 0 silk suture. Posterior and left in the porta, the anterior aspect of the portal vein (PV) is exposed.
- Division of distal extrahepatic biliary tree: With the hepatic vessels identified, the gallbladder is used for traction to dissect the posterior aspect of the atretic extrahepatic biliary tree from the vessels (**FIG 6A**). This dissection is carried distally to the head of the pancreas. The distal segment is ligated and sharply divided. The dissection is then followed proximally revealing a cone of tissue in the porta (**FIG 6B**).
- Proximal dissection: The outline of the portal plate dissection is the crescent-shaped boundary of the PV and the right and left hepatic arteries from which the atretic, extrahepatic biliary tree exits the hepatic parenchyma. As dissection enters the liver, there should be a transition from fibrotic, atretic, pale structures to softer, darker liver.
- Portal transection: The critical element of the operation is the depth and boundaries of the portal dissection. The confluence of the PV must be retracted inferiorly and the left and right branches must be retracted laterally with small tributaries ligated or cauterized (bipolar electrocautery can be useful). The entire liver plate is sharply transected either with angled scissors or a beaver-blade knife (**FIG 6C**). The optimal level is to be just at but not into the liver parenchyma. The optimal level for the portoenterostomy is represented by the virtually translucent, thin layer that is left in place. Bleeding is controlled with 1:100,000 epinephrine-soaked Gelfoam and pressure using cotton tip applicators. Very minimal needle tip/low-setting cautery can be used judiciously if absolutely necessary. The Gelfoam can be left in place and the liver returned to the abdomen as the Roux limb is created and the jejunojejunostomy performed. Some surgeons send this proximal margin of the portal dissection for specific evaluation of ductal diameter to guide further dissection and/or prognosis; however, the authors have not found this to be particularly useful intraoperative information.

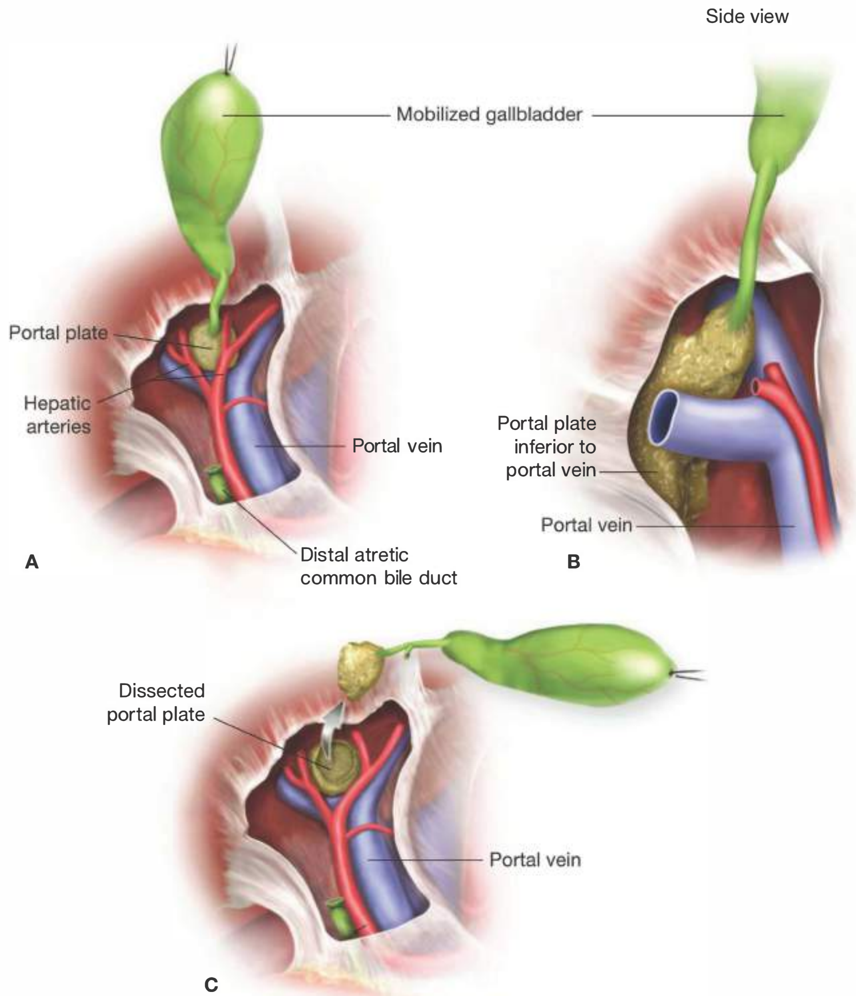

FIG 6 ● Portal dissection. The portal dissection commences once the vascular and ductal structures are identified. The CBD is divided and ligated distally, then dissected up until the tissue fans out into a conical configuration bordered by the PV inferiorly and laterally. **A.** The gallbladder is mobilized and used as traction to expose the cone of tissue at the porta. **B.** Lateral view of the dissection showing how the cone of the portal plate dips inferior to the PV confluence and why retraction down on the PV to place the posterior row of sutures is important. **C.** The dissected portal plate is transected just at the level of the liver capsule.

ROUX-EN-Y LIMB CREATION

- Retrocolic Roux-en-Y hepaticojejunostomy. The standard approach is to create a 40-cm Roux limb that originates 10 cm from the duodenojejunal junction. This is illustrated in the drawings in **FIG 7** and the initial anastomosis is shown in **FIG 8**. Numerous techniques are commonly used for the jejunojejunostomy. The authors prefer an end (proximal jejunum) to side (distal jejunum), single layer, hand-sewn anastomosis using interrupted 5-0 sutures. The end of the Roux limb is closed in two layers and then brought through a defect created in the transverse mesocolon to the right of the middle colic vessels.

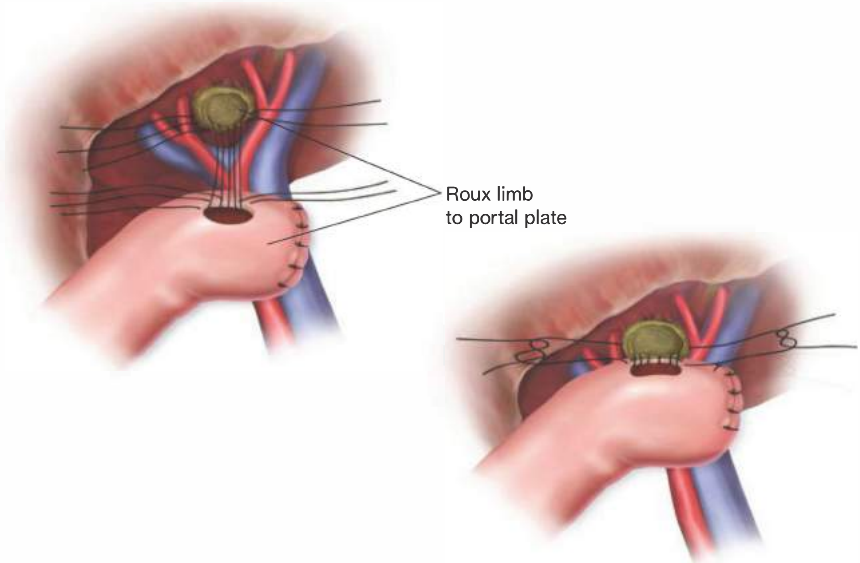

FIG 7 ● Portoenterostomy. The anastomosis is created using 5-0 absorbable monofilament sutures. The PV is retracted inferiorly and the sutures on the hepatic parenchyma/capsule are placed parallel to the PV. Knots can be inside or outside without affecting biliary drainage. The anterior row is placed with the same type of placement of suture on the hepatic parenchyma and knots on the outside.

FIG 8 ● Completed portoenterostomy. The intraoperative photograph shows a completed anastomosis at the level of the porta with a well-perfused Roux limb with a side anastomosis.

TECHNIQUES

PORTOENTEROSTOMY

- The antimesenteric border of the Roux limb is used for the anastomosis to the portal plate. Absorbable 5-0 monofilament sutures are used to create an interrupted, single-layer anastomosis (see **FIG 7**). First, the posterior row of sutures is placed in the liver capsule parallel to the porta border while inferiorly retracting the PV. This retraction maneuver minimizes the risk of occluding the plate with the edge of the anastomosis/jejunal border. The critical elements of the anastomosis are designed to capture the biliary drainage from the regions adjacent to the PV branches; these are lateral in the portal plate. To accomplish this, the hepatic capsular sutures should be oriented parallel to the PV, retracting the PV to get as far back from the site of drainage so as not to occlude these ductules with the subsequent anastomosis. The anterior suture line is then completed. **FIG 8** demonstrates a completed anastomosis. The limb is secured to the mesocolic defect with interrupted sutures, and the mesenteric defect of the jejunal anastomosis is closed as well.

PEARLS AND PITFALLS

Interpretation of cholangiogram	■ It is critical to occlude the distal CBD to ensure that potentially hypoplastic proximal ducts can fill. This avoids performing a Kasai for biliary hypoplasia.
Roux limb certainty	■ Always double check Roux limb anatomy such that distally divided jejunum is used for the limb; an error can be made by erroneously bringing proximal jejunum to the porta. Also, ensure that there is not a redundant segment that can kink as the normal anatomic position of the liver is reestablished.
Portal dissection/anastomosis	■ The critical dissection is to divide the porta just at the liver capsule to a translucent layer, behind which is the hepatic parenchyma. Do not cut into the liver as it only bleeds and increases scarring. ■ Ensure lateral dissection at the zone into which one can imagine the bile ducts exiting the liver normally. Do not allow hepatic sutures to occlude the sites of drainage; place these sutures parallel to the vessels as the PV is retracted.
Vascular injury	■ If the hepatic arteries are looped, do not allow them to stay on tension for any significant period of time; thrombosis has been reported.

POSTOPERATIVE CARE

- Standard—The postoperative care is routine. A nasogastric tube remains in place until the patient passes flatus (2 to 3 days). A small Jackson-Pratt drain can be left in Morrison's pouch, but this could easily be omitted without consequence. If present, the drain is removed once the patient is on a diet and there is no bile in the drain. Pain control is heavily augmented by an epidural catheter and allows minimization of narcotics. Avoid the use of acetaminophen or other hepatotoxic drugs.
- The most important prognostic sign is the transition of the color of the stool with a green diaper representing an excellent day for the patient and team; pigmented stools suggest successful bile flow.
- Antibiotic prophylaxis for cholangitis—Intravenous antibiotics against Gram-negative organisms are continued beyond the perioperative prophylaxis time period to minimize the risk of cholangitis. Once the patient has begun an oral diet (usually days 2 to 4), they can be transitioned to trimethoprim (TMP)-sulfamethoxazole at 2.5 mg/kg/day based on the TMP component.
- Nutritional supplementation—We routinely discharge patients with vitamins A, D, E, and K supplements.
- Steroids—The perioperative use of steroids is controversial. The rationale is that biliary atresia is a progressive inflammatory process and also has choleretic effects. Currently, approximately half of pediatric surgical centers use perioperative steroids. The Biliary Atresia Research Consortium is studying this issue; however, the results are not yet available. Davenport et al.[3] reported a hastening of jaundice resolution without an effect on transplant-free survival. Their regimen was 2 mg/kg/day of prednisolone from days 7 to 21 tapering to 1 mg/kg/day from days 22 to 28. We use a higher pulse dose and start earlier according to the schedule noted in Table 1.

Table 1: Post-Kasai Steroid Pulse-Taper Dosing Schedule

Dose	Days	Postoperative Day
10 mg/kg	1	1
8 mg/kg	1	2
6 mg/kg	1	3
4 mg/kg	1	4
2 mg/kg	1	5
1 mg/kg	7	6–12
0.5 mg/kg	7	13–19
0.3 mg/kg	7	20–26
0.2 mg/kg	7	27–33
0.1 mg/kg	7	34–40

OUTCOMES

- Early, successful biliary drainage is defined as a total serum bilirubin less than 2.0 mg/dL in the first 3 months post-Kasai. In multiple studies, the postoperative resolution of jaundice ranges from 40% to 60%. The 1-year transplant-free survival in those patients with successful drainage was approximately 50%, thus early successful bile drainage is a strong indicator of a durable operative result.[4,5]

COMPLICATIONS

- Cholangitis—This complication typically presents with fever, an acute rise in the bilirubin, and return of acholic stools. This occurs more frequently in the first 6 months post portoenterostomy, and we aggressively treat this with parenteral antibiotics against Gram negatives, a repeat steroid pulse/taper regimen, and occasionally, a brief course of phenobarbital as a choleretic. Repetitive bouts of cholangitis should be investigated with a hepatobiliary iminodiacetic acid (HIDA) scan to rule out an afferent limb obstruction as the etiology rather than failure of the portoenterostomy.
- Progressive hepatic failure/portal hypertension—Despite bile drainage, some patients develop progressive hepatic insufficiency with a normal bilirubin. Typically, this is first manifest by hepatosplenomegaly and platelet sequestration in the spleen. Ascites and growth failure typically ensue. Duplex imaging of the portal venous system should be performed to evaluate for thrombosis or hepatofugal flow in the PV. The complications of portal hypertension are usually long-term management issues (>10 years). Varices should be conventionally managed with sclerotherapy or banding as appropriate. Rarely is portosystemic shunting required, and this usually corresponds with the need for ultimate hepatic transplantation.
- Early cessation of bile flow—Portoenterostomy revision has traditionally been discouraged due to the successful results with hepatic transplantation and the assumption that reoperation would only increase the difficulty of ultimate transplantation. This issue has been recently challenged.[1] Candidates for revision of the portoenterostomy should be limited to those with initially satisfactory bile drainage, or those with recurrent cholangitis and jaundice. Revision in a select group of patients (i.e., good initial bile drainage, not primary failure of the portoenterostomy) converted these patients to similar long-term transplant-free survival as those patients with durable bile flow. It remains controversial but probably reasonable to revise the portoenterostomy in this select group of patients.

Chapter 15 Surgical Anatomy of the Liver

Teviah Sachs Timothy M. Pawlik

SIZE AND POSITION

- The human liver is the largest internal organ in the body. It is estimated to weigh 0.2% to 0.3% of ideal body weight, or approximately 1400 to 2100 g in an otherwise healthy adult patient,[1] depending on age, sex, and various disease processes.
- The liver sits in the right upper quadrant of the abdomen, beneath the diaphragm, and is sheltered by the ribs.
- In broad terms, the liver extends from the right 5th intercostal space superiorly to the edge of the costal margin inferiorly. A liver palpable below the costal margin often is a sign of hepatomegaly.
- The left lobe of the liver extends beyond the midline and can reach as far left as midclavicular line.
- Its location relative to external landmarks is neither consistent nor static and can vary depending on patient position, individual anatomy, and respiratory cycle. This must be taken into account when performing percutaneous procedures; radiographic guidance is essential.
- Liver dimensions vary depending on age, gender, and disease states. Average dimensions are presented in Table 1.
- The right and left hemilivers are anatomically and spatially divided by Cantlie's line, which runs from the fundus of the gallbladder to the suprahepatic inferior vena cava (IVC). Within the substance of the liver, the middle hepatic vein courses along this same path and is the true division of the right and left hemilivers (**FIG 1**).

COUINAUD'S SEGMENTS

- In 1954, Couinaud[2] published his seminal work, *Le Foie: Études Anatomiques Et Chirurgicales*, in which he classified the liver into segments, each with their own inflow, outflow, and biliary drainage (**FIG 2**). He based his segments on the arborization of the portal vein within the liver. These segments begin with the caudate lobe (segment 1) and continue in a clockwise fashion from left to right.
- Couinaud[3] further divided the liver based on sectors, which are based on the arborization of the hepatic veins, each of which relies on a portal pedicle (**FIG 3**).

Table 1: Average Dimensions of the Adult Liver

Direction	Length (cm)
Anterior to posterior	10.0–12.5
Right to left	20.0–25.5
Caudad to cephalad	15.0–17.5

From Kennedy PA, Madding GF. Surgical anatomy of the liver. Surg Clin North Am. *1977;57:233–244.*

GOLDSMITH AND WOODBURNE CLASSIFICATION

- Goldsmith and Woodburne[4] divided the liver into the caudate lobe and four distinct segments:
  - Left lateral (Couinaud segments 2 and 3)
  - Left medial (Couinaud segment 4)
  - Right anterior (Couinaud segments 5 and 8)
  - Right posterior (Couinaud segments 6 and 7)

BISMUTH CLASSIFICATION

- Bismuth divided the liver based on fissures: three vertical lines corresponding to the divisions made by the three major hepatic veins.[5]
- The fourth fissure, named the transverse fissure, is based on the level of the portal vein bifurcation within the liver and divides the "upper" liver from the "lower" liver.
- Bismuth identified eight subsegments:
  - Caudate lobe (Couinaud segment 1)
  - Left superior subsegment (Couinaud segment 2)
  - Left inferior subsegment (Couinaud segment 3)
  - Left medial subsegment (Couinaud segment 4)
  - Right anterior inferior subsegment (Couinaud segment 5)
  - Right posterior subsegment (Couinaud segment 6)
  - Right posterior superior subsegment (Couinaud segment 7)
  - Right anterior superior subsegment (Couinaud segment 8)

THE BRISBANE TERMINOLOGY OF LIVER ANATOMY AND RESECTION

- Due to the confusion between various classifications, the International Hepato-Pancreato-Biliary Association (IHPBA) formed a committee in 1998 to delineate an accepted and

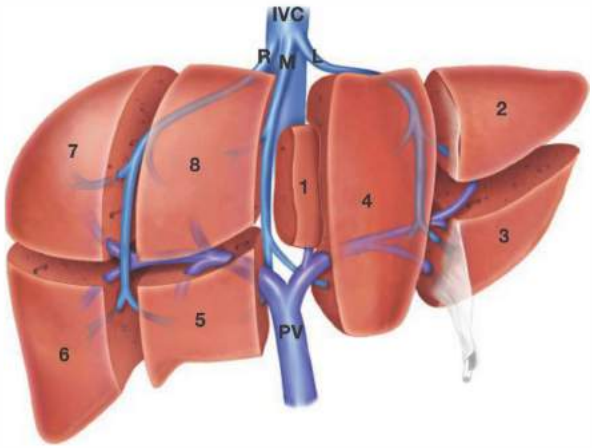

FIG 2 ● Diagram showing the segments (numbered *1* to *8*) of the liver as described by Couinaud. The *IVC* as well as the right *(R)*, middle *(M)*, and left *(L)* hepatic veins. The portal vein *(PV)* is also shown. (From Smadja C, Blumgart L. The biliary tract and the anatomy of biliary exposure. In: Blumgart L, ed. *Surgery of the Liver and Biliary Tract*. New York, NY: Churchill Livingstone; 1994:11–24.)

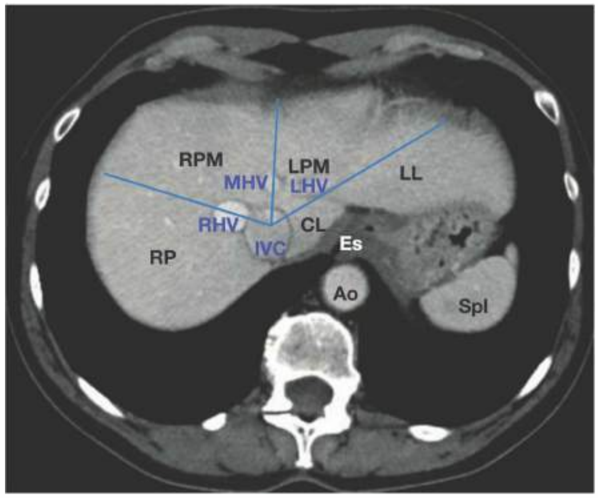

FIG 3 ● Axial CT image, venous phase, showing the right (RHV), middle (MHV), and left (LHV) as they enter the inferior vena cava (IVC). *Blue lines* show approximate direction of hepatic veins as they traverse the liver. Individual liver sectors are labeled (*RL*, right lateral; *RPM*, right paramedian; *LPM*, left paramedian; *LL*, left lateral). Also labeled are the caudate lobe *(CL)*, esophagus *(Es)*, aorta *(Ao)*, and spleen *(Spl)*.

universal terminology to describe hepatic anatomy and, more specifically, hepatic resections.[6] In 2000, their terminology was published. In it, a nomenclature for anatomic terminology and that of surgical resection were clearly delineated (Table 2).

CAUDATE LOBE

- The caudate lobe is distinct in many ways. Because of its distinct inflow, outflow, and drainage, it is sometimes termed "the third lobe of the liver."
- Embryologically, it is derived from the right lobe,[7] laying on the posterior surface of the right hemiliver, bordered on the left by the ligamentum venosus. It is bordered superiorly by the hepatic veins as they enter the IVC and posteriorly by the IVC itself. Inferiorly, it is bordered by the hilum of the liver and the bifurcation of the left and right portal veins.
- Anatomically, there are three portions to the caudate lobe (**FIG 4**), each based on the portal inflow:[8]
  - The Spiegelian lobe (or Spiegel's lobe)
  - The paracaval portion (or Couinaud's segment 9)
  - The caudate process

Table 2: The Brisbane 2000 Terminology of Liver Anatomy and Resections

Anatomical Term*	Couinaud Segments	Surgical Resection Term	Based Upon
Right Liver *Right Hemiliver*	5–8	*Right Hepatectomy* *Right Hemihepatectomy*	Midplane of liver
Left Liver *Left Hemiliver*	2–4	*Left Hepatectomy* *Left Hemihepatectomy*	
Right Anterior Section	5, 8	*Right Anterior Sectionectomy*	Hepatic artery and biliary duct divisions
Right Posterior Section	6, 7	*Right Posterior Sectionectomy*	
Left Medial Section	4	*Left Medial Sectionectomy*	
Left Lateral Section	2, 3	*Left Lateral Sectionectomy*	
Right Anterior Sector *Right Paramedian Sector*	5, 8	*Right Anterior Sectorectomy* *Right Paramedian Sectorectomy*	Portal vein divisions
Right Posterior Sector *Right Lateral Sector*	6, 7	*Right Posterior Sectorectomy* *Right Lateral Sectorectomy*	
Left Medial Sector *Left Paramedian Sector*	3, 4	*Left Medial Sectorectomy* *Left Paramedian Sectorectomy*	
Left Lateral Sector *Left Posterior Sector*	2	*Left Lateral Sectorectomy* *Left Posterior Sectorectomy*	

**Terms that include segment 1 should be stated as such (i.e., left hepatectomy extended to segment 1).*
Adapted from Strasberg SM. Terminology of liver anatomy and resections: the Brisbane 2000 terminology. In: Clavien PA, Sarr MG, Fong Y, eds. Atlas of Upper Gastro-intestinal and Hepato-Pancreato-Biliary Surgery. *Berlin: Springer; 2007:313–317.*

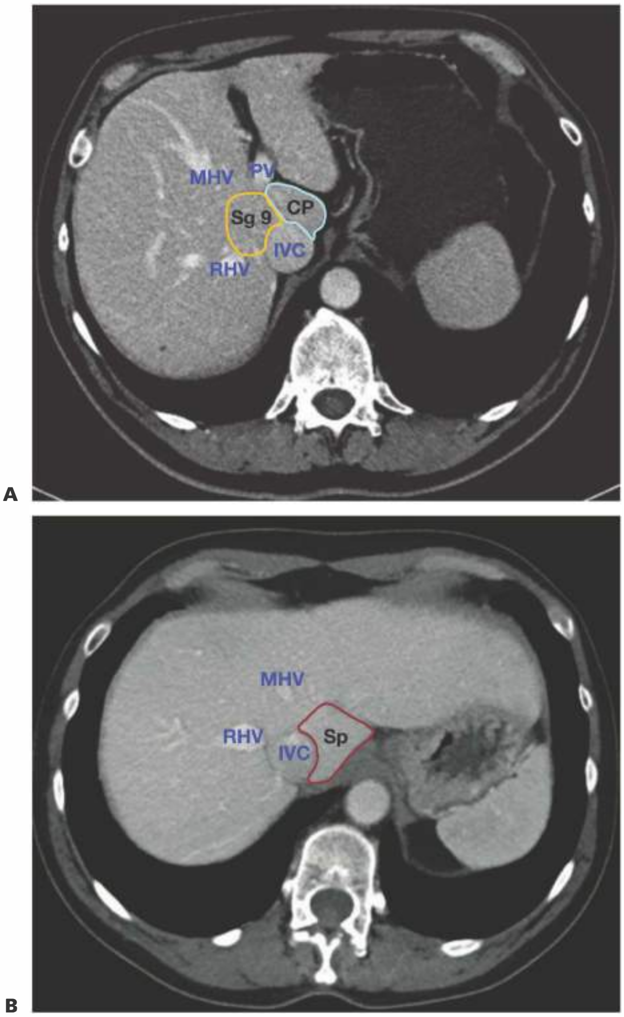

FIG 4 ● **A.** Axial CT image showing the caudate lobe. The caudate process *(CP)* is bounded by the anterolateral surface of the *IVC*, the left portion of liver hilum, and the left hepatic vein (not shown). Segment 9 *(Sg 9)* is known as the paracaval process and is bounded by the anterior surface of the *IVC*, the middle hepatic vein (*MHV*), and the right hepatic vein *(RHV)*. Also shown is the portal vein *(PV)*. **B.** Axial CT image (slightly more caudal than in **[A]**) showing Spiegel's lobe *(Sp)*—also known as segment 1—as it wraps around the medial aspect of the *IVC*.

- Surgically, the caudate can be divided in two: segment 1 (Spiegel's lobe) and so-called segment 9 (paracaval portion and caudate process) (**FIG 5**).
- The use of terminology related to Couinaud segment 9 is often dropped from the literature and this term is neither universally accepted nor used.
- The paracaval portion, which projects medially, can circumferentially wrap around the IVC.[9] This can be misinterpreted on computed tomography (CT) scan as an enlarged lymph node, and the surgeon should be aware of this to avoid inappropriate preoperative staging of a patient.
- The caudate derives its portal inflow from the left and right portal veins; venous drainage is directly into the IVC via multiple small caudate veins. Thus, in diseases of hepatic venous obstruction, such as Budd-Chiari syndrome, it will hypertrophy and provide alternate routes for obstructed hepatic venous flow.

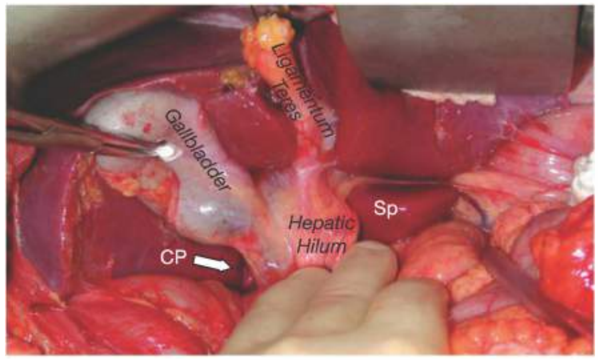

FIG 5 ● In situ photograph showing Spiegel's lobe *(Sp)* and the caudate process *(CP)* in relation to the hepatic hilum. Also shown are the gallbladder and the ligamentum teres.

SURFACE ANATOMY

- The liver is covered by a thin membrane called Glisson's capsule. This epithelial layer is contiguous with internal anatomy of the liver as sheaths around the portal veins, hepatic arteries, and bile ducts.[10]
- Despite its rounded, pyramidal shape, the liver can be described as having two surfaces: visceral and diaphragmatic.
  - The visceral surface is inferior.
  - The diaphragmatic surface can be divided into anterior, posterior, superior, and lateral aspects.
    - The anterior aspect opposes the diaphragm and the posterior abdominal wall. It is generally smooth and has few if any impressions.
    - The posterior aspect contains the bare area of the liver as well as the confluence of the hepatic veins prior to their entry into the IVC.
    - The lateral aspect opposes the right ribs 7 to 11, which often leave impressions on the liver surface.
    - The superior aspect is a continuation of the anterior surface and ends at the coronary ligament. It contains the cardiac impression and extends medially and laterally, sitting below the left and right lungs and pleura. This is clinically important as neoplasms of the dome of the liver can manifest by sympathetic effusions and diaphragmatic splinting.
- The majority of the surface of the liver is free of peritoneum, but there are several attachments and reflections of peritoneum—referred to as ligaments—that suspend the liver in its position.
  - Failing to properly understand these attachments can lead to injury to the associated visceral organs or the diaphragm.
- The falciform ligament is a bileafed peritoneal reflection, which envelops the ligamentum teres.
  - The ligamentum teres, or round ligament, is the remnant of the umbilical vein.
  - After enveloping the ligamentum teres, the peritoneum attaches anteriorly and superiorly to the posterior abdominal wall, tethering the liver slightly to the right of the midline.

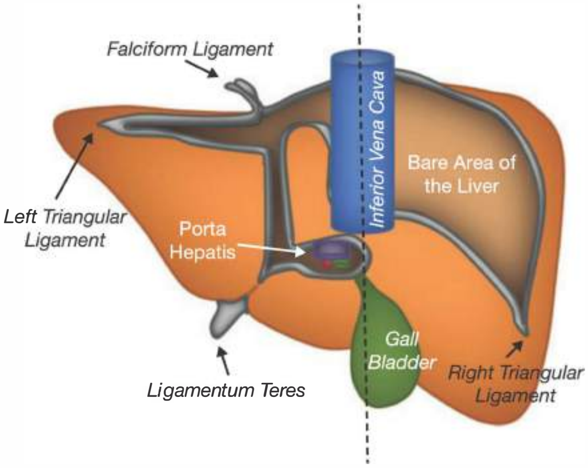

FIG 6 ● Posterior view, depicting the peritoneal reflections constituting the ligaments of the liver. Note the bare area at the caudal posterior surface of the liver. Also note the relative length of the left triangular ligament as compared to the right triangular ligament. The *dotted line* represents Cantlie's line, which divides the right and left hemilivers.

- Posteriorly and inferiorly, the ligamentum teres enters the liver between segments 3 and 4, whereas, in utero, the umbilical vein drains into the left portal vein.
- Although technically obliterated early in life, the umbilical vein recanalizes in cirrhotics and other patients with portal hypertension and must be carefully controlled when divided.

- The ligamentum venosus, also known as Arantius' ligament, in which the remnant of the ductus venosus lies, sits between the caudate lobe (segment 1) and the left lobe of the liver.
  - It forms a bridge between the left portal vein and the left hepatic vein, or sometimes to the junction of the left and middle hepatic veins. This can be very useful in locating the left hepatic vein during hepatic resection.
- The coronary ligament is the reflection of the visceral peritoneum as it attaches to the diaphragm. This creates a fibrous peritoneal ring or crown (Latin: *corona*) around the caudal posterior surface of the right hemiliver, encircling the bare area of the liver (**FIG 6**).
  - The bare area is so named because there is nothing between the liver and the diaphragm other than loose areolar tissue.
  - As the coronary ligament makes a sharp turn at the right posterior lateral edge of the liver, it creates an acute angle and is called the right triangular ligament.
  - On the left, the anterior and posterior edges similarly combine to form the left triangular ligament, which is longer and suspends the left lobe from the diaphragm.
- Visceral ligaments include the hepatorenal, gastrohepatic, and hepatoduodenal ligaments (**FIG 7**).
  - The hepatorenal ligament reflects off of the right coronary ligament posteriorly and inferiorly and then again off the right adrenal gland and superior pole of the right kidney.
  - The gastrohepatic ligament is a reflection off of the lesser curve of the stomach and the left coronary ligament inferiorly.
  - The gastrohepatic ligament is contiguous with the hepatoduodenal ligament, in which the porta hepatis runs, and together they form the lesser omentum.

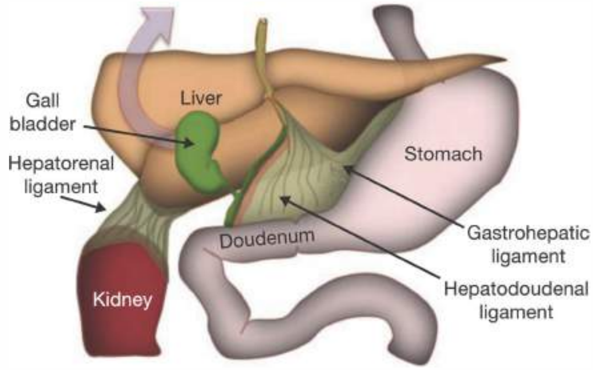

FIG 7 ● Diagram showing the attachments of the gastrohepatic, hepatoduodenal, and hepatorenal ligaments. The free edge of the liver is rotated superiorly as depicted by the *arrow*. The gastrohepatic and hepatoduodenal ligaments are contiguous.

BLOOD SUPPLY

- The liver has a dual blood supply, the hepatic artery and the portal vein, which equally provide the liver with oxygen.
- The portal vein supplies the liver with approximately 75% of its blood volume and the remainder is supplied by the hepatic artery.

Hepatic Arteries

- The common hepatic artery comes directly off the celiac trunk and gives rise to the right gastric and gastroduodenal arteries before becoming the proper hepatic artery (**FIG 8**).
- The proper hepatic artery travels within the hepatoduodenal ligament. It is spatially anterior to the portal vein and medial to the common bile duct. It divides into right and left hepatic arteries prior to entering the porta hepatis.
- The cystic artery most commonly comes off the right hepatic artery but can come off the proper hepatic artery or left hepatic artery, making misidentification of this structure a risk during cholecystectomy or other operations.

Right hepatic artery

- The right hepatic artery is generally longer than the left and follows a slightly more oblique angle, curving toward the

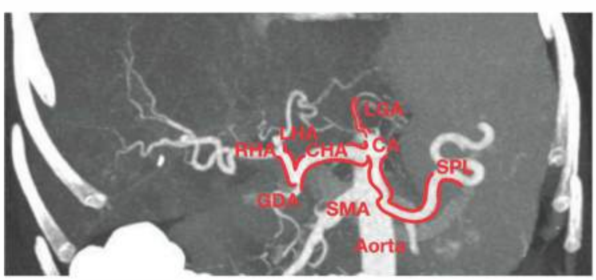

FIG 8 ● CT angiogram showing classic arterial anatomy. The common hepatic artery *(CHA)* and splenic artery *(SPL)* come off of the celiac axis *(CA)*. The CHA then gives off the gastroduodenal artery *(GDA)* and becomes the proper hepatic artery. This then divides into the right *(RHA)* and left *(LHA)* hepatic arteries. The *aorta* is also labeled, as is the left gastric artery *(LGA)* and the *SMA*.

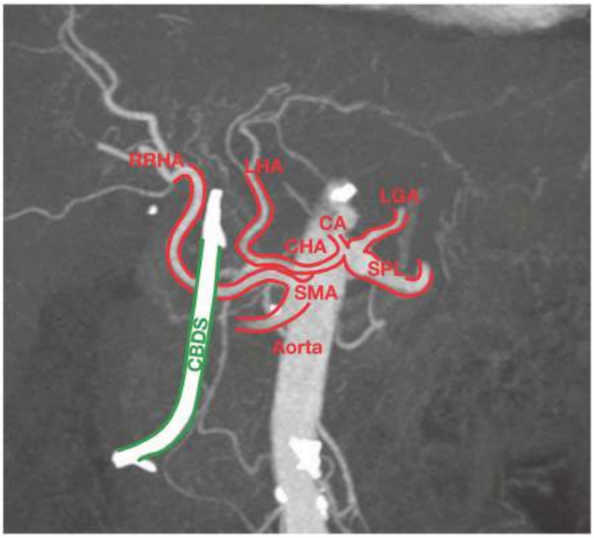

FIG 9 • A CT angiogram showing a replaced right hepatic artery *(RRHA)* coming off the *SMA*. A stent *(CBDS)* is seen in the common bile duct, which shows the anatomical relationship of the RRHA as it passes behind the common bile duct and portal vein (not shown).

neck of the gallbladder before arching again toward the posterior sector.[11] Due to its meandering course, it can be injured during cholecystectomy or misinterpreted as the cystic artery and ligated.

- After arching toward the gallbladder, it bifurcates intrahepatically into anterior (supplying segments 5 and 8) and posterior (supplying segments 6 and 7) sectoral branches. These, in turn, branch inferiorly and superiorly, to form the individual segmental branches.

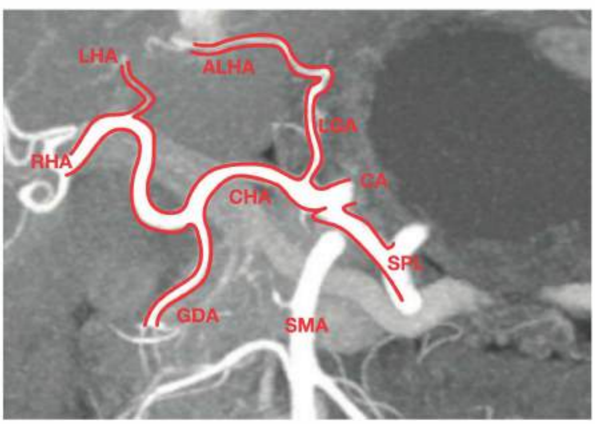

FIG 10 • CT angiogram showing an accessory left hepatic artery *(ALHA)* coming off of the left gastric artery *(LGA)*. The right hepatic artery *(RHA)* is seen coming off in normal anatomic position, from the common hepatic artery *(CHA)* just after it gives off the gastroduodenal artery *(GDA)*. The true left hepatic artery *(LHA)* is also seen, although it is far less pronounced than the RLHA which is the dominant arterial supply to the left hemiliver. Also shown are the following: *SMA*, celiac axis *(CA)*, and splenic artery *(SPL)*.

- In up to 20% of patients, the right hepatic artery has a variable anatomy.[12,13] The most common variant is the replaced or accessory right hepatic artery (**FIG 9**), which originates from the superior mesenteric artery (SMA), traveling posterior to the portal vein.
- The pancreatobiliary surgeon must always be cognizant of this aberrant anatomy.
- In approximately 10% of patients, the right hepatic artery will cross anterior to the common bile duct prior to entering the liver.

Left hepatic artery

- The left hepatic artery bifurcates early, into the medial (segment 4) and lateral (segments 2 and 3) sectoral branches. In some patients, the left hepatic artery does not exist, and the left medial sectoral branch arises from the right hepatic artery, crossing the midline passing posterior to the left lateral branch to supply segment 4.[14]
- The replaced or accessory left hepatic artery is less common, occurring in 10% to 15% of patients. When present, it arises from the left gastric artery, traveling instead in the gastrohepatic ligament (**FIG 10**).

Portal Veins

- The portal vein originates at the confluence of the splenic and superior mesenteric veins (**FIG 11**). It then runs superolaterally into the hilum of the liver, posterior and medial to the proper hepatic artery and common bile duct (**FIG 12**). The portal vein then divides early, most often while still in the hepatic hilum, into right and left portal veins.

Right portal vein

- The right portal vein follows a more linear path and branches early into anterior (segments 5 and 8) and posterior (segments 6 and 7) branches. These, in turn, give off the individual superior and inferior segmental branches.
- The right portal venous anatomy is often variable and preoperative as well as intraoperative; imaging is recommended prior to resection.

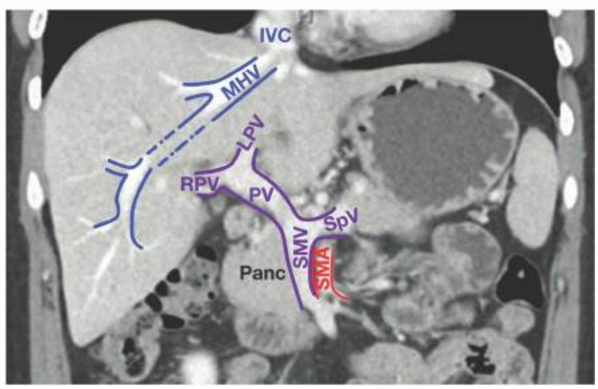

FIG 11 • Coronal CT demonstrating the confluence of the splenic vein *(SpV)* and the superior mesenteric vein *(SMV)* as they form the portal vein *(PV)*. The left portal vein *(LPV)* makes a sharp angle from the *PV*, whereas the right portal vein *(RPV)* is more direct. Note the proximity of the *SMV* and the *SMA* to the pancreatic head. Also shown are the *IVC* and middle hepatic vein *(MHV)*.

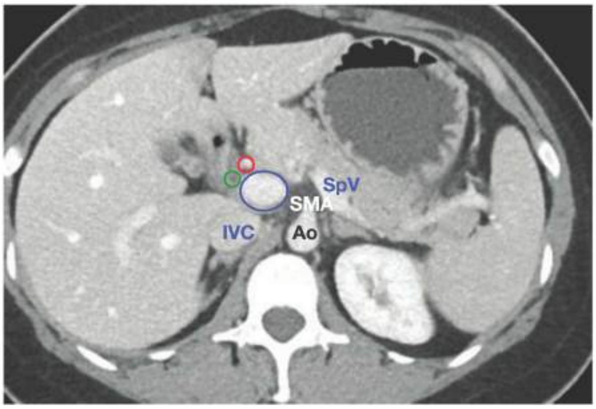

FIG 12 ● Axial CT demonstrating the normal anatomic relationship of the bile duct *(green circle)*, hepatic artery *(red circle)*, and portal vein *(blue circle)*. And they enter the hilum of the liver. Also labeled are the *IVC*, splenic vein *(SpV)*, aorta *(Ao)*, and *SMA*. This patient had a mass in the head of the pancreas.

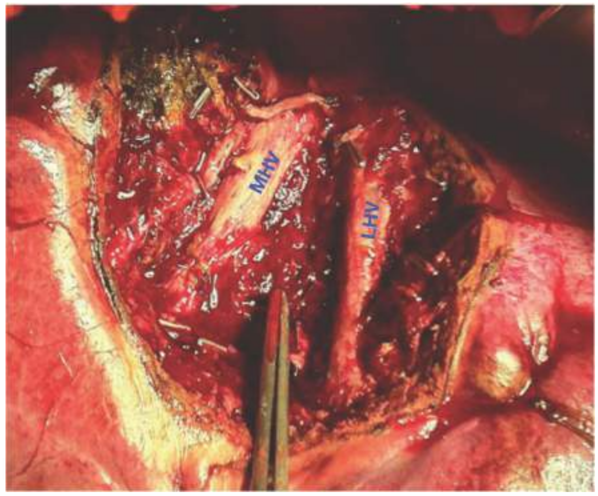

FIG 14 ● In vivo photograph showing the divided left hepatic vein *(LHV)* as it courses toward the divided *MHV*.

Left portal vein

- The left portal vein extends longer than the right. It makes an abrupt angle as it enters the liver from the hilum (**FIG 13**). The section of vein after the bifurcation and prior to the arborization of the left portal system is often referred to as the pars transversus.[13] This is important to identify when performing left hepatectomy.[15]
- The obliterated umbilical vein (ligamentum teres) and the obliterated ductus venosus (ligamentum venosus) join it as it enters the left lobe.
- The left portal vein most often gives off the dominant portal branch to the caudate lobe and usually does so prior to its segmental arborization.
- The left portal vein differs from the segmental anatomy of the hepatic artery and bile ducts, in that it does not give off a main branch to segments 2 and 3. Instead, it gives off branches to segments 3 and 4 and then continues as a single portal pedicle, sometimes referred to as the umbilical portion of the portal vein, before supplying segment 2.[16]

Hepatic Veins

- The hepatic veins divide the liver into its Couinaud sectors.
- The left and middle hepatic veins combine to form a common vein (truncus communis) prior to entering the IVC, although this occurs with some variety (**FIGS 14** and **15**).
- The caudate lobe has direct venous drainage to the IVC and is not drained by the three major hepatic veins.

Right hepatic vein

- The right hepatic vein separates segments 6 and 7 from segments 5 and 8.

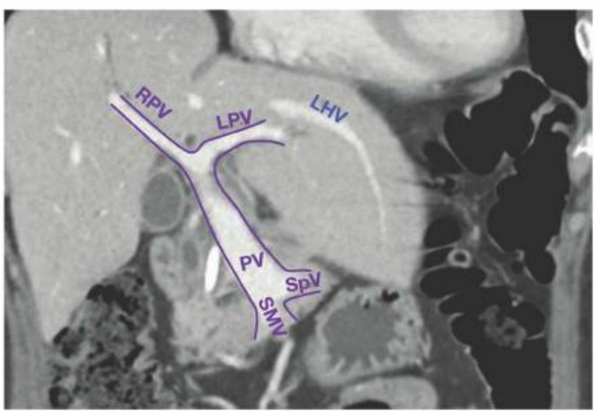

FIG 13 ● Coronal CT demonstrating the branching of the left *(LPV)* and right *(RPV)* portal veins off the main portal vein *(PV)*, which originates at the confluence of the superior mesenteric vein *(SMV)* and the splenic vein *(SpV)*. Note the acute angle made by the *LPV* as it enters the liver. Also shown is the left hepatic vein *(LHV)*.

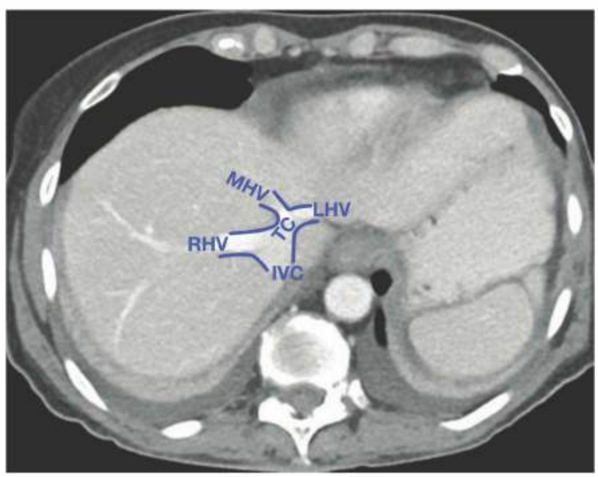

FIG 15 ● Axial CT scan showing the relationship of the hepatic veins as they converge to the *IVC*. The middle *(MHV)* and left *(LHV)* hepatic veins join to form the truncus communis *(TC)*, which empties into the *IVC*. The right hepatic vein *(RHV)* is also shown, similarly draining into the *IVC*.

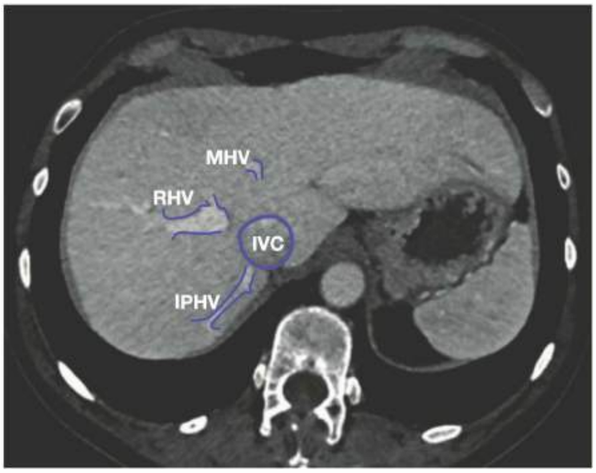

FIG 16 ● Axial CT showing an accessory hepatic vein. The inferior posterior right hepatic vein *(IPHV)* occurs in up to 25% of patients. Notice the position of the IPHV, far posterior on the liver. This is of utmost importance to characterize prior to operating on the liver. Also seen are the right hepatic vein *(RHV)*, *MHV*, and the *IVC*.

- It drains segments 6 and 7 as well as parts of segment 8.
- There can be accessory right hepatic veins, the most common of which is the inferior posterior right hepatic vein (**FIG 16**), which occurs in 20% to 24% of patients and can lie within the portocaval ligament. The surgeon must be aware of this possible anatomy prior to performing right hepatectomy.[17]

Middle hepatic vein

- The middle hepatic vein (MHV) follows Cantlie's line and is the line of division for right and left hepatectomy.
  - Right hepatectomy is performed just to the *right* of the MHV, preserving its length and ligating its rightward branches.
  - Left hepatectomy is conversely performed just the *left* of the MHV, preserving its length and ligating its leftward branches.
- It drains segments 4 and 5 and parts of segment 8.

Left hepatic vein

- The left hepatic vein drains segments 2 and 3 as well as parts of segment 4.
- Its arborization is variable, and careful identification of both the left and middle hepatic veins is paramount prior to performing left hepatic vein ligation for left hepatectomy.

BILIARY SYSTEM

- Bile is made by the hepatocytes and travels via an interlobular network of capillaries and ductules to the minor, then major biliary ductules, and eventually into the hepatic ducts.
- The right and left hepatic ducts come together to form the common hepatic duct (CHD), which accepts the cystic duct approximately 4 to 6 cm distal to the hepatic duct confluence. This then forms the common bile duct and travels another 4 to 8 cm before joining the pancreatic duct and emptying into the ampulla of Vater.
- There is considerable variation in biliary anatomy. The "typical anatomy" only occurs in 50% to 60% of patients[18,19] (**FIG 17**).
- The cystic duct is often tortuous and also often displays variable anatomy leading to misidentification and injury during cholecystectomy.
- The gallbladder sits in the gallbladder fossa between segments 4 and 5 and is attached to the liver surface. It is covered by peritoneum, and its fundus projects beyond the liver anteroinferiorly. Surgical considerations and anatomy of the gallbladder will be discussed further elsewhere in this book.

Right Hepatic Duct

- The right hepatic duct (RHD) is formed from the confluence of the right anterior hepatic duct (RaHD) and the right posterior hepatic duct (RpHD).
  - The RaHD drains the anterosuperior (segment 8) and anteroinferior (segment 5) ducts.
  - The RpHD drains the posterosuperior (segment 7) and posteroinferior (segment 6) ducts.
  - There exists considerable variation in the drainage pattern of the right system. The most common variant is Type C_1, where the RaHD drains directly into the CHD (**FIG 18**).
- The RHD is anterior and lateral while in the hilum of the liver; however, intrahepatically, it dives posterior to the portal vein in both RaHD and RpHD branches.

Left Hepatic Duct

- The left hepatic duct is longer than the right and can display similarly variable anatomy.[20]
- It drains the left lateral and medial hepatic ducts.
  - The left lateral hepatic duct drains the laterosuperior (segment 2) and lateroinferior (segment 3) branches.
  - The left medial hepatic duct drains the mediosuperior (segment 4A) and medioinferior (segment 4B) branches
- Unlike the right side, the left hepatic ductal system remains anterior to the portal vein throughout its intra- and extrahepatic course.

Biliary Drainage of the Caudate Lobe

- The caudate lobe drains directly into the left and right hepatic ducts, although this is variable.
- There is often a direct branch draining the caudate process into the RHD.

INNERVATION

- The liver has both sympathetic and parasympathetic innervations.
- The parasympathetic innervation is mostly via the left vagus nerve as it rotates anteriorly upon entering the abdomen. This is the anterior hepatic nerve plexus and travels mostly with the hepatic artery. There are also posterior hepatic fibers, which come from the right (posterior) vagus nerve, and travel mostly with the portal vein.
- Sympathetic innervation arrives via the splanchnic divisions of T7–T9, through the celiac ganglion, and runs mostly with the hepatic artery.
- Sensory fibers of the peritoneum of the liver run via the right phrenic nerve, and this leads to referred pain interpreted to be from the subscapular region with hepatic and diaphragmatic irritation from infection, tumor, or insufflation.

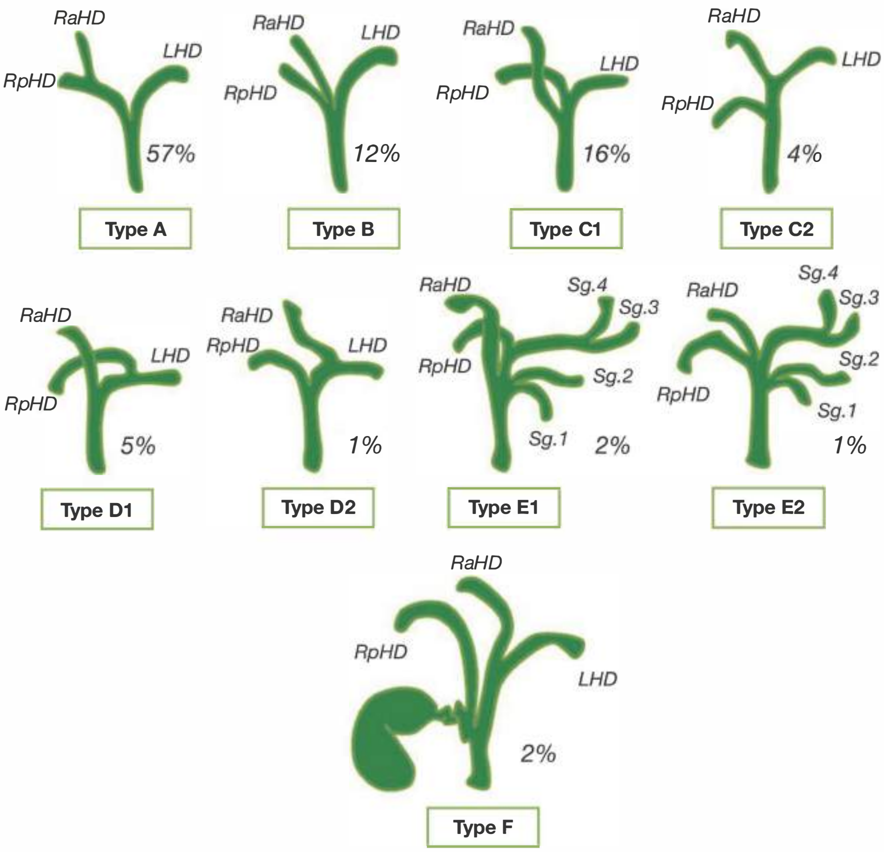

FIG 17 ● Typical and atypical variant anatomy, with percentages of frequency, of the hepatic ducts and biliary tree. Type A is typical anatomy. Type B shows the absence of a true RHD. Type C is a variation in which the one of the right hepatic branches drains into the CHD directly. Type D is a variation in which one of the right hepatic branches drains into the left ductal system. Type E is a variation in which there is an absence of a true confluence of right and left hepatic ducts. Type F shows a variant where the right posterior hepatic duct drains directly into the cystic duct. *RaHD,* right anterior hepatic duct; *RpHD,* right posterior hepatic duct; *LHD,* left hepatic duct; *Sg,* segmental branch with corresponding Couinaud segment number. (From Smadja C, Blumgart L. The biliary tract and the anatomy of biliary exposure. In: Blumgart L, ed. *Surgery of the Liver and Biliary Tract*. New York, NY: Churchill Livingstone; 1994:11–24.)

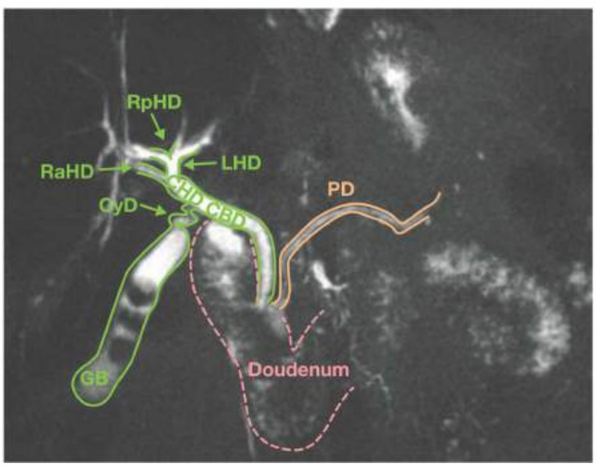

FIG 18 ● Magnetic resonance imaging (MRI) showing biliary anatomy. The right and left systems draining into the *CHD*. This is joined by the cystic duct *(CyD),* which is notably tortuous as it drains into the biliary tree. This confluence marks the beginning of the common bile duct *(CBD),* which joins the pancreatic duct *(PD)* to drain into the second portion of the duodenum. The gallbladder *(GB)* can also be seen, with three large stones present. This patient's anatomy reveals a common variant (Type C_1), with the right posterior hepatic duct *(RpHD)* joining the left hepatic duct *(LHD)* while the right anterior hepatic duct *(RaHD)* drains directly into the *CHD*.

LYMPHATICS

- The liver parenchyma drains lymph via empty spaces (space of Disse) between the endothelium and the hepatocytes themselves. This lymph is collected into larger spaces in the portal triad (space of Mall).[21] These are not actual lymphatics but rather nonendothelialized channels through which lymph passes. Lymph is eventually collected in true lymphatics within the portal triad and follows the path of these vessels.
- Lymphatics drain primarily into the lymph nodes of the porta hepatis followed by the celiac nodes. These lymph nodes should be evaluated for metastasis prior to resection when indicated (**FIG 19**).
- Secondary lymphatics follow the hepatic veins and drain into the phrenic lymph nodes.
- Superficially, beneath Glisson's capsule, lymph drainage from the liver follows one of five avenues:[22]
  - Anterior phrenic lymph nodes: drain anterosuperior surface
  - Lateral phrenic lymph nodes: drain posterosuperior surface
  - Left gastric lymph nodes: drain posterolateral surface
  - Celiac lymph nodes: drain posterior surface
  - Hepatic lymph nodes: drain visceral surface

CONCLUSIONS

- The anatomy of the liver is extremely complex and requires in-depth preoperative study prior to undertaking any liver operation.

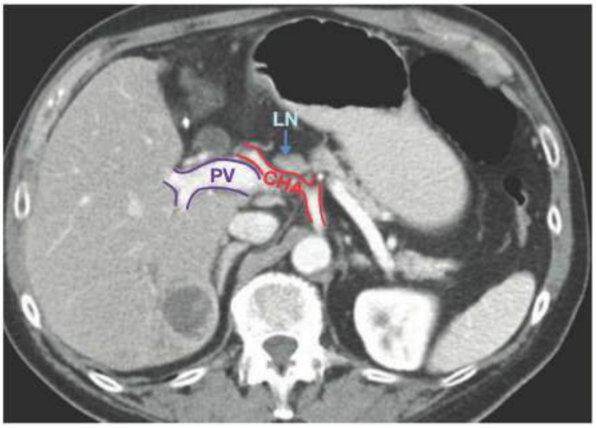

FIG 19 ● Axial CT showing an enlarged lymph node *(LN)* abutting the celiac bifurcation. A hepatocellular carcinoma can be seen in segment 6. Also labeled are the portal vein *(PV)* and the common hepatic artery *(CHA)*.

- The segmental anatomy as described by Couinaud is based on the portal venous anatomy. This knowledge has allowed surgeons of the modern era to perform increasingly specific and sparing resections, thus expanding the number of patients who can receive surgical therapy of liver disease and reducing the incidence of postoperative liver failure.
- The inflow and outflow of the caudate lobe are distinct from that of the rest of the liver.
- The liver has many variations of the biliary and vascular anatomy, and preoperative imaging is increasingly important in planning and executing successful liver operations.

Chapter 16

Intraoperative Ultrasound of the Liver

Kristopher Croome KMarie Reid Lombardo

INTRODUCTION

- Intraoperative ultrasound (IOUS) of the liver involves the use of ultrasound imaging to provide real-time assessment during surgical procedures of the liver.[1–3]
- In 1981, Makuuchi et al.[4] described the use of IOUS (**FIG 1**) of the liver as an adjunct for hepatectomy; since then, the use of IOUS has expanded to include open percutaneous ablative techniques and various laparoscopic applications.
- During laparoscopic surgery, where tactile examination is less feasible, IOUS can be extremely valuable during the exploratory phase of the operation. The following chapter provides a review on the technical aspects of IOUS of the liver.

The Physics behind Ultrasonography

- Ultrasound measures the reflectivity of tissue to sound waves.
  - *Amplitude* is the maximum variation occurring in the sound wave (**FIG 2**).
  - *Wavelength* is the distance between the onset of peak compression or cycle to the next (**FIG 2**).
  - *Velocity* is the speed at which sound waves travel through a particular medium. Velocity is equal to the frequency × wavelength. Higher frequency will allow for greater penetration of the liver.
  - $V = f \times \lambda$

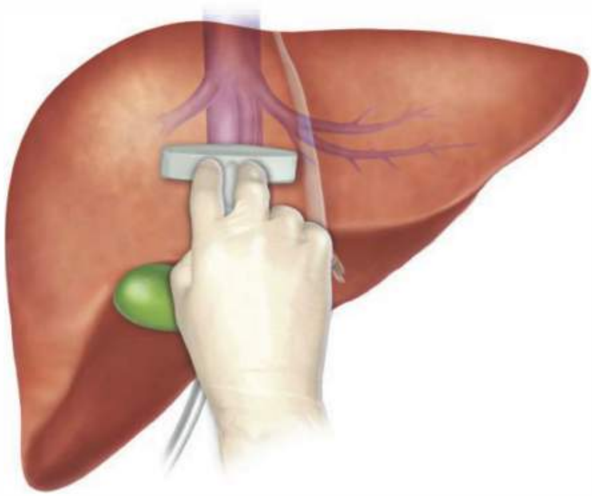

FIG 1 ● IOUS with T-probe.

Applications

- IOUS has numerous applications with the goal of improving surgical decision making, guiding the operation, and thereby improving outcomes. Here are common examples of its use:
  - **Evaluation of known hepatic lesions** to determine the extent of known disease and scrutinize the proximity of lesions relative to major structures such as hepatic and portal veins. For primary liver tumors, this can be helpful in staging.
  - **Detection of occult lesions** not detected on preoperative imaging. Subcentimeter metastatic lesions may not be detected by preoperative computed tomography (CT) or magnetic resonance imaging (MRI). Their number and locations may alter surgical plan. IOUS has a reported sensitivity of 90% for the detection of hepatic lesions with positive and negative predictive values of 90% and 78%, respectively.[2]
  - **Operative planning** as resection planes may not follow anatomic segments and as such, it is important to delineate the mass and relationship to hepatic or biliary pedicles to ensure adequate hepatic vein and biliary drainage. IOUS has been shown to alter the operative plan, when that plan was based on preoperative imaging, in 17% to 44% of cases in several reports.[2,5]
  - **Targeting** of lesions for biopsy. If an unsuspected lesion is identified during surgery, IOUS-guided biopsy will help to determine the next steps.
  - **Targeting** of lesions for therapeutic ablation, microwave, or cryotherapy. Metastatic disease such as colorectal liver metastases may require a multimodality approach to treatment in order to achieve optimal control of disease.

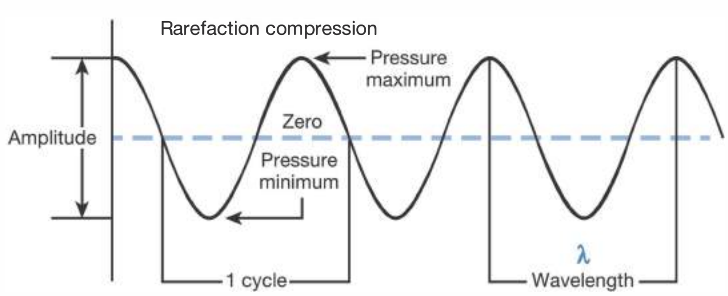

FIG 2 ● Wave properties such as amplitude and wavelength.

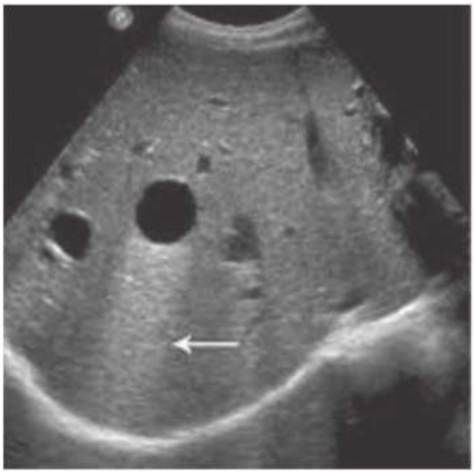

FIG 3 ● Simple hepatic cyst with posterior acoustic enhancement *(arrow)*.

Liver Parenchyma

- Normal liver parenchyma has a homogeneous echo pattern. Steatotic and cirrhotic livers have poor sound transmission and may appear diffusely hyperechoic.

Differential Diagnosis of Hepatic Lesions

- If a lesion is encountered, it should be examined in both transverse and longitudinal directions to determine its full extent. Its proximity and extension to neighboring vessels should be determined.
  - Benign lesions
    - Cyst—The ultrasound appearance is a well-defined lesion, with very thin, almost unapparent walls, without circulatory signal at Doppler investigation. The content is transonic suggesting fluid composition (**FIG 3**).
    - Hemangioma—Hemangiomas frequently appear as well-circumscribed hyperechoic lesions with sizes of 2 to 3 cm. Doppler exploration reveals no circulatory signal, because although the lesions are highly vascular, the blood flow through them is relatively slow (**FIG 4**).
    - Adenoma—Adenomas can be very difficult to distinguish from other benign lesions such as focal nodular hyperplasia (FNH). The appearance of adenomas can range from hyper- to hypoechoic; however, they are most frequently hypoechoic (**FIG 5**).

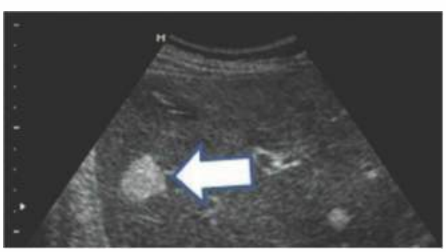

FIG 4 ● Hemangioma *(arrow)*.

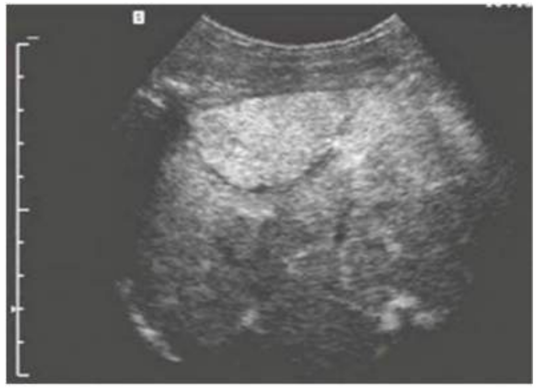

FIG 5 ● Adenoma.

  - Neoplastic lesions
    - Hepatocellular carcinoma (HCC)—HCC appearance on 2-D ultrasound is that of an isoechoic or hypoechoic solid tumor, with imprecise delineation, with heterogeneous structure, uni- or multilocular (encephaloid form). HCC may also frequently invade portal and hepatic veins and so these should be examined particularly in larger tumors (**FIG 6**).
    - Colorectal liver metastases (CRLM)—CRLM usually appear hypoechoic. They may take on a "target" or "bull's-eye" appearance due to alternating layers of hyper- and hypoechoic tissue. This pattern is highly suggestive of malignancy (**FIG 7**).
    - Neuroendocrine tumors (NETs)—Because NETs are hypervascular, they often appear as a hyperechoic lesion (**FIG 8**).

Required Equipment for Ultrasound

- Liver IOUS is best performed using a real-time B-mode scanner system with a 5-MHz or 10-MHz side fire T-shaped linear array probe. Saline or conductive gel can be applied to the liver surface to augment wave transduction. Required components for IOUS include the following:
  - Transducer—Transducers help to transmit ultrasound waves through the hepatic parenchyma. There are a

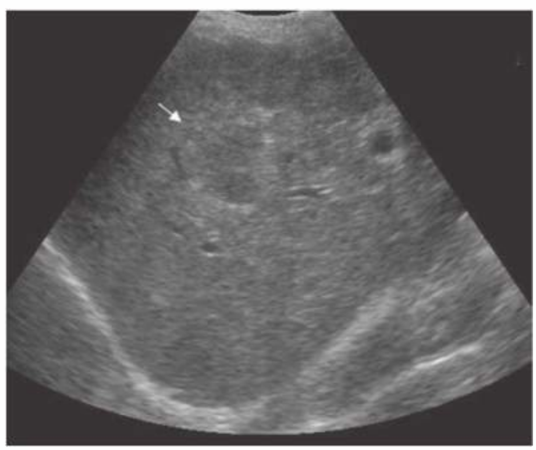

FIG 6 ● HCC *(arrow)*.

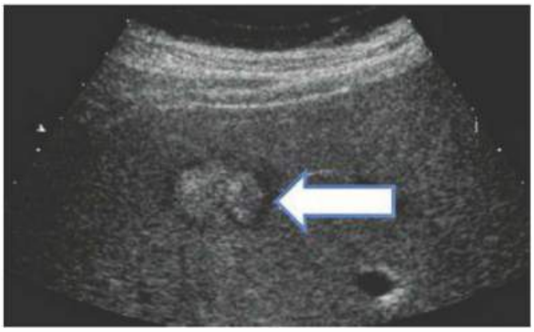

FIG 7 ● CRLM showing peripheral rim or bull's-eye appearance *(arrow)*.

variety of probes that are currently available and selection is based on the goal for the examination, body habitus and quality/character of hepatic parenchyma, and user preference. High-frequency probes allow for more adept superficial imaging, whereas lower frequency probes allow for deeper evaluation of the parenchyma. The most commonly used probe in open surgery is a T-probe. Probes can either be chemically sterilized or used with a sterile cover. Our group uses chemically sterilized probes (**FIG 9**).

- Processing unit: A variety of processing units are commercially available, most will include preset controls to adjust frequency, gain, depth, focus, freeze screens, and calipers to acquire measurements. We recommend familiarizing yourself with the processing unit available in your institution.
- Common controls:
  - Frequency: Determines how much tissue penetration will occur with scanning (higher frequency allows for better resolution).
  - Gain: Gain amplifies the echography, which manifests as contrast. This determines how the brightness of the image is depicted. To reduce the brightness of an image one would lower the gain.
  - Depth: The depth from which the returning ultrasound signals will be displayed. The scale on the image represents the depth. The maximum amount of depth will depend on the probe frequency. Higher frequencies will allow for improved depth penetration and potentially improved resolution.
  - Measurements: By freezing the image, calipers can then measure areas of interest.
- Display: Units are usually depicted as black and white with color available in Doppler mode.

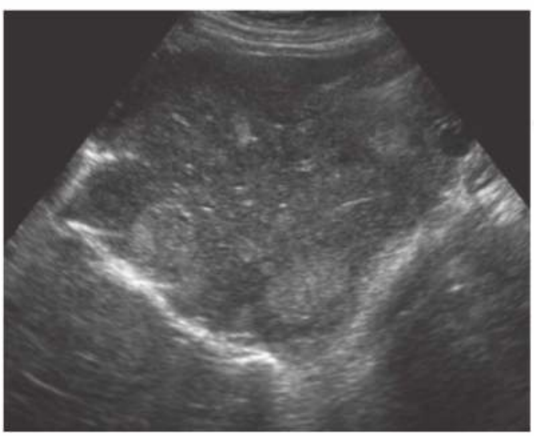

FIG 8 ● NET.

FIG 9 ● Example of some transducer probes available.

Three Modes Commonly Used for Intraoperative Ultrasound of the Liver

- B-mode or 2-D mode: In B-mode (brightness modulation) ultrasound, a linear array of transducers simultaneously scans a plane through the liver that can be viewed as a two-dimensional image on screen (**FIG 10**).

FIG 10 ● B-mode of the liver.

- Doppler mode: Information is sampled along a line through the body, and all velocities detected at each time point are presented (on a time line). When sound is reflected from a moving object, the frequency of the reflected echo changes in proportion to the velocity of the object (**FIG 11**).
- Duplex mode: The simultaneous presentation of 2-D (B-mode) and (usually) pulsed wave (PW) Doppler information. (Using modern ultrasound machines, color Doppler is almost always also used; hence the alternative name Triplex.) (**FIG 12**).

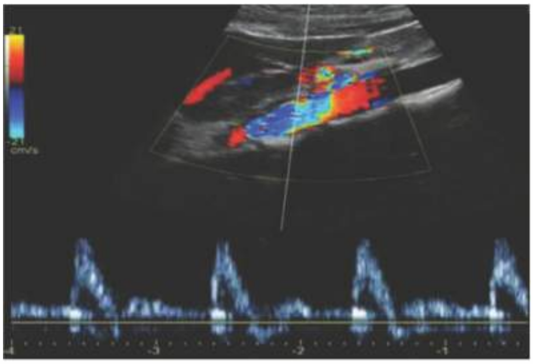

FIG 11 ● Doppler mode.

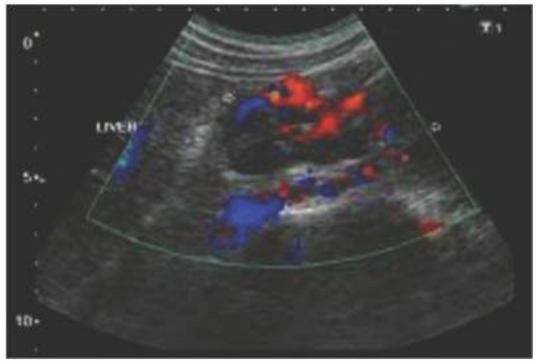

FIG 12 ● Duplex mode of the liver.

PRESCAN PREPARATION

First Step

- The lights of the operating room should be dimmed to improve visualization of the screen.

Second Step

- No coupling gel is generally required except if the transducer is placed in a sterile bag. If a sterile bag is used, then care should be taken to ensure no air bubbles are present at the contact surface.

Third Step

- Instill saline into the abdomen to aid in the transduction of sound waves.

Fourth Step

- The operator should be in good position to adequately visualize the console monitor (**FIG 13**).

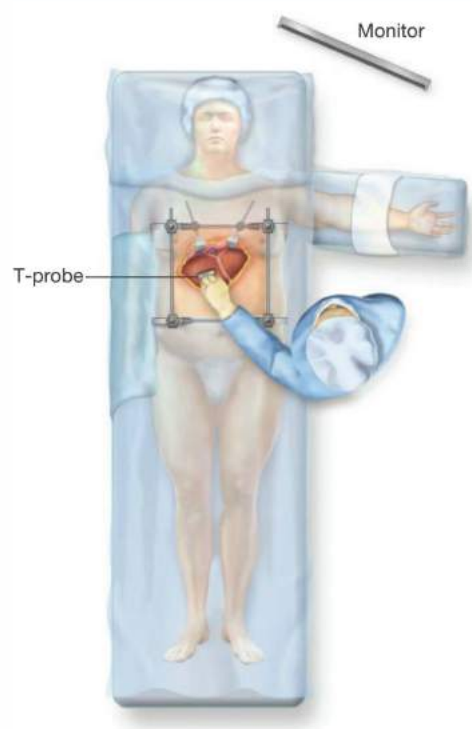

FIG 13 ● Operating positioning for adequate visualization of the monitor.

SCANNING

- Having a systemic technique to hepatic ultrasound is of utmost importance. There are many approaches that have been described. You will need to use two methods for ultrasound placement in open and laparoscopic cases.

Contact Scanning

- For contact scanning, the probe should be in direct contact with the liver surface.
- This technique is used for surveying the liver in most situations, with a systematic approach across the liver surface (Figure 14).

Stand-off Scanning

- In stand-off scanning, water is applied to the surface of the liver for coupling in order to adequately visualize the right posterior segments (segments 6 and 7). The probe is then held off of the liver surface immersed within the water. This technique can be particularly useful for superficial lesions and to detect lesions in the posterior segments of the liver.

Systematic Approach

- Identify the confluence of the hepatic veins with the inferior vena cava (IVC). This can be used as a rough indicator of the patient's central venous pressure (CVP) or volume status based on IVC distention. Follow the left, middle, and right hepatic veins, respectively.
- Identify the portal vein bifurcation. Follow the left portal vein to identify segment 4 and the bifurcation of segments 2 and 3.
- Again, identify the portal vein bifurcation and follow the right branch to its bifurcation and identify the right anterior and right posterior pedicles.
- If there are known lesions, identify these ultrasonographically in order to determine the echogenic profile that will aid in identifying occult lesions of the same pathology.
- Next, survey the entire liver for any additional disease. The two most commonly used survey methods are the lawn-mower method and the pedicle tracking method.

METHODS

Lawn-Mower Method

- The liver is scanned with overlapping fields from the dome to the caudal edge, proceeding from left to right through the entire organ in a sequential manner (FIG 14).

Pedicle Tracking Method

- To scan the liver, the pedicle tracking method can be used instead of the lawn-mower method. Using this technique, the liver is scanned segment by segment by following the vascular inflow and outflow. The hepatic ultrasonographer should be well versed in hepatic segmental anatomy following Couinaud nomenclature (The Brisbane 2000 terminology of hepatic anatomy and resections).[5]

In-Plane and Out-of-Plane

- It is important to understand the concepts of in-plane and out-of-plane when visualizing structure. In-plane refers to the visualization of structures in their long axis. Out-of-plane refers to visualizing structures at a 90-degree angle (FIG 15).

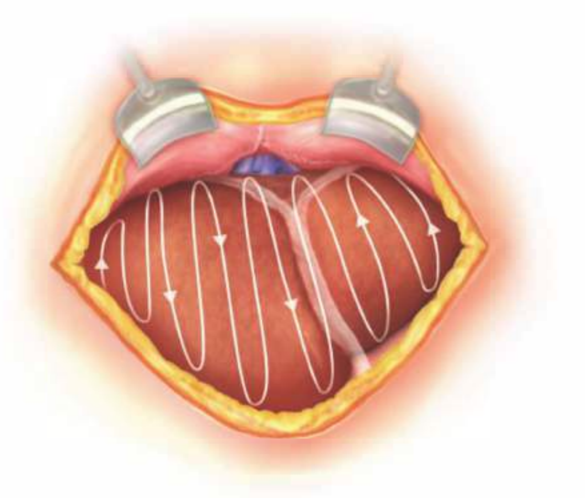

FIG 14 ● The pattern for scanning with the lawn-mower method.

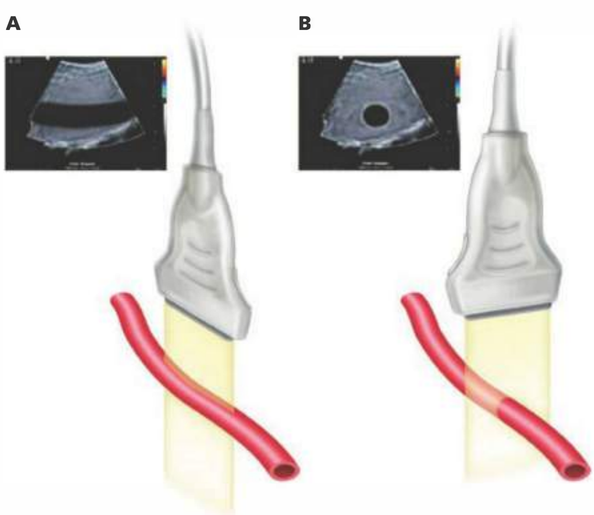

FIG 15 ● **A.** An ultrasound probe in plane with structure (vessel in this case). **B.** The ultrasound probe at 90 degrees with structure.

IMAGING EXAMPLES

Hepatic Vein Confluence into Inferior Vena Cava (FIG 16)

- The three hepatic veins can be identified entering into the IVC.
- The middle and left veins can usually be seen forming a common confluence before going into the IVC.
- The hepatic veins are anechoic vessels, frequently lacking a visible wall structure.

Portal Vein Bifurcation (FIGS 17 and 18)

- The portal vein can be identified branching into its main right and left branches.
- The portal veins can be differentiated from the hepatic by their white outline, a result of invested Glisson's capsule.
- The hepatic hilum can be located at the base of segments 4 and 5.
- The right and left portal veins then ramify into their section branches (anterior and posterior on right and medial and lateral on the left).
- The arteries and bile ducts run parallel to the portal veins from the liver, branching out into the liver from the hilum.
- The arteriole and biliary branches lie anterior to the portal veins.
- Duplex color imaging is useful in differentiating the hepatic arteries from the bile ducts.

Left Portal Vein Bifurcation into Segments 2, 3, and 4 (FIG 19)

- The left portal vein branch is longer than its right counterpart. It turns anteriorly (toward the probe) as it ascends into the umbilical fissure.

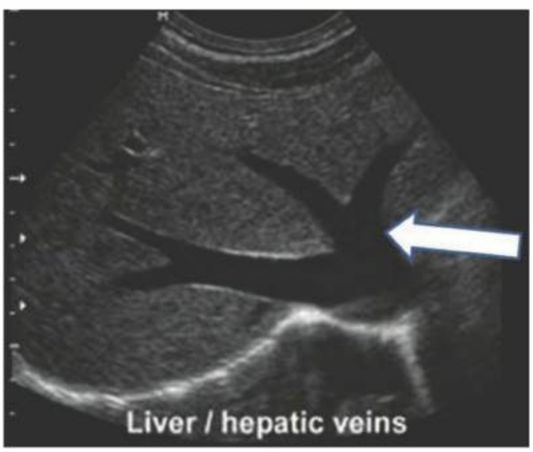

FIG 16 ● The hepatic vein confluence with the IVC. Note that the left and middle hepatic veins often share a common trunk *(arrow)*.

FIG 17 ● Portal vein bifurcation into its main right and left branches.

Right Portal Vein Bifurcation into Anterior and Posterior Pedicle (FIG 20)

- If one follows the right portal vein from its origin, one can identify the bifurcation into the right anterior (supplying segments 5 and 7) and the right posterior (supplying segments 6 and 7) branches.

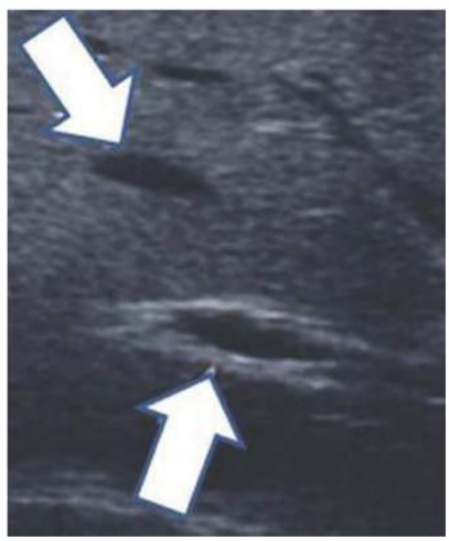

FIG 18 ● Differentiating portal branches from hepatic vein *(top arrow)* branches can be done by looking for the white outline in portal vein *(bottom arrow)* branches as a result of invested Glisson's capsule.

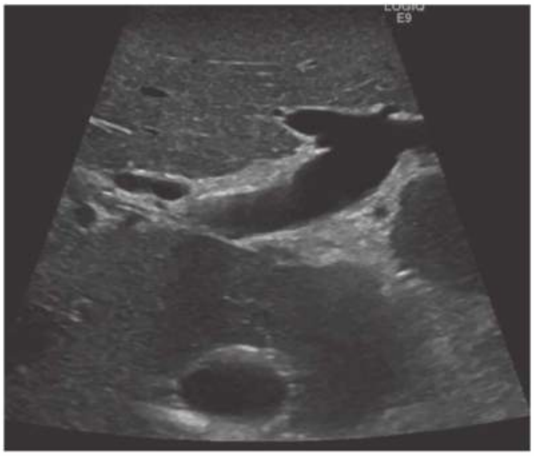

FIG 19 ● Left portal vein bifurcation into segments 2, 3, and 4.

FIG 20 ● Right portal vein bifurcation into anterior and posterior pedicle.

TARGETING OF LESIONS

- Multiple different methods of IOUS-assisted targeting ablation technologies.
    - The ablation probe and the ultrasound should be "in plane" so that the approach to the targeting lesion can be visualized (**FIG 21**). Once the probe has reached its intended target, the ultrasound probe can be turned 90 degrees to ensure that it is in the center of the intended target.
- Following ablation, a significant artifact will be generated, limiting ability to target further lesions in that field. As such, deeper lesions should be targeted first if multiple lesions are being targeted in one area.
- Pre- and postablation images should be captured for the medical record.

FIG 21 ● Imaging in-plane targeting of lesion.

LAPAROSCOPIC ULTRASOUND

- Laparoscopy has obvious shortcomings in evaluating the liver because it eliminates the surgeon's ability to palpate the hepatic parenchyma to detect lesions. IOUS attempts to restore some of the loss of tactile feedback while providing important information as seen in open procedures (FIG 22). The main goals of laparoscopic IOUS are the same of ones presented earlier in this chapter in open liver surgery. Laparoscopic IOUS has a few theoretical drawbacks if compared to traditional IOUS, including the difficulty in the ultrasound study of the superior and posterior segments. Some of this is dependent on probe type, as probes with varying degrees of freedom are available.

FIG 22 ● Laparoscopic IOUS. Typically, start high on the patient, to the right of the falciform.

CHECKING FOR BILIARY LEAK BY USE OF AIR CHOLANGIOGRAM

- This technique has been shown to result in a lower rate of postoperative bile (1.9% vs. 10.8%)[6] (FIGS 23 and 24).
  - A cholangiography catheter is inserted into the cystic duct and secured with a silk tie.
  - A syringe of air is then injected to fill the biliary tree while occluding the distal common bile duct by finger compression.
  - IOUS is then used to look at all liver segments to ensure bile duct patency. If there is an excluded segment, it will have an absence of pneumobilia.
  - Nonvisualization of pneumobilia suggests that there is a bile duct obstruction, a massive air leak via a large open bile duct, or incomplete manual occlusion of the distal common bile duct.

A  B

FIG 23 ● **A.** Injection of air into cystic duct following resection. **B.** Appearance of the liver following injection on air. The appearance is that of "Christmas tree lights" in liver segments that are in continuity.

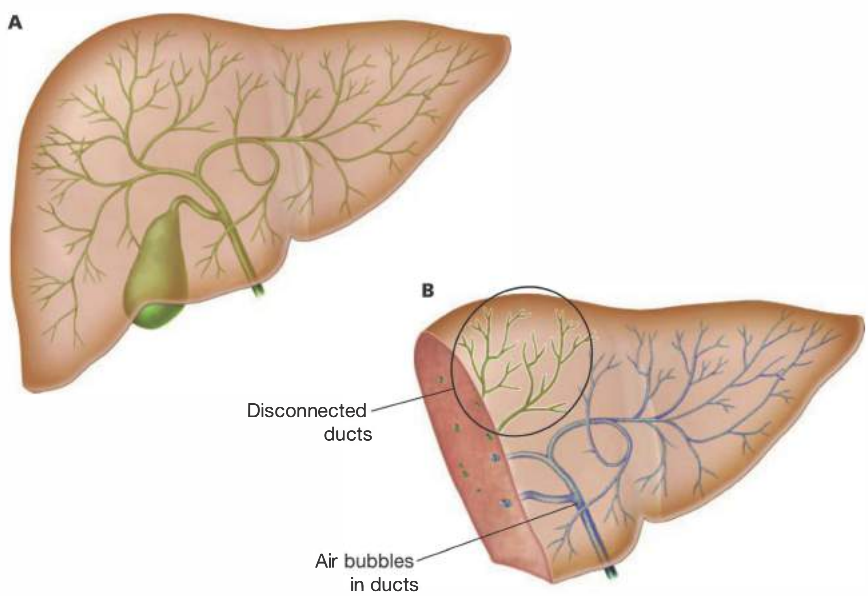

FIG 24 ● **A.** The liver, prior to resection, showing the biliary system. **B.** The liver following resection, showing air within segments in continuity and no air in excluded segments.

IDENTIFYING STRUCTURES IN THE HEPATIC HILUM

- Ultrasound of the hepatic hilar structures can be performed by placing the probe directly on the hepatic hilum (**FIG 25**). The classic appearance of the hepatic hilum on IOUS has been described as "Micky Mouse ears" consisting of the bile duct to the right, the hepatic artery to the left, and the portal vein posteriorly.
- The use of IOUS in the hilum can be useful for identifying the level of the hepatic artery bifurcation as well as any other anamolous anatomy such as a replaced right hepatic artery.

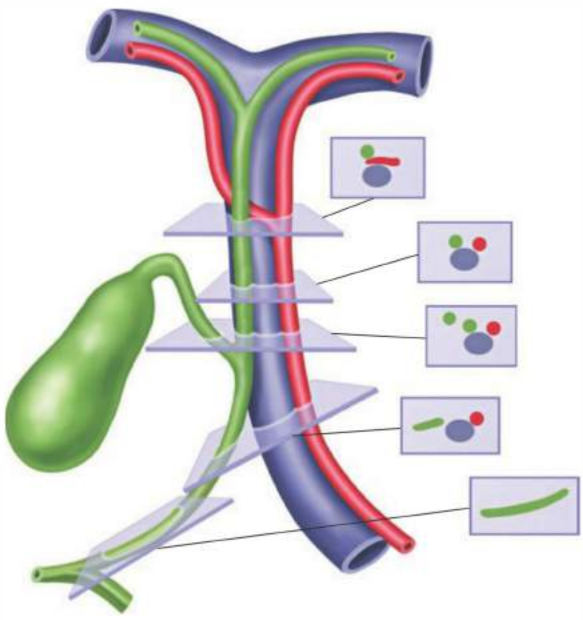

FIG 25 ● Relationship of structures of the hilum.

PEARLS AND PITFALLS

Indications	■ Ultrasound (US) is an essential adjunct during laparoscopic procedures.
Prescan preparation	■ Be familiar with your institution's US transducers and processor. ■ Immerse the liver in saline to optimize resolution.
Scanning	■ Scan a known lesion first to identify the US imaging characteristics of the pathology of interest. ■ Use a system to assure the entire liver is assessed. ■ Use "stand-off" scanning to avoid missing superficial lesions.
Targeting	■ Obtain permanent images for the medical record before and after ablation.

Chapter **17**

Fenestration or Enucleation of Hepatic Cystic Disease

Purvi Y. Parikh

DEFINITION

- Fenestration is defined as the removal of the free wall of a hepatic cystic lesion with the intent of forming a permanent communication between the residual cyst cavity and the peritoneal cavity. Thus, the procedure allows for any secreted fluid subsequently produced by the cyst lining to be absorbed by the peritoneum.
- Enucleation involves removal of the cyst in toto without spillage of contents; the intent is to use the capsule of the cyst as a resection plane to preserve hepatic parenchyma.

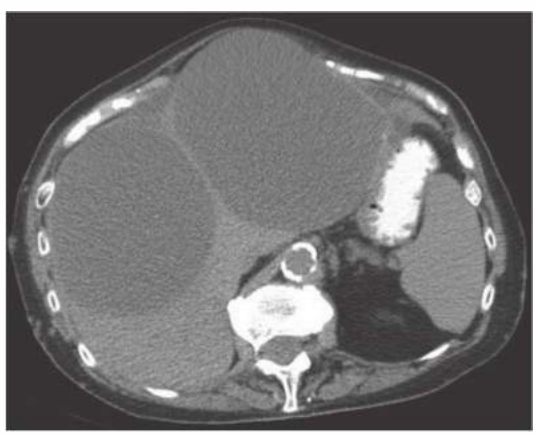
DIFFERENTIAL DIAGNOSIS

- Common cystic lesions range from the single, simple, small liver cyst to polycystic liver disease.
- More uncommon lesions are mesenchymal hamartomas, biliary hamartomas, and ciliated foregut hepatic cysts.
- Parasitic infection of the hepatic cyst must be ruled out prior to proceeding with surgery. Serology and characteristic imaging features make this determination straightforward.
- Biliary cystadenomas/cystadenocarcinomas that have malignant potential require enucleation rather than fenestration. The identification of bile in the cyst is the most important factor in identifying cysts with malignant potential that warrant the increased morbidity of enucleation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most simple hepatic cysts are asymptomatic and detected as an incidental finding during imaging of the abdomen.
- Simple hepatic cysts are congenital lesions, which are progressive dilatations of biliary microhamartomas known as von Meyenburg's complexes. Such cysts are lined by flattened biliary epithelium without a separation from adjacent hepatic parenchyma. They do not communicate with the biliary tree. These cysts contain serous fluid, which is continuously excreted by thin lining of epithelial cells.
- The prevalence of hepatic cysts is 16% to 18%. Females are affected more frequently than males.
- The frequency increases with age, with the peak incidence between ages 50 and 60 years.
- Large cysts may exert a mass effect and cause upper abdominal discomfort and early satiety (**FIG 1**).
- Symptoms are more common with right-sided cysts.
- Ultrasound-guided percutaneous cyst aspiration has minimal role in treatment of symptomatic cysts, as the recurrence rate is high and as rapid as 2 weeks.
- If symptoms persist after needle aspiration, the cyst is not the likely cause and other diagnoses should be investigated.
- Alternatively, if symptoms resolve after aspiration and return with recurrence of the cyst, definitive treatment of the cyst is indicated.
- Indications for intervention include pain, jaundice, infection, and hemorrhage. Occasionally, compression results in portal hypertension and indicates resection is appropriate.
- Most cysts that are incidentally identified do not warrant resection, provided the cyst lacks features of malignant potential. These features include septations; heterogenous attenuation; and a thickened, enhancing cyst wall.
- Complications are rare but include intracystic hemorrhage, biliary obstruction due to compression, cyst rupture, and cyst torsion. Bacterial infection leading to symptoms is occasionally observed.

A



B

FIG 1 ● **A.** Large, simple bilobar liver cyst. **B.** Large, simple bilobar liver cyst (axial).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Because most hepatic cysts are asymptomatic, they are most frequently detected on imaging of the abdomen obtained for other indications.
- Laboratory tests of liver enzymes (aspartate aminotransferase [AST], alanine aminotransferase [ALT], bilirubin, alkaline phosphatase) and tumor markers (carcinoembryonic antigen [CEA], carbohydrate antigen 19-9 [CA 19-9]) and serologies (hydatid)
- Ultrasound scanning demonstrates a rounded, anechoic intrahepatic mass with good thorough transmission and an imperceptible wall.
- Computed tomography shows a benign hepatic cyst as a homogenous lesion of low attenuation with no enhancement of the wall or content following administration of contrast.
- Magnetic resonance scanning diagnostic criteria are a homogenous lesion with low attenuation in T1 weighted images and a very high–signal intensity on T2 weighted images.
- Importantly, neuroendocrine and sarcoma hepatic metastases occasionally appear cystic.

FENESTRATION

Preoperative Planning

- Prior to operation, the patient should be counseled regarding the pros and cons of laparoscopic versus open surgery.
- Although the risk of infection after liver surgery is low, antibiotic prophylaxis significantly reduces the risk of postoperative infection.

Laparoscopic Fenestration

- Laparoscopic cyst fenestration has evolved to be the first-line surgical approach for symptomatic cysts.
- **Port placement**. A three-port laparoscopic technique is used (**FIG 2**): camera (30 or 45 degree), grasper for the cyst wall, and cutting instrument (cautery, Harmonic scalpel, or scissors). One of the ports should be 10 mm for clip application.
- **Grasping of cyst**. The cyst can be elevated with a grasper once it has been punctured through the exposed wall immediately adjacent to the liver parenchyma by insertion of a cutting instrument. The contents are drained and sent for analysis (**FIG 3**).

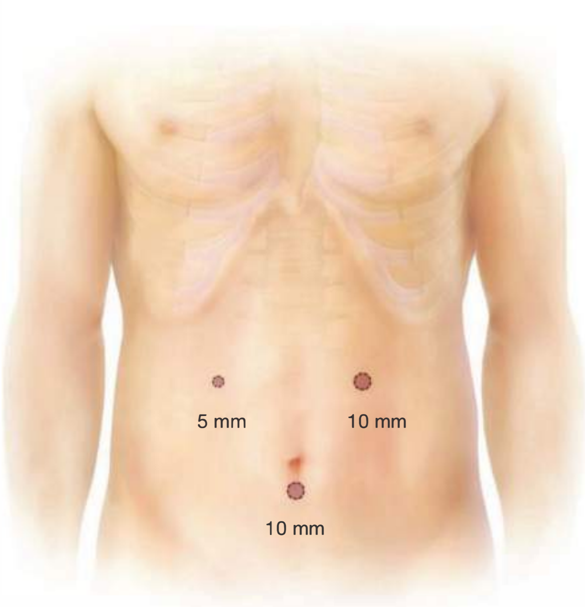


FIG 2 ● Trocar placement.

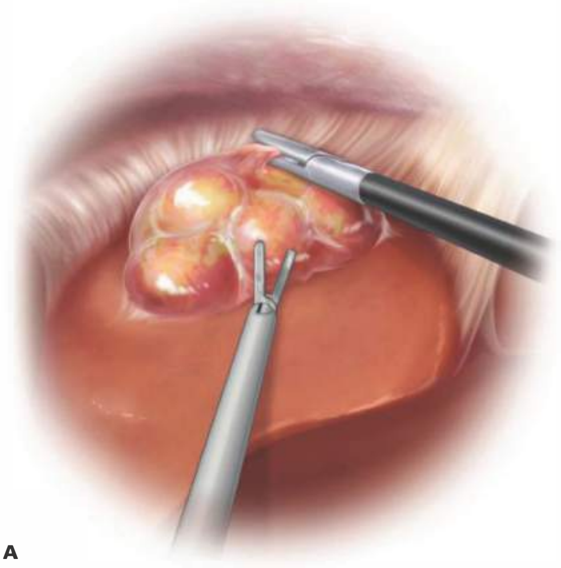
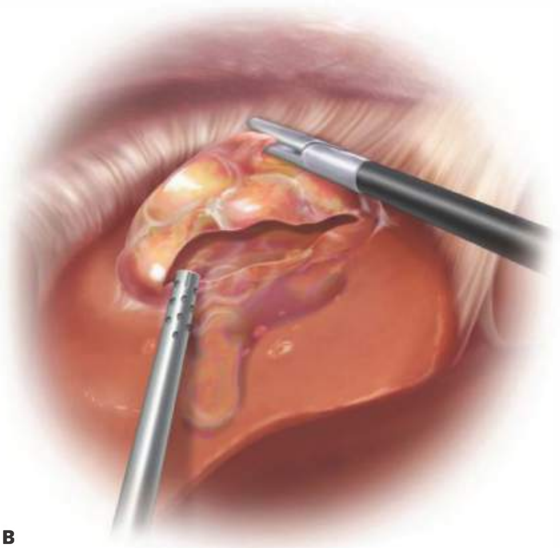


A



B

FIG 3 ● **A.** Grasping of the liver cyst wall. **B.** Grasping and elevating the liver cyst.

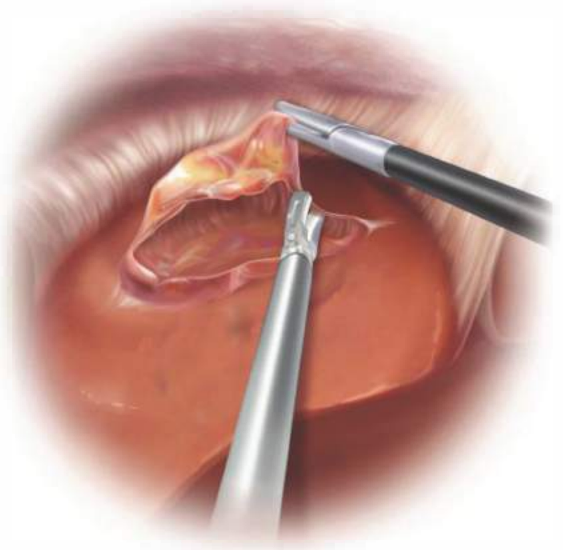


FIG 4 ● Resection of liver cyst wall.

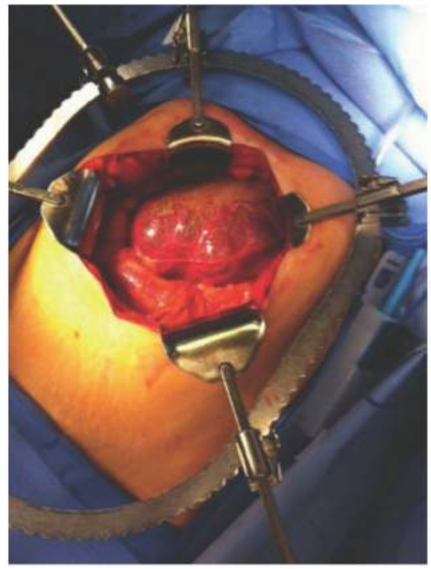

FIG 5 ● Open biliary cystadenoma resection.

- **Resection of cyst wall**. A wide excision of the cyst wall is performed using bipolar electrocautery or Harmonic shears. The intent is to excise the entire free wall and not to venture into the hepatic parenchyma (**FIG 4**).
- **Removal of resected cyst**. The resected cyst wall is removed in an endoscopic retrieval bag and the remnant cyst epithelium inspected.
- **Obliteration of remnant cyst epithelium**. Obliteration of the remnant cyst wall against the hepatic parenchyma should be treated with electrocautery, argon beam coagulation, or topical sclerosant.
- **Omentoplasty**. To minimize the risk of the resultant space-occupying defect evolving into a fluid collection, an omentoplasty is advised. A pedicle of omentum is mobilized from the transverse colon and advanced into the cyst cavity. It can be sewed in place with sutures or held in place with laparoscopic clips.
  - If omentoplasty is not possible, it is important to resect the maximal amount of the wall of the cyst to enhance retraction of the remnant edge of the cyst, thus preventing reapproximation of the rim by contraction with subsequent recurrence.
- After removal, the cyst wall is assessed histologically.

Open Fenestration

- Open cyst fenestration is reserved for recurrent disease or patients with extensive abdominal adhesions from prior surgical procedures.
- **Incision**. A right subcostal or midline incision; triangular and coronary ligaments are divided to rotate the liver (**FIG 5**).
  - Using the nondominant hand, the surgeon pulls the liver toward the midline to complete the exposure of the cyst. The cyst is unroofed to the level of the parenchyma.

ENUCLEATION

Laparoscopic Enucleation

- Laparoscopic enucleation can be effectively employed in the management of peripheral cysts, especially those located in the left lateral lobe or in the anterior segments.
- The epithelial wall and associated pseudocapsule easily lacerate, and cystic lesions often compress adjacent vasculature; thus, laparoscopic enucleation of hepatic cysts is often perceived as a straightforward option that can rapidly deteriorate into a loss of the surgical plane, significant hemorrhage, and carbon dioxide gas venous embolism.
- A minimum of three ports are necessary. Additional trocars can facilitate this approach.
- The most common instruments used to establish a hemostatic plane between the pseudocapsule of the cyst and the hepatic parenchyma are ultrasonic shears, bipolar electrocautery, and surgical staplers (**FIG 6A,B**).
- Additional ports should be placed to provide optimal positioning of the instrument to achieve complete cyst resection with the intent of sparing of healthy parenchyma. The development of a dissection plane is most efficiently and safely achieved with the shaft, rather than the tip, of the instrument.
- Once the dissection is completed circumferentially and the cystadenoma is enucleated, the specimen should be sent for immediate gross inspection and histologic analysis, as indicated, to exclude occult cystadenocarcinoma.

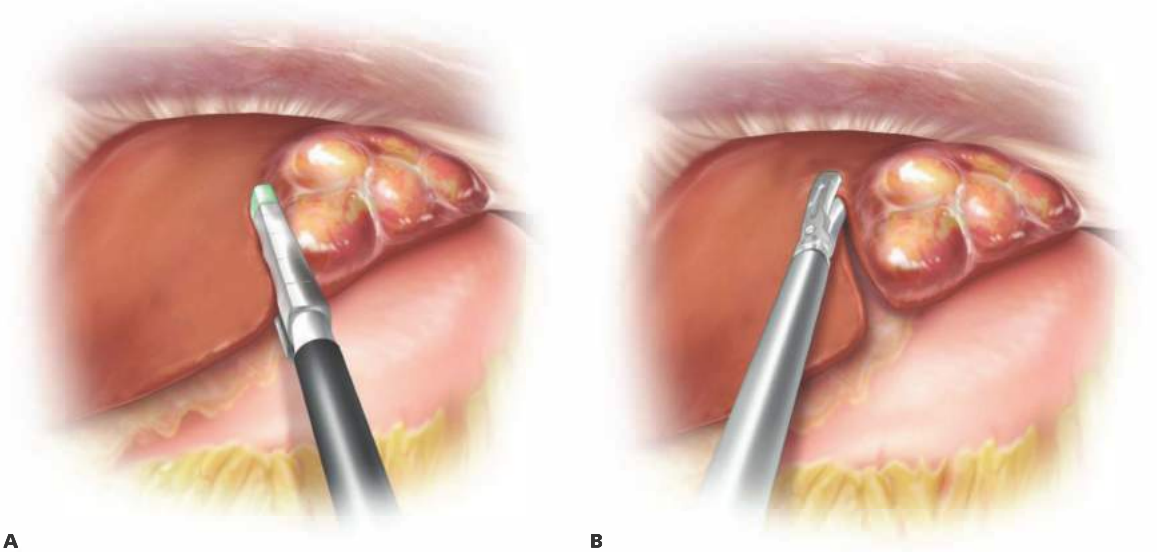

FIG 6 ● **A,B.** Techniques to resect a liver cyst.

- After dissection of the cyst from the hepatic parenchyma is completed, hemostasis is achieved and confirmed by electrocautery and direct inspection.
- If a bleeding vessel is identified, hemostasis is secured by electrocautery, surgical clips, and hemostatic agents or devices.

Open Enucleation

- Small cysts and biliary cystadenomas concerned for malignancy require enucleation of the cyst en toto.
- **Mobilization of the liver**. The affected lobe should be fully mobilized prior to enucleation. After mobilization of the liver, countertraction is maintained by the non-dominant hand of the surgeon.
- **Identification of interface**. The interface between the cyst pseudocapsule and the hepatic parenchyma is identified and developed (**FIG 7A,B**). Electrocautery is typically employed to initially enter the dissection plane between the cyst wall and the parenchyma. Blunt dissection should be adopted shortly thereafter, as this approach will facilitate deviation from the surgical plane and external identification of major vascular structures that have been compressed by cyst expansion.

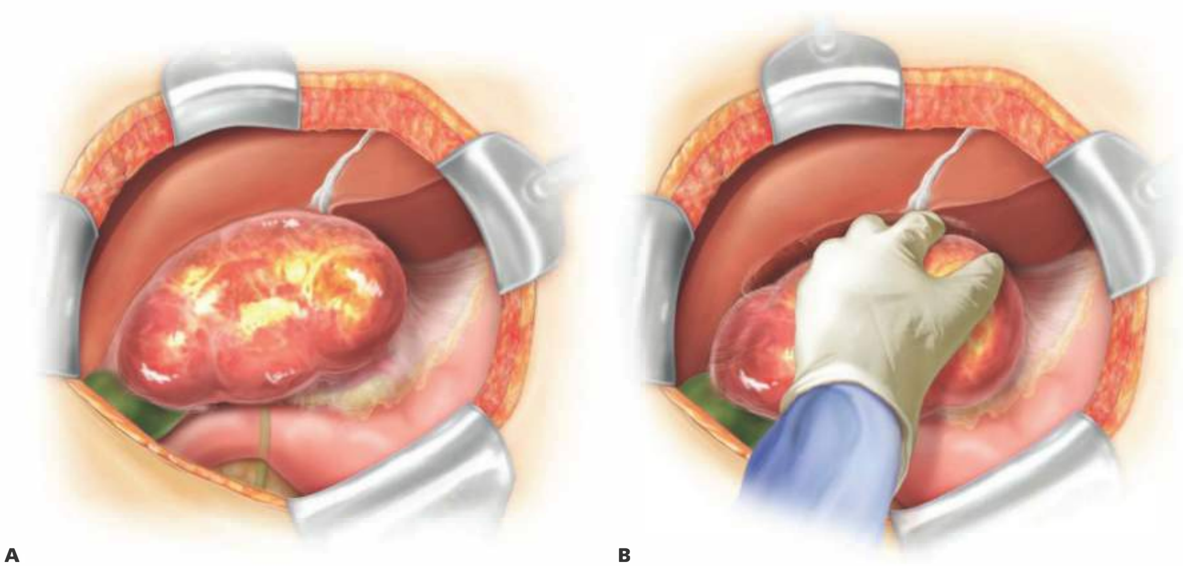

FIG 7 ● **A.** Mobilization of the liver. **B.** Identification of the interface.

- **Dissection and enucleation**. The dissection should proceed anterior to posterior, maintaining a broad plane; avoid the development of narrow, deep dissection planes. Once the dissection is completed circumferentially and the cystadenoma is enucleated, the specimen should be sent for immediate gross inspection and histologic analysis, as indicated, to exclude occult cystadenocarcinoma (**FIG 8**).
- Injury to the adjacent, compressed bile ducts can be intrinsic to this procedure. A fine (4-0 or 5-0 absorbable) monofilament suture is used for repair. Abdominal drainage in this setting is optional, but the author routinely places a closed suction drain in this clinical setting (**FIG 9**).
- Complete excision of the cystadenoma eliminates risk of recurrence.

FIG 8 ● Enucleation of entire cyst.

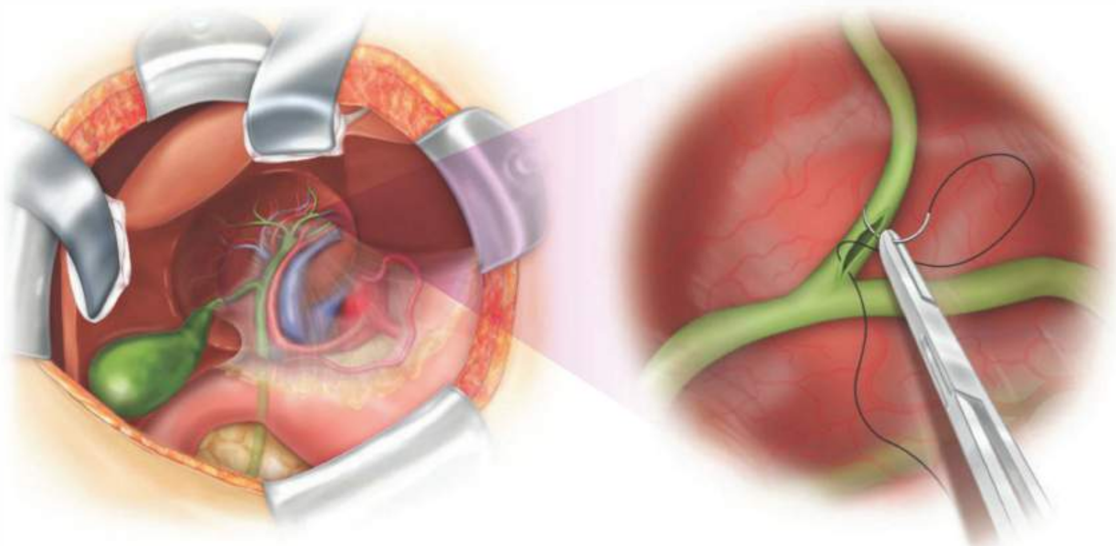

FIG 9 ● Repair of inadvertent injury.

PEARLS AND PITFALLS

Differential diagnosis	▪ Fenestration is straightforward; enucleation is considerably more morbid. Concern for malignant potential must be present to justify enucleation. ▪ Bile in the cyst warrants enucleation. The site of communication with the biliary tree is often not obvious. A cholangiogram via the cystic duct with methylene blue can facilitate identification of this site of communication.
Surgical technique	▪ Make certain the portal triad is accessible for a Pringle maneuver. ▪ During laparoscopic resection of hepatic cysts, be aware that major pedicles may not be amenable to sealing devices. Surgical staplers are the best option to laparoscopically control and divide these structures. ▪ When encountering significant hemorrhage during laparoscopic procedures, delay from hesitation to convert to an open procedure often leads to unnecessary transfusion or carbon dioxide embolism that can be life threatening. ▪ In an emergent conversion, use a midline incision. ▪ Look for small biliary radicals after enucleation. Drainage is not a good alternative for repair or ligation.

POSTOPERATIVE CARE

- If a drain has been placed, it can be removed on the first postoperative day, provided there is no bilious effluent.
- After a liver cyst fenestration, most patients should have routine postoperative surveillance.
- Consider intermediate or intensive care units for complicated cases of polycystic disease or for resections resulting in significant blood loss (>1,000 mL).

OUTCOMES

- The results of laparoscopic cyst fenestration are excellent. Three studies have reported outcomes in patients treated with laparoscopic cyst fenestration with a near follow-up of more than 4 years. There is no reported mortality with asymptomatic recurrence seen in up to 50% but symptomatic recurrence noted in only 4.5%.

COMPLICATIONS

- Intraabdominal bleeding
- Bile leak
- Subphrenic abscess
- Biloma
- Wound infection

Chapter **18**

Surgical Management of Hepatic Trauma

Walter L. Biffl Carlton C. Barnett, Jr.

DEFINITION

- Hepatic trauma is defined as injury to the liver. It may be associated with hemorrhage, bile leak, or devitalized tissue. There is a spectrum of severity of liver trauma (Table 1),[1] and a broad range of techniques may be employed to manage various injuries.[2–4]

DIFFERENTIAL DIAGNOSIS

- Abdominal trauma can be associated with injuries to any abdominal organ. Major sources of hemorrhage include solid organs (e.g., liver, spleen, kidneys) and major vessels in the retroperitoneum (e.g., aorta, inferior vena cava [IVC], renal vessels) or mesentery. Peritonitis may result from bile leak or from any injury to a hollow viscus (e.g., bowel, biliary tree, pancreas).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Liver injuries may occur following either blunt (e.g., motor vehicle crash, fall) or penetrating (e.g., gunshot or stab wound) trauma to the abdomen.
- The liver is one of the most commonly injured organs following blunt trauma. Impact to the lower right chest or the abdomen puts the patient at risk of liver injury. Any high-energy mechanism should raise concern of intraabdominal injury.
- The liver, due to its large surface area, is frequently injured in penetrating abdominal or lower thoracic trauma. The path of gunshot wounds to the torso cannot be determined based on physical examination alone.

Table 1: Grading of Liver Injuries

Grade		Injury Description
I	Hematoma	Subcapsular, <10% surface area
	Laceration	<1 cm parenchymal depth
II	Hematoma	Subcapsular, 10%–50% surface area; intraparenchymal, <10 cm diameter
	Laceration	1–3 cm parenchymal depth, <10 cm length
III	Hematoma	Subcapsular, >50% surface area or expanding; intraparenchymal, >10 cm diameter or expanding, or ruptured
	Laceration	>3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%–75% of hepatic lobe or 1–3 Couinaud's segments in a single lobe
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud's segments in a single lobe
	Vascular	Juxtahepatic venous injuries
VI	Vascular	Hepatic avulsion

Advance one grade for multiple injuries up to grade III.

From Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling: spleen and liver (1994 Revision). J Trauma. *1995;38:323–324.*

- Abdominal pain or tenderness on examination raise concern for abdominal injury; however, patients may have severe liver injuries in the absence of pain or tenderness. Vital signs are a critical component of the assessment of trauma patients, as the decision to proceed with surgical (versus nonoperative) management is primarily based on physiologic condition of the patient. The vast majority of liver injuries are managed nonoperatively.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Ultrasound—in particular, the focused abdominal sonographic examination for trauma (FAST)—is increasingly used as an initial triage tool in trauma patients. Following blunt trauma, the finding of free fluid in the abdomen in the presence of shock is an indication to proceed to exploratory laparotomy (LAP) without delay. The finding of hemoperitoneum on FAST exam in the absence of hemodynamic instability is not an indication for LAP; injuries to abdominal wall, omentum, or liver often stop bleeding spontaneously and do not require any interventions.
- The FAST exam is less useful in penetrating trauma victims. Those with gunshot wounds should undergo immediate LAP. Those with stab wounds should undergo LAP if they exhibit shock, evisceration, or peritonitis. Otherwise, they should be admitted for serial clinical assessments to detect ongoing hemorrhage or hollow viscus injury.
- Most liver injuries due to blunt trauma are diagnosed by computed tomography (CT) (**FIG 1**). CT is indicated in any patient with major abdominal blunt trauma mechanism, abdominal pain or tenderness, hemoperitoneum on FAST exam in a stable patient, pelvic fractures, or the inability to clinically assess the abdominal exam and the potential

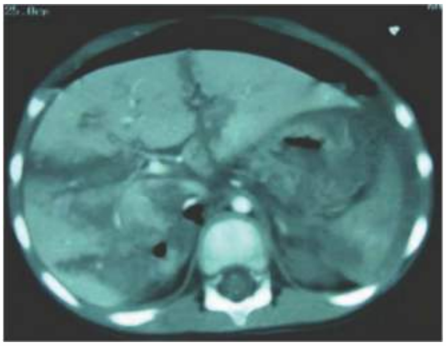

FIG 1 ● CT scan image of a grade IV liver injury. Despite the extensive injury to the liver, note the relative paucity of blood surrounding the liver. This is a pitfall of FAST ultrasonography, as it detects primarily free fluid. It also speaks to the lack of sensitivity of FAST for individual organ injuries. It detects blood but not the source of the bleeding.

for abdominal trauma (e.g., a patient with severe traumatic brain injury following motor vehicle crash). Specific to liver laceration, the identification of intravenous contrast extravasation warrants treatment rather than observation.
- Arteriography with embolization can be selectively employed as a primary treatment or as an adjunct to surgical management of liver lacerations with arterial hemorrhage. This may be employed more frequently in centers with hybrid operating room (OR)/interventional radiology (IR) suites.
- Cholangiography is sometimes useful to determine whether there is biliary injury and ongoing bile leak. This is generally performed later in the postinjury course. The presence of a biliary injury and bile leak generally calls for intervention either surgical or endoscopic.
- Magnetic resonance imaging has little role in the management of liver trauma.

SURGICAL MANAGEMENT

- Severe abdominal pain or tenderness, peritonitis, evisceration, or shock with a presumed abdominal injury warrant LAP.
- Following stab wounds, the presence of shock, evisceration, or peritonitis is a clear indication for LAP. Gunshot wound to the abdomen, given its high association with significant injury, is an indication for LAP regardless of the initial physical findings.

Preoperative Planning

- Prior to taking the patient to the OR, the surgeon should communicate with the OR team regarding the suspected diagnoses and planned interventions, anticipated blood loss and transfusion requirements, positioning and incisions, extent of skin preparation, the need for imaging, and any special equipment needs.

Positioning

- The patient should be positioned supine. There is no advantage to tucking the arms. In the setting of trauma, it is best to leave both arms out to allow the anesthesiologist's access for venous and arterial catheterization and sampling.

TECHNIQUES

SKIN INCISION

- Exploratory LAP for trauma should be performed through a generous midline abdominal incision. Although it may not initially extend from the xiphoid to pubis, as is classically suggested, once a major liver injury is identified, extension up to the xiphoid process is recommended to afford optimal exposure. Some elective liver surgery is performed through right or bilateral subcostal incisions, with or without cephalad extension in the midline. This may be chosen if the operation is performed later in the patient's clinical course for complications of liver injury, typically bile leak. However, this may limit access to the lower abdomen in the event there are multiple injuries. If a midline incision has been made, the surgeon should not hesitate to extend the incision to the right if necessary. Adequate exposure is critical to repairing major hepatic injuries.

ABDOMINAL EXPLORATION

- The initial objective of trauma LAP is to determine if there is exsanguinating hemorrhage and from where it emanates. Blood must be evacuated and the source identified. Primary culprits are solid organs, retroperitoneal vessels, and mesentery. The surgeon should be able to rapidly assess the liver for major lacerations, by inspecting it and palpating its surface.

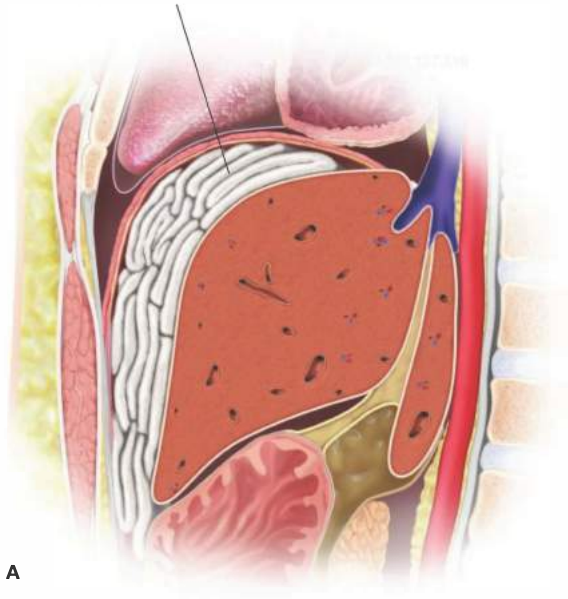
MANUAL COMPRESSION

- The first step in hepatic hemorrhage control is manual compression (**FIG 2**). This should be able to control the vast majority of liver bleeding. The importance of simultaneous aggressive resuscitation cannot be overemphasized. Restoration of blood volume and maintenance of tissue perfusion, correction of coagulopathy, and active warming of the patient are critical to avoid the "bloody vicious cycle" that can lead to early mortality.

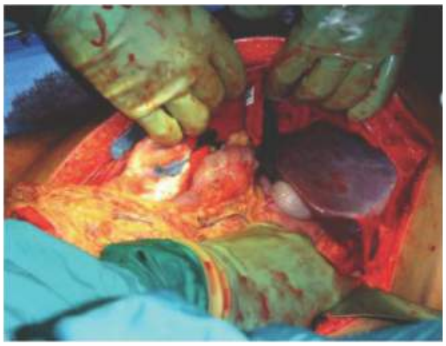
FIG 2 ● Manual compression of the liver is performed to restore the normal anatomic contour of the liver and tamponade bleeding. This maneuver can control hemorrhage while planning packing or definitive interventions.

PERIHEPATIC PACKING

- Perihepatic packing should be performed in such a manner to maintain hemostatic compression on the liver (**FIG 3**). The supporting ligaments of the liver are left intact at this stage, as they may provide tamponade of venous bleeding. However, should the patient have stellate lacerations or extensive subcapsular injury, one should not hesitate to mobilize the suspensory ligament of the falciform or the right and left triangular ligaments to allow better exposure. Packing should be performed in a systematic fashion, placing packs between the liver and the abdominal wall, diaphragm, and retroperitoneum.



A



B

FIG 3 ● The liver is packed with LAP pads to provide compression against the abdominal wall, diaphragm, and retroperitoneum. **A.** In the sagittal view, packs are present between the liver and the diaphragm and abdominal wall. **B.** In the photograph, the right lobe is compressed by packs.

TOPICAL HEMOSTASIS

- Grades I and II lacerations (see Table 1) may stop bleeding spontaneously or after a short period of packing (**FIG 4**). Ongoing hemorrhage can usually be controlled with electrocautery or argon beam coagulation, with or without application of topical hemostatic agents such as microcrystalline collagen, fibrin glue, or other agents (**FIG 5**).

FIG 4 ● Low-grade lacerations *(arrow)* may often stop bleeding spontaneously or following a brief period of compression or packing.

A 

B 

FIG 5 ● Low-grade injuries with persistent bleeding may be treated by topical hemostatic techniques such as argon beam coagulation **(A)** or microcrystalline collagen application **(B)**.

DAMAGE CONTROL

- In the physiologically compromised patient, the decision to pursue damage control must be made early in order to optimize the patient's chance of survival. Time-consuming efforts to stop relatively minor bleeding should not distract the surgeon from the primary objective. The liver should be packed quickly and other damage control maneuvers completed prior to a temporary abdominal closure. In order to facilitate later pack removal without disrupting clot, a nonadherent plastic drape may be spread over the liver surface, with the packs placed on top of the plastic.

DEEP PARENCHYMAL HEMORRHAGE CONTROL

- If the patient's condition allows, the liver should be examined to determine the extent of the injury. Grades II and III lacerations should be inspected to determine whether a discrete vessel may be ligated (FIG 6). Bleeding can generally be controlled by packing the wound with an omental pedicle or a plug of topical hemostatic agents such as absorbable gelatin sponge wrapped in oxidized regenerated cellulose (FIG 7). Suture hepatorrhaphy is an option, but one must avoid leaving a large dead space and avoid devitalizing tissue or lacerating vessels or bile ducts. Extensive lacerations may need to be explored to control major vessels. The finger fracture technique allows one to reach major vessels for ligation (FIG 8). Stapling devices can also be useful in dividing the hepatic parenchyma to reach deep vessels (FIG 9).

FIG 6 ● The laceration should be explored to identify discrete vessels to ligate.

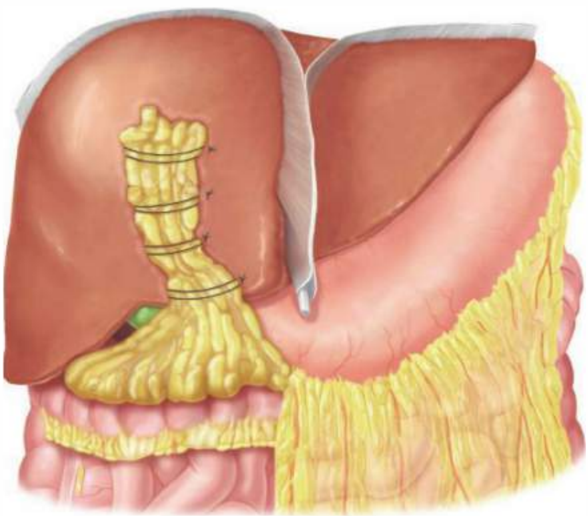


FIG 7 ● Omental pedicle packing may provide hemostasis for deeper injuries.

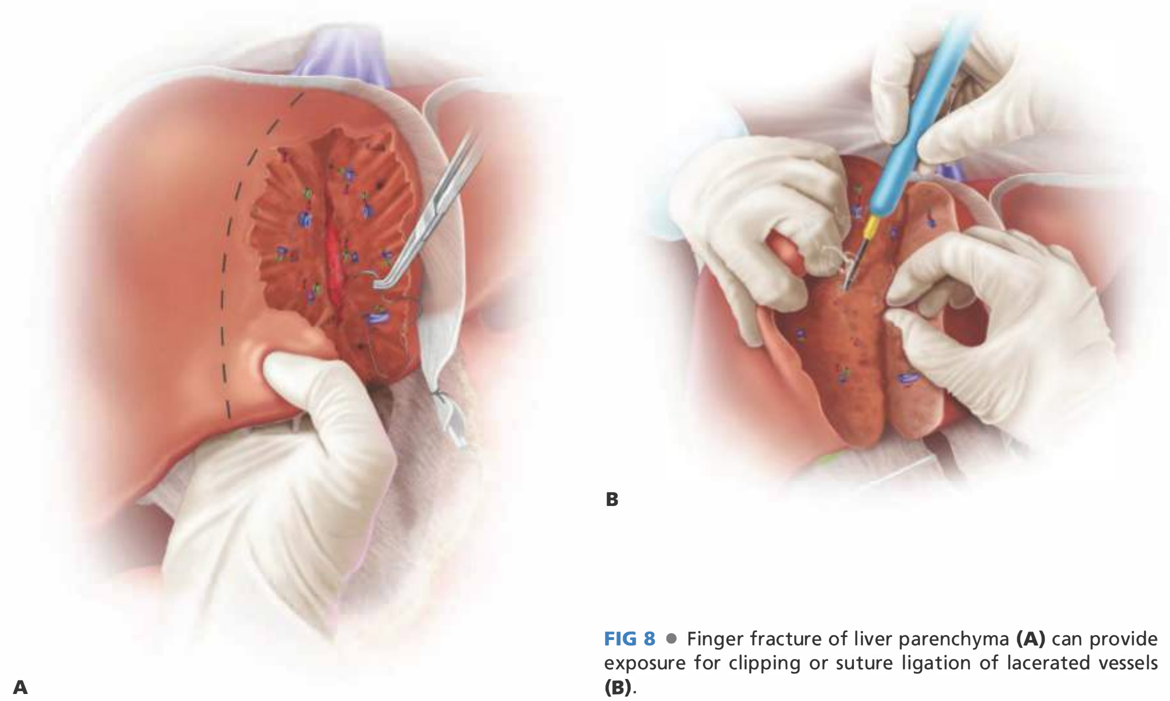

FIG 8 ● Finger fracture of liver parenchyma **(A)** can provide exposure for clipping or suture ligation of lacerated vessels **(B)**.

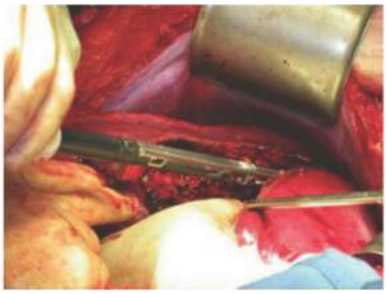

FIG 9 ● Surgical staplers may be used to divide liver parenchyma to reach bleeding vessels.

BALLOON TAMPONADE

- Transhepatic penetrating wounds may leave a long intracavitary defect that is difficult to access for vascular control. Balloon tamponade may be accomplished by a device originally described by Poggetti and colleagues.[5] This may be fashioned by ligating a 1-in Penrose drain at one end. A red rubber catheter is inserted into the open end and secured with a second ligature. The Penrose drain is pulled through the wound, with the red rubber catheter and drain exiting the abdominal wall. The balloon is inflated with saline to achieve tamponade (**FIG 10**).

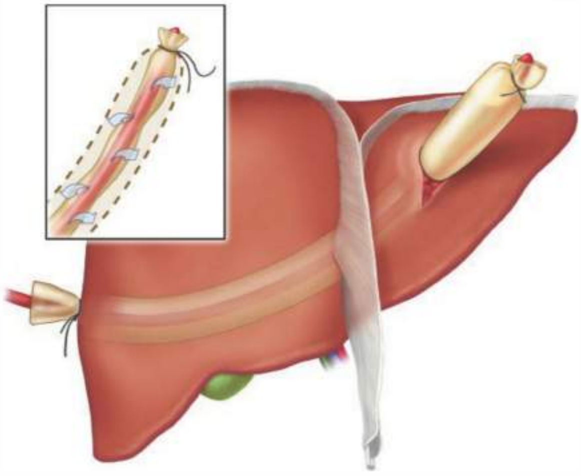

FIG 10 ● Balloon tamponade is an effective means of hemorrhage control for penetrating wounds through the middle of the liver.

PRINGLE MANEUVER

- Bleeding that persists despite packing may be arterial in origin. The Pringle maneuver—that is, control of the hepatoduodenal ligament with a Rumel tourniquet or vascular clamp—should be employed (**FIG 11**). If this controls hemorrhage, it is likely that the bleeding is from either a hepatic arterial branch or major branch of the portal vein. This cannot be left in place for a prolonged period. Intermittent unclamping decreases the degree of ischemia/reperfusion injury. Definitive maneuvers must be undertaken and the clamp should be released within 60 minutes if possible. Ligation of the right or left hepatic artery may control the bleeding. Alternatively, in the appropriate setting, the patient may undergo arterioembolization.

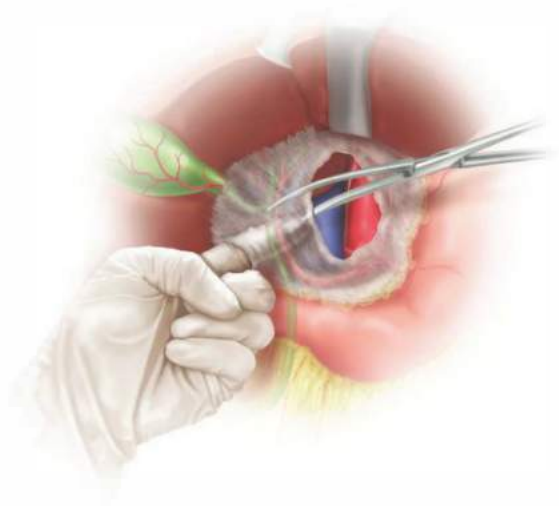

FIG 11 ● The Pringle maneuver. A vascular clamp is applied to the hepatoduodenal ligament, passing the posterior blade through the foramen of Winslow, guided by the index finger.

HEPATIC RESECTION

- Resection of devitalized tissue may be performed at the initial operation; in the damage control setting, however, this is reserved for subsequent LAP. The extent of devitalized tissue is generally readily apparent (**FIG 12**). Resection may be necessary to control major vascular or biliary structures. Again, in the patient who is severely compromised physiologically, this is best done after resuscitation.

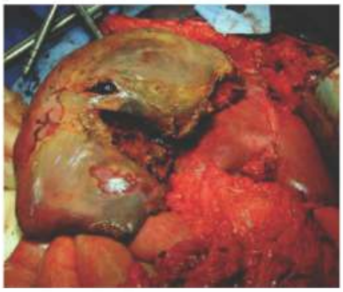

FIG 12 ● Hepatic necrosis may result from major injury or vascular ligation to control bleeding.

HEPATIC VASCULAR ISOLATION

- Bleeding that persists despite the Pringle maneuver is likely from the hepatic veins. Hepatic vascular isolation with or without venovenous bypass should be considered (**FIG 13**).[6] This entails control of the suprarenal IVC, the suprahepatic IVC, and a Pringle maneuver. If the interruption of venous return results in cardiovascular collapse, the aorta may need to be cross-clamped while venovenous bypass is established. The suprahepatic clamp may be placed below the diaphragm, but this is not ideal. The clamp optimally should be placed within the pericardium. This can be accomplished from within the abdomen, but the exposure is markedly improved by median sternotomy (**FIG 14**).

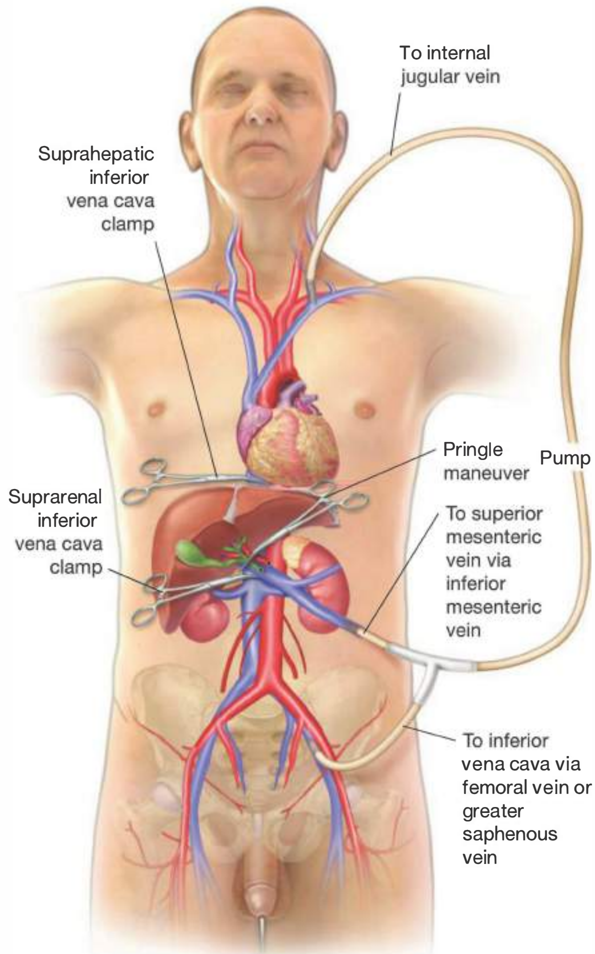

FIG 13 ● Hepatic vascular isolation and venovenous bypass is performed by clamping the suprarenal IVC, the suprahepatic IVC, and a Pringle maneuver. Venous cannulae are positioned in the femoral vein and superior mesenteric vein, and blood is shunted into the internal jugular vein.

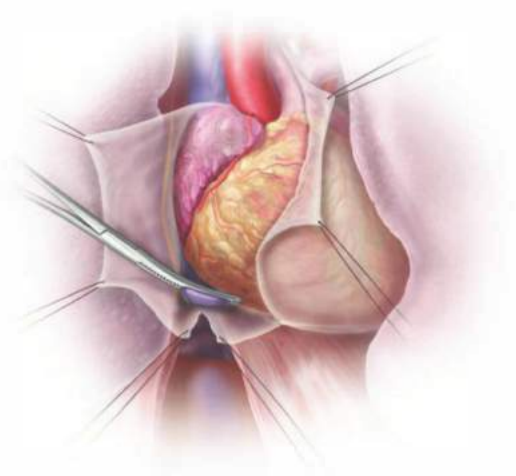

FIG 14 ● Combining a median sternotomy with a midline LAP incision provides exposure to the hepatic veins and retrohepatic vena cava while avoiding injury to the phrenic nerves. The pericardium and diaphragm can be divided down the center toward the IVC.

CLOSURE

- If the liver is to remain packed, a temporary abdominal closure should be performed. Goals are rapid closure, containment of abdominal viscera, prevent bowel from adhering to fascial edges, allow room for swelling of abdominal viscera, provide a means for egress of ascites, maintain sterility of the abdominal cavity, avoid damage to fascia and skin edges, and minimize cost. The "Vac-Pack" dressing satisfies all of these requirements (**FIG 15**). A plastic sheet is draped over the bowel and extended to the paracolic gutters to keep the bowel from adhering to wound edges. Slits are cut in the sheet to allow egress of ascites. A towel is placed over the sheet to prevent suction drains from adhering to bowel through the slits. Drains are placed on top of the towel. An adhesive drape is placed over the entire wound. Definitive closure may be achieved by simple running fascial suture (e.g., no. 2 nylon) and skin staples.

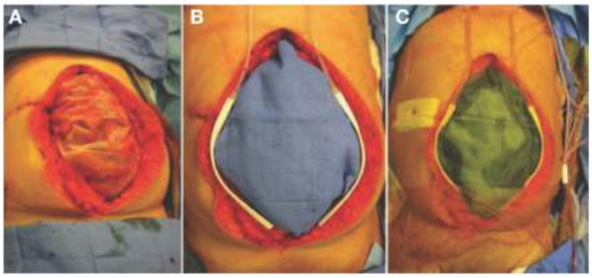

FIG 15 ● Temporary closure of the abdomen entails covering the bowel with a fenestrated plastic drape **(A)**, placement of closed suction drains and a blue towel **(B)**, followed by an adhesive occlusive dressing **(C)**.

PEARLS AND PITFALLS

Indication for LAP	■ Unstable patients should go to the OR promptly. Pursuing angioembolization in an unstable patient is not advisable and may prove disastrous.
Incision	■ A midline incision is the best choice in an unstable trauma patient. The surgeon should not hesitate to extend the incision rightward or into the chest in order to gain exposure and control. Median sternotomy markedly improves exposure for retrohepatic venous repairs.
Damage control	■ The decision to pack the liver should be made very quickly, as should the decision to adopt a "damage control" strategy.
Resuscitation	■ Ongoing resuscitation is critical during the operative phase.
Definitive procedures	■ Avoid major definitive procedures at the first operation, if the patient's condition warrants damage control.

POSTOPERATIVE CARE

- Trauma patients should be monitored for response to resuscitation. Once resuscitated, postoperative care is routine for abdominal surgery, with provision of diet as tolerated and early ambulation.

OUTCOMES

- Severe liver injuries may be associated with high morbidity and mortality rates. However, patients who survive without significant complications should be expected to have normal life span and functional status vis-à-vis the liver injury.

COMPLICATIONS

Hemorrhage

- Postoperative bleeding is not common outside of the damage control setting. Bleeding may continue despite liver packing. In this case, depending on the patient's condition, angioembolization may be reasonable to control arterial hemorrhage. On the other hand, if the patient is physiologically compromised, it is prudent to return to the OR to control surgical hemorrhage while resuscitating the patient.

Abdominal Compartment Syndrome

- The abdominal compartment syndrome refers to intraabdominal hypertension that is associated with organ dysfunction (see Part 3, Chapter 26). It is often seen in association with damage control surgery in the presence of liver packing. The accumulation of ascites and retroperitoneal edema, coupled with bowel swelling, lead to a progressive rise in abdominal pressure. Patients may develop the abdominal compartment syndrome in spite of an open abdomen, so the intraabdominal pressure and organ function should be monitored.

Bile Leak

- This is the most common major complication of liver injury. Leaks may come from any biliary repair or anastomosis. They may also originate from peripheral biliary radicals. If a bile duct repair has leaked, it may be managed via endoscopic means (e.g., stenting). Peripheral leaks usually spontaneously seal, but occasionally, leakage persists. This may be managed by endoscopic stenting. Bile collections should be drained.

Hemobilia

- Generally caused by injuries to an adjacent hepatic artery and bile duct, hemobilia is heralded by right upper quadrant pain, jaundice, and falling hemoglobin level. A more dramatic presentation may be upper gastrointestinal hemorrhage, as blood enters the duodenum via the common bile duct. Endoscopy can make the diagnosis, as blood is seen exiting from the ampulla of Vater. Angioembolization of the involved artery may be definitive treatment, but occasionally, drainage and/or debridement of a large hematoma/biloma cavity is needed.

Bilhemia

- Bilhemia results from a biliovenous fistula. Bilirubin levels can rise dramatically. Endoscopic biliary stenting may facilitate resolution, but hepatic resection may be required.

Hepatic Necrosis

- Although this may result from the initial injury, ligation or embolization of major vascular branches may also result in hepatic necrosis. This generally requires operative debridement or resection.

Chapter **19**

Hepatic Neoplasm Ablation and Related Technology

Ido Nachmany Ravit Geva

DEFINITION

- Hepatic ablation represents the use of chemical or physical means to destroy a neoplastic lesion and surrounding normal tissues as an alternative to resection.

INTRODUCTION

- The liver is one of the most common sites for development of malignancy—either primary or metastatic disease.
- As a general concept, the main curative option for liver tumors is surgical resection via partial hepatectomy or whole liver replacement. A variety of clinical situations preclude this approach; ablation is an attractive and viable option in some of these clinical situations.
- The most common indications for liver resection are colorectal cancer liver metastases (CLM), primary liver cancer (mainly HCC and CCA).
- In the case of CLM, about 50% of patients will ultimately develop liver metastases. Only about 15% to 20% are resectable at presentation.[1]
- Oncologic benefit of liver resection has been shown only when complete clearance of metastatic disease is achieved.
- Factors limiting resection include extent of tumor involvement, volume of the postresection liver remnant, anatomic proximity to essential intrahepatic structures, underlying liver disease, and comorbidities.
- HCC is the only universally accepted oncologic indication for liver transplantation (OLT). Only a small subset of patients is suitable for OLT, mainly due to stringent criteria influenced by the limited organ availability and inferior long-term survival in patients with locally advanced disease.
- For patients with unresectable liver tumors or those beyond criteria for OLT, life prolongation and control of symptoms are the major goals. This can be achieved by systemic therapy or by different locoregional modalities, grouped under two major categories: tumor ablation and transarterial treatment (chemotherapy infusion, embolization, combination of the two and irradiation).
- Ablation can be achieved by direct application of thermal energy (by cooling: cryoablation; heating: radiofrequency ablation [RFA] or microwave ablation [MWA]), chemical ablation: percutaneous acetic acid (PAI) or percutaneous ethanol injection (PEI), or newer techniques: irreversible electroporation (IRE).
- The most commonly applied modality is thermal ablation using RFA technique. In recent years, MWA has also been rapidly gaining acceptance.
- Based on accumulating data supporting the clinical benefit of ablation techniques, there had been an expansion of the indications. Ablation is now introduced in combination with liver resection and, in limited cases, as a replacement of resection with curative intent.
- Ablation can be performed percutaneously, laparoscopically, or via laparotomy.
- The main advantage of a percutaneous approach is the minimal invasiveness of the procedure.
- The advantages of using ablative modalities in surgery are the ability to reach any territory of the liver, the ability to combine ablation with resection, and the control of inflow and outflow. This may counteract the cooling effect of blood flow in major vessels (referred to as the "heat sink" effect). Laparoscopic ablation may combine the benefits of surgery with those of minimally invasive treatment.
- Studying the long-term effectiveness of ablative modalities has been challenging; in part, this is due to the rapid evolution of ablative tools (probes and energy sources), thus the field is in constant development. Also, the results of most studies are limited by sample size, methodology, and follow-up time.

INDICATIONS

- HCC
  - The vast majority of patients with HCC have background chronic liver disease. The management of these patients takes into account the primary liver disease (synthetic dysfunction and portal hypertension) as well as the extent of the tumor.
  - The most commonly used algorithm outside of the United States for HCC management is the Barcelona Clinic for Liver Cancer (BCLC) staging and treatment strategy.[2] Other criteria (Milan and University of California, San Francisco [UCSF]) have also been forwarded.
  - Based on the BCLC algorithm, patients suitable for curative treatment are those with very early and early stages (stages 0 and A).
  - Curative options include resection, liver transplantation, and, in some cases, ablation. The choice between the different options is based on the extent of liver disease, tumor stage, tumor location, and patient comorbidities.
  - There are three subsets of patients specifically suitable for ablation:
    - Patients with unresectable HCC beyond transplant criteria. Tumor ablation is usually combined with other treatment modalities, such as transarterial chemoembolization (TACE). These patients are not considered curable.
    - Patients with very early stage HCC (stage 0—single, up to 2 cm tumor with Child A cirrhosis, and in good performance status) are usually considered resection candidates. Recent data suggest that they can also be managed by ablative modalities. The main potential benefit of resection over ablation is the availability of

the pathologic specimen. The presence of microvascular invasion or microsatellites in the specimen, which are major risk factors for recurrence, is considered by some an indication for "salvage OLT."[3] Therefore, if the patient is a transplant candidate, resection is preferred over ablation. On the other hand, ablation offers a less invasive procedure and may be attractive alternative to patients.
    - Patients with early stage HCC (stage A—up to 3 lesions, largest ≤3 cm, with Child A–B cirrhosis, and in good performance status) are best treated by OLT unless they have significant comorbidities. In such cases, ablation may be an alternative.
- Colorectal liver metastases
    - The only curative option for patients with CLM is resection, but unfortunately, this is possible in only about 15% to 20% of cases. Some patients may become resectable with neoadjuvant chemotherapy or with anticipated liver remnant volume manipulation such as portal vein embolization.[4]
    - The advantages of RFA include low complication rates, fast recovery, and good safety profile in patients with marginal liver reserve. The main disadvantages are the higher local recurrence rates and limitations in treating large or multiple lesions.
    - Tumor ablation is a valid option for
        - Patients with limited disease that cannot achieve R0 resection with surgery
        - Patients who are not surgical candidates due to systemic conditions or because of multiple previous operations on the liver
        - Some authors consider ablation an alternative in patients with resectable metastases. There are currently no studies to support this approach.[5] In the future, with improving devices and technique, the equivalence of ablation and resection may eventually be demonstrated.
        - Ablation can also be used in combination with resection of other metastases. This is usually done for relatively small and deeply seated lesions for which resection would dramatically increase the morbidity of the procedure.

CONTRAINDICATIONS

- There are very few contraindications for ablative therapy.
- An absolute contraindication for thermal ablation is abutment of hilar structures, mainly the bile ducts and gallbladder, due to the high risk of thermal injury. This may not apply for IRE.
- The vicinity of major blood vessels (specifically hepatic veins and large portal branches) is associated with significantly reduced efficacy due to the heat sink effect and is a risk factor for local recurrence. This can be overcome surgically to some degree by flow manipulation such as the Pringle maneuver or outflow obstruction and thus is not considered an absolute contraindication.

- Chemical ablation with injection (usually percutaneously) of ethanol or acetic acid was used mainly for HCC, because this tumor is soft and accepts the fluid injected well. Currently, use of chemical ablation is not common mainly due to inferior efficacy, as compared to thermal ablation and the need for repeated treatments.[6]
- RFA
    - RFA uses alternating electric field delivered through a needle or multiple needle electrodes. It can be inserted percutaneously, laparoscopically, or at laparotomy (**FIGS 1** and **2**).
    - Ions in the tissue follow the direction of the rapidly changing current. This causes frictional energy to produce heat and coagulative necrosis.
    - As temperatures approach 100°C, changes in the physical properties of the tissue increase impedance and limit the flow of current (tissue desiccation due to evaporation of tissue fluid, charring, and the formation of electrically insulating gas between the electrode and the tissue due to boiling). This limits treatment of larger tumors.
- MWA[7]
    - MWA uses electromagnetic radiation, much higher on the spectrum of electromagnetic radiation than

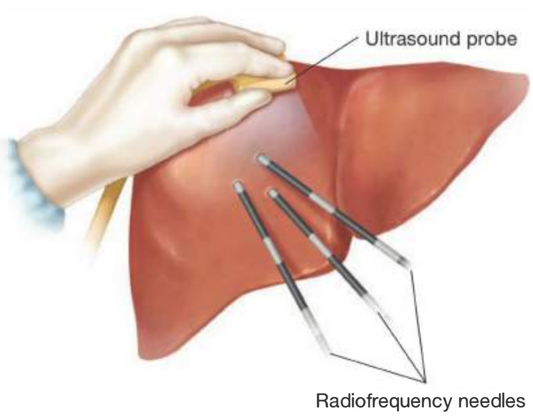

FIG 1 ● Three RF needles liver insertion.

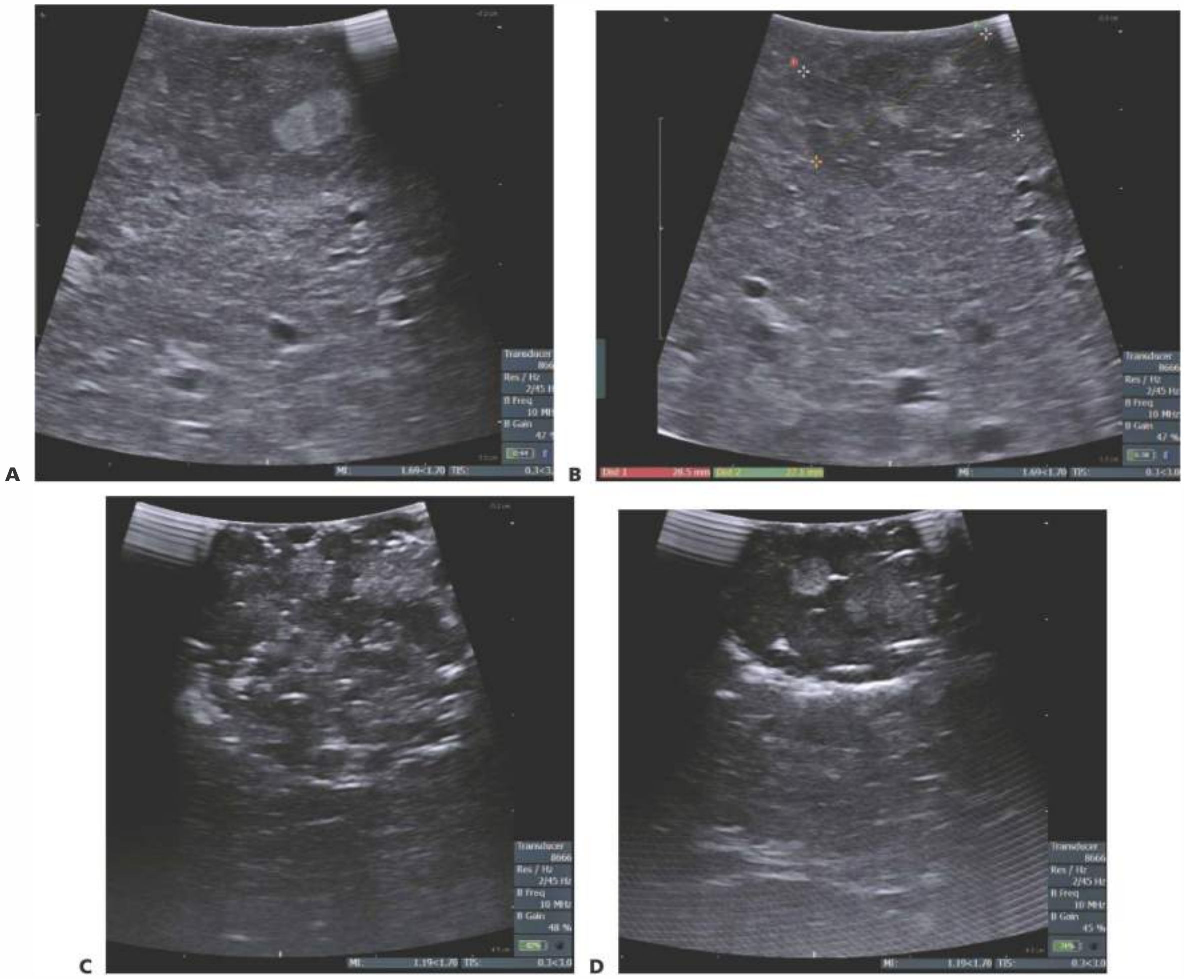

FIG 2 ● Laparoscopic ultrasound (US)-guided RFA of a peripheral HCC. **A.** Before ablation. **B.** Lesion measurements. **C.** During ablation. **D.** Immediate postablation. Note the typical artifacts created by the gas formed by tissue boiling.

RFA (usually in the range of 900 to 2,450 MHz) (**FIGS 3** and **4**).

- Polar molecules in the electromagnetic field (mainly water) try to align in the direction of the current. As the direction changes constantly, continuous realignment causes friction and heating effect. Like RFA, the heat causes cell death by coagulative necrosis.
- Unlike RFA, MW causes oscillation of water molecules in the entire field, so heat is uniformly distributed in the MW field throughout the activation. This achieves immediate and homogeneous heating and therefore faster tissue destruction.
- Heat is conducted outside of that field, so the ultimate ablation size is the sum of the microwave field and the conductive heat zone.
- The size of the microwave field is determined by the wavelength and the antenna design.
- Within the microwave field, heat sink and current sink effects are not present. Outside the microwave field (in the conduction zone) there will be a heat sink effect, similar to RFA.[8]
- MWA does not require point-to-point currents.
- No current flows through the patient and no grounding pads are required.

- IRE[9]
  - IRE is a new technique, based on nonthermal tissue destruction.
  - IRE is performed by placing electrodes into the tissue and delivering multiple high-voltage electrical pulses to induce pores in the lipid bilayer of cell membrane. This starts a process that leads to cell death.
  - IRE is not influenced by the heat sink effect.
  - Because the location of IRE activity is the cell membrane, acellular structures are preserved. Because hilar structures are wrapped in a fibrous sheet, they are protected. This allows for application of IRE to lesions in the vicinity of intrahepatic vital structures, unlike thermal ablation.[10]

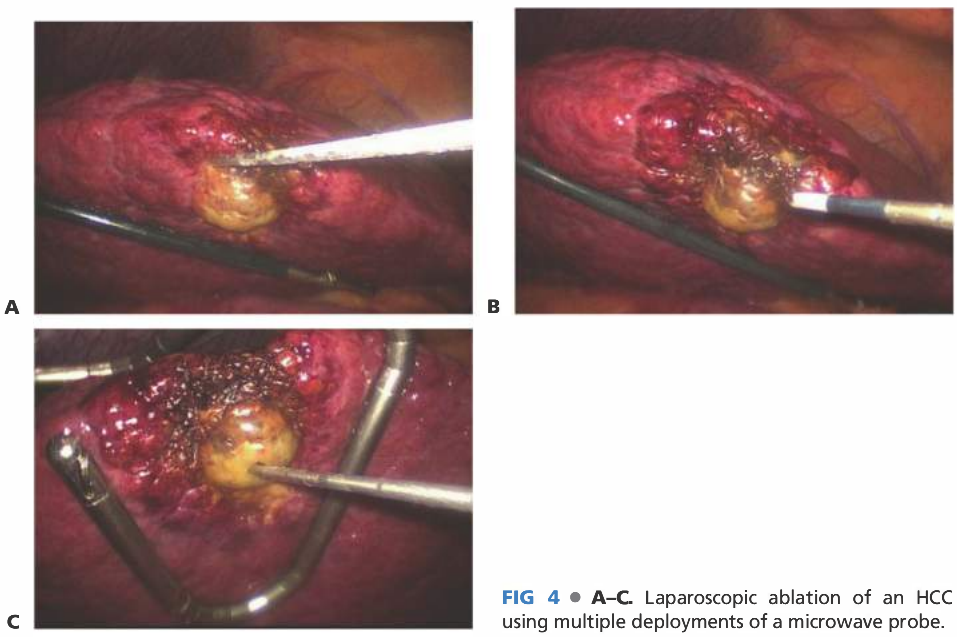

FIG 4 ● **A–C.** Laparoscopic ablation of an HCC using multiple deployments of a microwave probe.

PEARLS AND PITFALLS

Indications	■ Resection is not an option. ■ The lesion is not too big. ■ The lesion is not adjacent to a heat sink or vital structure. ■ Ultrasound in cirrhotic livers is technically challenging.
Technique	■ Confirm appropriate probe placement with ultrasound—Record the images. ■ Confirm complete destruction of the lesion by ultrasound—Record the images. ■ Precoagulation prior to parenchymal transection (**FIG 5**)

FIG 5 ● MWA as a precoagulant strategy prior to parenchymal transection.

OUTCOMES

- Factors influencing outcome include the following:
  - Tumor size. Best results are achieved for the treatment of small tumors less than 3 cm for RFA. MWA achieves effective results in somewhat larger lesions but is also limited by lesion size.[11]
  - Ablation margin. In order to minimize the chance for local recurrence, it is advised to leave a rim of 1 cm of ablated tissue beyond the tumor margin.
  - Vicinity to major vascular structures, mainly large veins, due to the heat sink effect
  - Mode of application. Surgical application usually achieves better outcome than percutaneous.
  - Ablation is operator dependent and therefore experience plays a major role.
- Assessing the isolated effect of ablation is difficult. In most cases, ablation is not considered curative; therefore, it is usually combined with other treatment modalities. Also, there are no high-quality randomized studies, the follow-up is usually short, and the devices used are in constant evolution.
- The most representative benchmark of ablation efficacy is local recurrence at the ablation site. This is widely variable, and in the case of RFA, runs from 2% to 60%.[12]
- HCC
  - In a large study on nearly 3,000 RFA treatments done on more than 1,000 patients, the 5- and 10-year survival rates were 60.2% and 27.3%, respectively, and the 5- and 10-year local progression rates were both 3.2%.[13]
  - Complete pathologic response for HCC smaller than 3 cm is as high as 65% with RFA and similar results had been shown with MWA.[14–16]
  - Combining eight studies and more than 1,000 patients, Giacomo et al.[6] found that RFA was superior to PAI or PEI with regard to survival, complete tumor necrosis, and local recurrence.
- CLM
  - During the past decade, RFA has superseded other ablative therapies, due to its low morbidity, mortality, safety, and patient acceptability. In the near future, MWA may become the leading modality due to some benefits over RFA.
  - Multiple studies have compared RFA to liver resection as a radical approach to CLM. These studies demonstrated higher local recurrence of RFA as compared to resection.[11,17–19]
  - A recent Cochrane analysis comparing RFA to hepatic resection concluded that the current data is insufficient to consider RFA to be as effective as surgery.[5]
  - In the case of nonresectable CLM, the addition of ablation to systemic chemotherapy probably increases the progression-free survival, although it was not found to have significant effect on the overall survival.[20]

COMPLICATIONS

- Morbidity and mortality are relatively low. Complications include bleeding, vascular thrombosis, abscess formation, and injury to intrahepatic structures (mainly bile ducts and gallbladder) and extrahepatic organs (colon, duodenum, etc.).
- In the case of RFA, morbidity had been reported in about 10% of cases and mortality is very rare.[12]
- For MWA, Martin et al.[21] reported an overall 90-day mortality and morbidity rate of 0% and 29%, respectively, from a cohort of 100 patients treated with a total of 270 ablations. Only 1 patient developed hepatic abscess (**FIG 6**), and there were no bleeding complications.
- Needle track seeding is extremely rare. For percutaneous MWA, it was found to be 0.47% per tumor and 0.75% per patient.[22]

Chapter 20

Catheter-Based Treatment of Hepatic Neoplasms

Darren W. Postoak

DEFINITION

- Catheter-based treatment of hepatic neoplasms is a percutaneous, minimally invasive, image-guided therapy in which the anticancer regimen is delivered to the arterial supply of the tumor. The most common therapies are transarterial chemoembolization (TACE) and radioembolization using yttrium 90 (^{90}Y).

DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of the different types of hepatic neoplasms is made by using tissue biopsies, tumor markers, and imaging characteristics. Dynamic computed tomography (CT)/magnetic resonance imaging (MRI) demonstrating intense arterial uptake followed by venous or delayed phase "washout" of contrast is considered to be diagnostic of hepatocellular carcinoma (HCC).[1]
- TACE and radioembolization are usually performed in patients with liver-dominant disease. These tumors may be primary liver malignancies or metastatic disease where the liver is the dominant site of the disease.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be obtained prior to treatment including a past medical history, medications, and allergies. Prior therapy should be evaluated, especially if radioembolization is being considered and the patient has previously had external beam radiation to the liver.
- Performance status (ECOG [Eastern Conference Oncology Group] or Karnofsky) must be evaluated. Patients with poor performance status may not be suitable candidates for intra-arterial therapy.
- Arterial pulse examination is needed for planning of the arterial access site. Typically, the puncture site is the common femoral artery, but this may need to be adjusted if the patient has severe iliofemoral atherosclerotic disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients should have a preprocedural multiphase CT or MRI examination. A positron emission tomography/CT may be helpful in some instances.
- Imaging should be evaluated for tumor number, tumor volume, and portal vein invasion/thrombosis. The vascular anatomy should be evaluated for vascular disease and anatomic variants as this may change the treatment plan.
- Laboratory evaluation should include a complete blood count, coagulation profile, creatinine, albumin, and liver function studies.
- Exclusionary criteria include immediate life-threatening extrahepatic disease, tumor volume greater than 50% to 70%, uncorrectable flow to the gastrointestinal (GI) tract, and significant hepatopulmonary shunting.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients need to be well hydrated, typically with 150 to 300 mL per hour of normal saline prior to and during the procedure.
- Preprocedure medications may include antiemetics and steroids.
- Antibiotics are administered as needed. This is important in patients without an intact sphincter of Oddi due to sphincterotomy, biliary stent or catheter placement, and surgical biliary-enteric anastomosis. The regimen is 2 weeks in total, beginning 2 days prior to the embolization procedure.[2,3]
- Radioembolization is a multistep procedure with a need for arterial embolization of vessels leading to the GI tract and a simulation of the procedural injection prior to the actual injection of ^{90}Y particles. This will be discussed in more depth in the "Techniques" section.
- Proton pump inhibitors are started about 2 weeks prior to radioembolization.
- Octreotide pretreatment is indicated in patients with metastatic carcinoid to help prevent a carcinoid crisis. Typically, 250 μg is administered intravenously about 1 hour prior to the procedure.

Positioning

- The patient is placed supine with both groins prepped and draped (**FIG 1**). If there are iliac arterial occlusions or other technical problems, then brachial artery access is the next choice with the left arm being preferred. For brachial access, the arm is extended 45 to 90 degrees away from the body.

FIG 1 • The patient is supine with both groins prepped and draped. The C-arm fluoroscopic unit and monitors are in position to visualize the puncture site in the common femoral artery and the entire abdomen.

TRANSARTERIAL CHEMOEMBOLIZATION

Superior Mesenteric Arteriogram with Venous Phase Imaging

- A 4- or 5-Fr catheter is used to selectively catheterize the superior mesenteric artery (SMA). The arterial phase (**FIG 2**) is inspected for anatomic variants such as a replaced right hepatic artery (**FIG 3**) or other anatomic variants. The potential for "parasitized" blood flow recruited from the SMA to the liver must also be assessed.
- The venous phase (**FIG 4**) is inspected to evaluate patency of the portal vein and to evaluate for hepatofugal flow. TACE can be performed in cirrhotic patients with hepatofugal portal flow, but a smaller volume of liver should be embolized each time.

Celiac and Common Hepatic Arteriograms

- The 4- or 5-Fr catheter is used to selectively catheterize these vessels. The arteriograms (**FIG 5**) are evaluated for anatomic variants such as a replaced or accessory left hepatic artery arising from a gastrohepatic trunk (**FIG 6**) and phrenic arteries, which may arise at the origin of the celiac.
- If the celiac artery is occluded, the occlusion can often be crossed and possibly stented to allow access or the procedure may be performed from the superior mesenteric artery in a retrograde approach via the pancreaticoduodenal arcade (**FIG 7**).
- Evaluate where the arterial supply to the tumors is arising. Try to limit embolization of branches that do not supply the tumors.

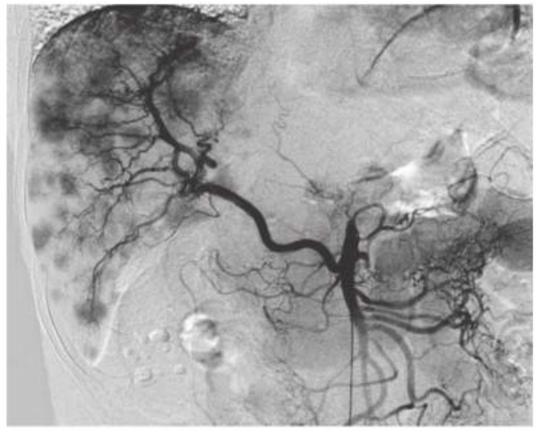

FIG 3 ● The replaced right hepatic artery is one of the anatomic variants more commonly seen. The replaced right hepatic artery arises as a branch of the superior mesenteric artery.

Advancement of the Catheter to Point of Embolization

- Commonly, this will be performed using a coaxial microcatheter.
- Advance the catheter as selectively as possible; however, a lobar embolization may be required if the tumors are scattered throughout the liver.
- In patients with intact gallbladders, evaluate where the cystic artery originates (**FIG 8**). Ideally, embolization

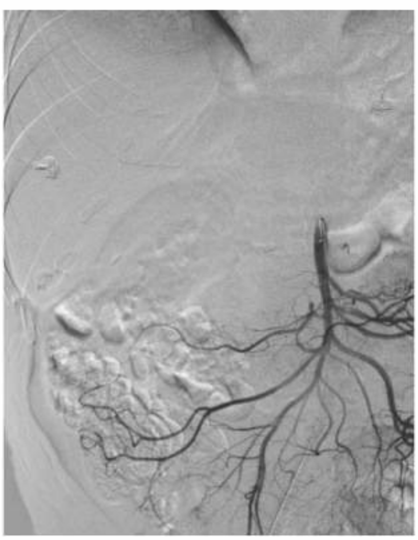

FIG 2 ● A superior mesenteric arteriogram is obtained to evaluate for anatomic variants. The patient is positioned to visualize the portal vein during the venous phase of the exam.

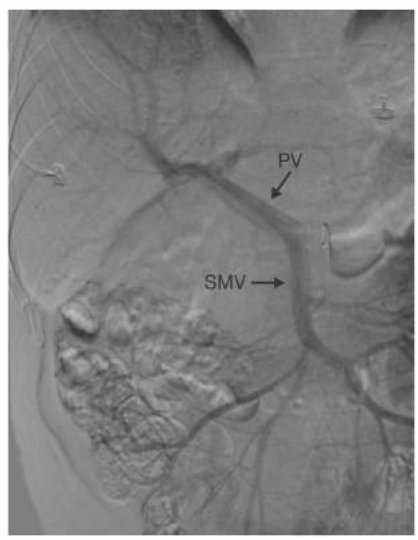

FIG 4 ● Venous phase following a superior mesenteric arteriogram demonstrates patency of the superior mesenteric and portal veins (same patient as **FIG 2**). PV, portal vein; SMV, superior mesenteric vein.

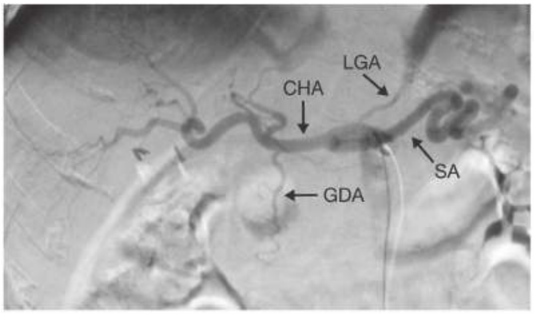

FIG 5 ● Celiac arteriogram demonstrating typical celiac and hepatic arterial anatomy. LGA, left gastric artery; SA, splenic artery; GDA, gastroduodenal artery; CHA, common hepatic artery.

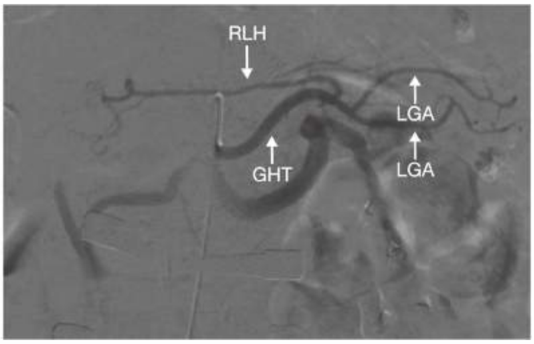

FIG 6 ● The catheter tip is in a gastrohepatic trunk arising from the celiac artery. The replaced left hepatic artery supplies the left hepatic lobe, whereas the remaining left gastric artery branches supply the fundus of the stomach. When embolizing the replaced left hepatic artery, the catheter must be distal to the left gastric artery branches. GHT, gastrohepatic trunk; RLH, replaced left hepatic artery; LGA, left gastric artery branches.

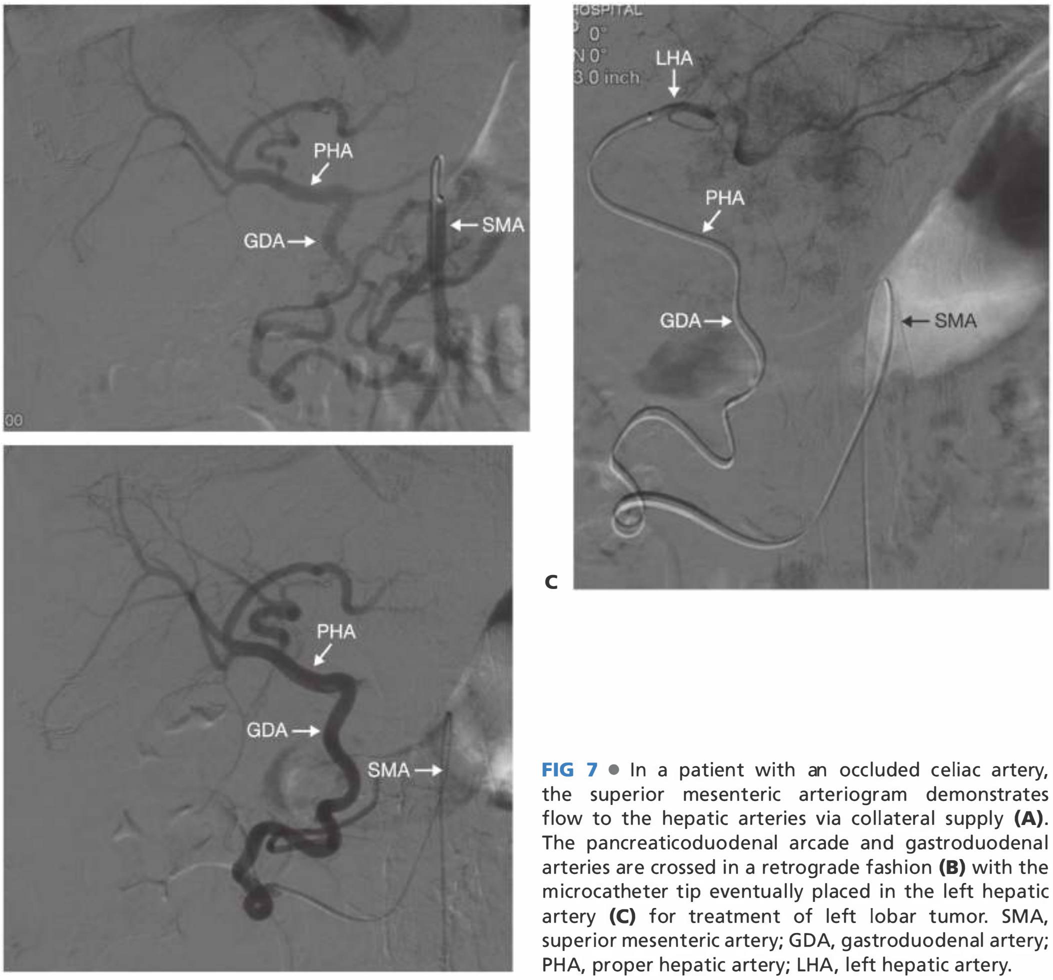
A



B

C

FIG 7 ● In a patient with an occluded celiac artery, the superior mesenteric arteriogram demonstrates flow to the hepatic arteries via collateral supply **(A)**. The pancreaticoduodenal arcade and gastroduodenal arteries are crossed in a retrograde fashion **(B)** with the microcatheter tip eventually placed in the left hepatic artery **(C)** for treatment of left lobar tumor. SMA, superior mesenteric artery; GDA, gastroduodenal artery; PHA, proper hepatic artery; LHA, left hepatic artery.

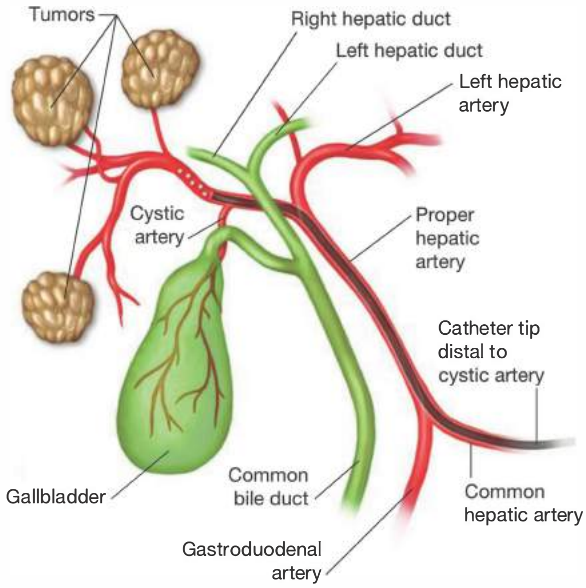


FIG 8 ● The catheter tip is placed distal to the origin of the cystic artery prior to chemoembolization to prevent a chemical cholecystitis.

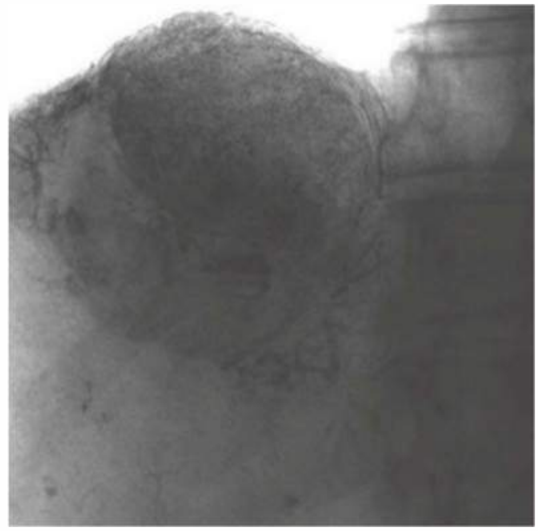

FIG 9 ● Fluoroscopic image following oily chemoembolization shows the Ethiodol mixture within the tumor.

should be performed distal to the cystic artery. Treatment proximal to the cystic artery can cause a chemical cholecystitis with a more severe postembolization syndrome.
- Arteriogram to evaluate selective cannulation of the feeding vessel(s) and to assess for arteriovenous shunting

Embolization Using the Embolic Material

- Oily chemoembolization
  - Ethiodol is a poppy seed oil-based contrast. The Ethiodol vehicle is mixed, most commonly with a combination of cisplatin, doxorubicin, and mitomycin-C. The Ethiodol acts as a carrier and the chemotherapy is released slowly from the mixture. The Ethiodol is retained within the tumor and the neovasculature of the tumor (FIG 9). This is followed by particulate embolization of the target vessels.
- Drug-eluting microspheres
  - LC beads are a polyvinyl alcohol-based microsphere and QuadraSpheres are a copolymer microsphere.
